Even though the cable companies slowed their cable-telephony effort considerably during the last decade, they actually have more than 1.5 million voice subscribers today. From an architecture perspective, not much has changed: Telephony represents an incremental revenue stream on their existing installed plant. What has changed today is that DOCSIS 1.1 is just now being deployed, which will enable VoIP over the cable access network. The cable-industry effort to do telephony was not abandoned—it was simply delayed for a few years. Now, however, it will be built on the highly successful DOCSIS foundation rather than the proprietary circuit-switched systems of the past. Cable telephony never really went away, and now it is poised to come back with a vengeance. We expect cable television (CATV) early adopters to offer VoIP with DOCSIS 1.1 in 2H02. Mass deployment will commence in 2003. It is not as if the cable companies have the ILECs squarely in their gun sights. Rather, they need revenue growth and are targeting voice, video on demand (VOD), and other services to get growth. With second-line service clearly threatened and perhaps main line as well, what is a telco to do?

ILECs' Alternatives

The ILECs have several alternatives. They can continue business as usual and watch their second lines, then main lines, and ultimately entire service bundles migrate to the cable companies over time. They can bundle plain old telephone service (POTs)/local, long distance, cellular, and today's DSL Internet access with a targeted marketing approach to fight off the cable companies. They can attempt to level the playing field in the regulatory arena to enhance their bundling capability and burden the cable companies with some of their Title II requirements. While these last two alternatives will help the telcos to compete against the cable companies, they will still lack parity with cable's high-speed Internet access and video bundle. We believe the telcos must also modify their outside plant architecture to provide parity with the CATV broadband service bundle.

The telco's outside plant alternatives for fighting the MSO service bundle are as follows:

- Fiber-to-the-curb/fiber-to-the-home (FTTC/FTTH)
  - Passive optical network
  - Point to point (star)

- Utilize existing copper with DSL
  - Existing next-generation digital loop carrier (NGDLC), current distribution area (DA) architecture, current ADSL deployment plans
  - New fiber sweet spot, broadband digital loop carrier (DLC), and modified DA architecture

Not Fiber-to-the-Home

FTTH is the ultimate future-proof access technology. It has always been held up as the holy grail of ILEC access. Unfortunately, FTTH economics make it all but undeployable.

Not Enough Money

The basic reason is that the labor and material associated with a FTTH plant are not on any significant cost-curve decline. Construction costs have been steady even with advances in trenchless technology. Cable costs are already at commodity pricing. Even if dramatic reductions in optoelectronic equipment costs are possible in the future, the anticipated revenues from FTTH video/voice/data services do not justify the construction cost.

In a recent study, RHK stated flatly that "…it does not seem as if there will be any viable solutions for competitive residential fiber deployment in the near future." RHK studied a number of fiber architectures and found that all of them fell well short of viability for residential access. The most cost-effective FTTH architecture in their study was a 32:1 PON. To get a reasonable return on investment (ROI), the 32:1 PON architecture allows only $417 of equipment cost per home passed after PON construction. This equipment cost includes all network and subscriber termination equipment, routers, switches, servers, etc.—basically everything needed to deploy voice, video, and data but the PON itself. Note that the $417 target is exceeded today by the subscriber device *alone*, which ranges from $500 to $1,000 for an optical termination device. These numbers apply to new construction and not overbuild, where the economics would be considerably worse. Our analysis shows that a fiber/PON overbuild for a buried distribution area would cost about $2,000/subscriber.

For the sake of argument, let us assume that stupendous advances in technology and cost reduction enable the 32:1 PON architecture by driving per-home equipment costs below $417. Or alternatively, assume that some new service appears that dramatically changes the revenue side of the business model. In either case, a carrier would then have a reasonable business model and presumably could attract the capital necessary to deploy the plant and equipment. Even if the capital markets are willing to go along, there is another problem with FTTH that money can't solve: time.

Not Enough Time

It has been estimated that if all telco network construction was halted today and these resources re-applied to FTTH, a complete fiber buildout would take 15 years. It is a reasonably safe bet that the broadband winners and losers will be decided long before that time. There simply isn't enough time to deploy FTTH. To make matters worse, if a new service indeed appeared that made the FTTH business case attractive, then the MSOs would be in a better position to exploit it. They already have fiber to the node in their architecture and typically have lit optics to within 3 to 6 kft of a subscriber. This lead would save them considerable time and money in getting fiber to the home should service evolution support it.

Not Competitively Relevant

FTTH architectures are being trialed today in greenfield developments by major carriers and are also being deployed by some rural independents. Both of these deployments are, of course, highly subsidized. While FTTH trials are useful as a technology proving ground, there is simply no question that the FTTH architecture is not competitively relevant. There is not enough time or money for FTTH to make a difference in meeting the MSO threat. The simple facts are that 97 percent of the outside plant is already in the ground every year. At $2,000/subscriber, it is simply too expensive and would take too long to overbuild the existing plant with

FTTH. Telcos must find a way to optimize their most precious asset, which is the existing copper distribution plant.

Not Fiber to the Carrier Serving Area with Today's NGDLC and DAs

Project Pronto was SBC's plan to revamp their access architecture to offer nearly ubiquitous DSL service. Their stated goal was to offer a minimum of 1.5 megabits per second (Mbps) data service to more than 80 percent of their subscribers. Their architectural approach was to offer DSL out of remote terminals (RTs) and shorten loops to less than 12 kft. Although Project Pronto has been a part of SBC's DSL rollout to more than one million subscribers, they are in their own words, "fairly dramatically curtailing the build." Why?

Not Enough Deregulation, Bandwidth, or Revenue Opportunity

SBC blamed the regulatory environment as its primary reason for slowing down Project Pronto. The support for loop undbundling and co-location at RTs increased their costs considerably. SBC also claimed that the costs associated with active electronics in their neighborhood gateways were a large impediment to the business case. This is because the revenue potential and economic service life of the current platform and DA architecture is insufficient to provide an adequate ROI. The cost associated with remote electronics needs to drop by using next-generation technology, and they need to be able to evolve in a way that will generate more revenue per upgraded line by adding more services. The bandwidth target of 1.5 Mbps is too low for the scale and level of investment required in Pronto. This bandwidth is appropriate for Internet browsing, but this rate is likely to be more commodity oriented in the future.

Current NGDLC and Architecture Incapable of LAN/Video Speeds

The current generation of NGDLC platforms are incapable of local-area network (LAN)/video speeds. They have backplane bus-speed limitations, power distribution and consumption constraints, and heat dissipation issues. This means that the current planned expensive upgrades to existing NGDLC equipment only add Internet access as an application and will have limited economic service life. We estimate this service life to be two to three years. Today's generation of NGDLCs is fine for DSL services as long as a telco does not expect to be very successful and deploy many DSL services over the existing platform. In addition to the platform's limitations, there are also bandwidth limitations imposed by the current carrier serving area (CSA)/DA architecture. Loop lengths up to 12 kft will limit speeds to less than 1.5 Mbps. This combination of platform and architecture will never support LAN/video speeds. To truly compete with the MSOs on a full-service basis, the delivered bandwidth must be capable of video and that means an order of magnitude increase to 20–25 Mbps. Getting to these rates will require pushing fiber deeper into the network.

New Fiber Sweet Spot and Broadband DLC/DSLAM Required

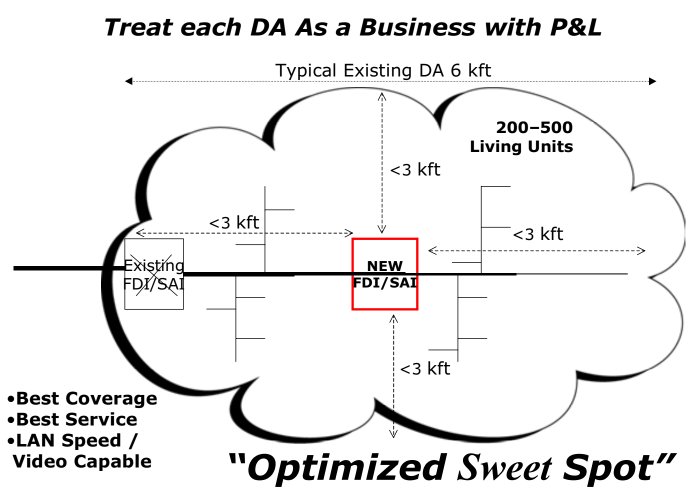
We believe that a new fiber "sweet spot" and broadband DLC (BBDLC)/DSL access multiplexer (DSLAM) is required (see *Figure 3*). New platforms deployed must provide backplane speeds and software capable of supporting LAN/video speeds and services. The emerging generation of BBDLCs are designed from the get go to provide LAN/video speeds, QoS, and significantly improved densities. We also believe that DAs need to be reconfigured to new broadband DAs at distances less than or equal to 3 kft. This provides LAN/video speeds and competitive parity with the cable companies.

Capital Expenditure and Economics

On first blush, one would think that placing fiber within 3 kft and reconfiguring existing DAs to a new broadband design would significantly increase the capital investment and cost over today's plans of deploying DSL at the CSA (12

FIGURE 3

New BBDA



kft) (see *Figure 4*). This ignores the economic service issue of putting in an asset that will be short-lived versus one that is future-proofed. Based on a model of a CSA of three existing DAs and one new DA, totaling 2,000 POTS lines and 400 DSL customers, it would cost $120,000 in upfront capital with today's NGDLC and architecture. For the same model, using a BBDLC and reconfigured DAs to less than 3 kft, it would cost $220,000 in upfront capital.

However, the BBDLC and reconfigured DA would be LAN–speed/video-capable with an estimated service life of 10 years, while the NGDLC solution would only be capable of 1.5 Mbps Internet access with an estimated service life of three years. The higher $220,000 BBDLC/DA reconfigured capital investment has a lower monthly revenue requirement ($3,410) than the $120,000 NGDLC capital investment ($4,080). Not only is it capable of producing more revenue from LAN speed and video services, but it also costs $670 or 16 percent less per month. A comparison of the two alternatives is included in *Figure 5*.

If we assume that the average service bundle in this CSA is $150/month, the total revenue is $300,000/month (2000 subscribers x $150/month) and the annual revenue is $3,600,000 ($300,000 x 12 months). Surely protecting this kind of revenue with a more feature-rich, higher-speed capability is worth $100,000 more upfront capital, especially in light of the life-cycle cost reduction. The monthly revenue requirement per DSL customer would be $10.20 ($4,080/$400) with today's platform/DA versus $8.52 ($3,410/$400) for a BBDA. Thus, the cost reduction would be approximately $1.70/DSL customer/month.

Capital Expenditure Reality—"One DA @ a Time"

While having LAN–speed/video-capable DLC/DSLAM and DA architecture is the desired end game for telcos, reality is that they are unable to complete all DAs at once because of limited capital and resources. Therefore they must optimize their capital investment based on the following:

- Competitive threat
- Revenue opportunity
- Condition of outside plant
- ROI
- Feeder relief requirements
- Targeted marketing plans

In other words, telcos must plan "One DA @ a Time." The endgame for the ILEC is to optimize their copper distribution plant by having a BBDLC/DSLAM that is LAN–speed/video-capable within 3 kft of all customers. However, they cannot get there immediately, and " One DA @ a Time" is how to evolve to the endgame. The copper outside plant spans decades of time and technology. There are a wide variety of deployment rules, cable materials, and rehab scenarios used over the years. The intent here is not to cover these cases in exhaustive fashion but to give a set of general guidelines to be applied on a case-by-case basis. These recommendations are as follows:

- ILECs should only deploy DLC/DSLAMs that are LAN–speed/video-capable. Future-proof the network for greater revenue capabilities and economic service lives rather than upgrade aging NGDLC platforms.
- For all greenfield DAs and feeder relief projects, telcos should place BBDLCs within new BBDAs. These DAs should be designed with loop lengths less than 3 kft.
- Small, low-cost, line-powered, reusable DSLAMs should be used tactically to offer Internet access and retain existing customers when capital is scarce for low- and medium-priority DAs. These reusable DSLAMs should be moved and reused as BBDLC/DSLAM is brought to an area.
- Fiber should be placed to the new sweet spot and the DAs reconfigured for broadband when any construction occurs.
- ILECs need to be making their plans for value-added services over DSL, including voice, data, and video, as soon as possible.
- A targeted marketing program should be implemented to match the DSL service deployment.

FIGURE 4

2000 Living Units CSA Model

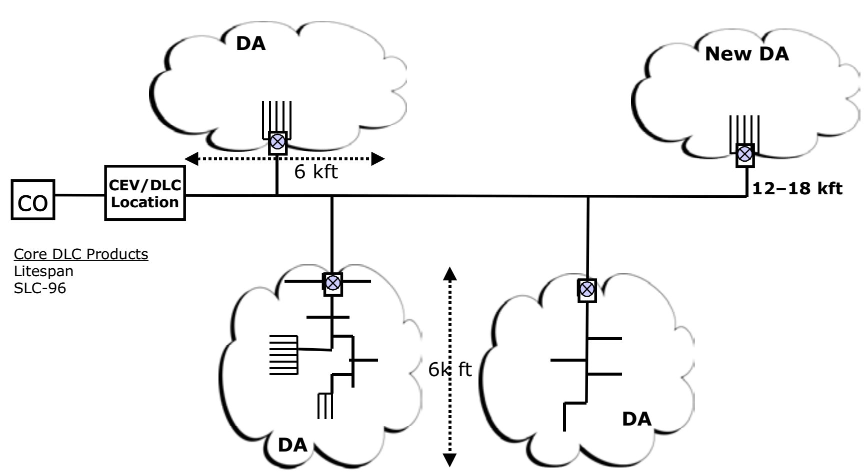


FIGURE 5

Capital Expenditure Comparison

2000 LU CSA, 4 DAs (3 Existing, 1 new), 20% DSL

	Today's Platform/DA	BBDA
Platform	NGDLC Upgrade	BBDLC
Loop Length	≤ 12,000′	≤ 3,000′
Speeds	≤ 1.5 Mbps	10–15 Mbps
First Cost	$120,000	$220,000
Service Life	3 years	10 years
Mothly Rev. Req.	$4,080	$3,410

- ILECs need to focus on the cable threat as their main regulatory story to achieve a level playing field. They need to be able to bundle their services to the same degree as the cable company.

Summary

The "war" for the residential customer is heating up and about to explode. The stakes are high with the entire bundle of telecommunications services, including local POTS, long distance, Internet access, cellular, and video ($150–$250) being at risk. For the ILECs, this time the cable threat is real. They aren't going away like the competitive local-exchange carriers (CLECs). The networks, technology, and ownership issues are converging, making the cable companies formidable competitors. ILECs have several choices. They can continue business as usual and watch the cable companies take market-share. They can aggressively bundle service capabilities and attempt to achieve regulatory parity. These actions will help to stave off the cable companies for a while but will not achieve parity with the cable companies' broadband services. We believe the outside plant architecture and DSL platforms must be modified to offer parity with the cable companies. FTTH is not the answer. It is both too expensive and too long to deploy. Today's DLC/DSLAM platform is not the answer. It will not have enough bandwidth or service capabilities to compete with the cable companies. It will result in expensive upgrades with very short service lives. The answer for the ILECs is optimizing their copper through "One DA @ a Time" planning. Fiber needs to be run to the new sweet spot, and DAs must be reconfigured for broadband. ILECs must be able to compete with cable companies on an equal bandwidth and service-capability basis. The cable companies are coming! The cable companies are coming!

A Software Library Perspective of DOCSIS 1.1: Enabling Cable Connectivity to Applications in a Diverse Environment

Mariano Schain
Chief Software Architect
Texas Instruments, Cable Broadband Communications (CBC)

Summary

The new 1.1 version of the data over cable service interface specification (DOCSIS) standard is targeted by the cable industry as the platform for consistent and reliable Internet over cable digital services through the use of sophisticated quality of service (QoS), security, and network management mechanisms. As a result, a variety of products are expected to embed DOCSIS 1.1 functionality, serving different applications such as home gateways, game consoles, telephony terminals, health and home monitoring systems, and more. The DOCSIS 1.1 component in such devices is viewed as a software library enabling the cable connectivity and control through a dedicated set of application program interfaces (APIs).

In this paper, the set of required software APIs is explored. A unified approach is taken, aimed at enabling the needs of the different applications with a generic collection of exposed functionality.

Introduction

DOCSIS 1.1 can be viewed as a framework—a set of tools that, if properly used, allows applications a reliable, secure, and efficient use of the cable medium. The functionality defined in the specifications is generic—no specific application is assumed; however, voice and video transmission needs are addressed.

With the aim to serve a variety of different applications, sometimes concurrently, a library approach as presented in this paper isolates the applications from the DOCSIS 1.1 details and hides them from the details of the native DOCSIS 1.1 messages and mechanisms. Instead, the DOCSIS 1.1 functionality and some common system resources are exposed through a dedicated set of APIs. This approach not only simplifies the system software architecture, but can also enable non-embedded applications to directly control the DOCSIS 1.1 library operation.

Packet cable is a set of specifications by CableLabs that builds on top of the DOCSIS 1.1 framework to implement an intellectual property (IP)–based packet telephony system. A natural example of a user application is the implementation of a packet cable embedded message transfer agent (MTA) on top of a DOCSIS 1.1 library.

In this paper, the DOCSIS 1.1 system and mechanisms are explained and the different set of APIs is presented. Throughout the discussion, packet cable is used as an example of a "real-world implementation" using the DOCSIS 1.1 API. This serves as an illustration of the way the APIs are used in a packet cable system to achieve efficient and reliable voice processing and signaling through a cable-modem system.

The DOCSIS Framework

Cable modem (CM) and the cable-modem termination system (CMTS) are the main entities in the DOCSIS network protocol. Several CMs, residing in the customer premises, are connected to a CMTS, which resides at the cable operators' head end through a hybrid fiber/coax (HFC) network. The HFC network is constructed in a tree-like structure, where the head end is the root and the CMs are the leaves.

The DOCSIS downstream (DS) channel, which carries information from the CMTS to the CMs, uses a typical television channel (6 MHz wide in the United States; 8 MHz wide in Europe) to carry Ethernet-like packets over a continuous digital Moving Pictures Experts Group (MPEG) stream. As the DS channel is shared, the channel bandwidth (about 40 Mbps in the United States) is distributed among all active CMs. Note that all the DS packets are received by all connected CMs. The Ethernet address is used by the CMs to filter out the packets that they need.

The DOCSIS upstream (US) channel carries Ethernet-like packets and uses the lower frequencies below the range allocated to television channels, which are prone to occasional interference. To cope with such situations, the US channel configuration, including bandwidth, rate, error correction, and other transmission parameters, is diverse and dynamically controlled by the CMTS. The transmission scheme is decided on a burst-by-burst basis. Again, the US channel is shared among several CMs, hence a multiple access mechanism is implemented and the channel bandwidth of up to 10 Mbps in the current specification is managed and allocated to active CMs by the CMTS. Note that US packets are received by the CMTS only. Packets from CM to CM always pass through the CMTS.

A DOCSIS domain may include several DS and US channels—paired accordingly to achieve the required network balance. CMs may be instructed by the CMTS to move from channel to channel as a load-balancing implementation or as a means to overcome channel-quality problems. A CM acts as a transparent bridge by forwarding packets that are received from the CMTS toward its local network interface (e.g., Ethernet, universal serial bus [USB], etc.) and vice versa. Packets that are destined to the CM, such as packets to the embedded simple network management protocol (SNMP) agent, dynamic host configuration protocol (DHCP) client, or other IP–based agents residing in the CM, are consumed by the CM and not forwarded.

As CMs reside in varying distances from the CMTS, the time division multiple access (TDMA) scheme implemented in the US requires subtle synchronization mechanisms. All CMs align to the CMTS clock, which is distributed through dedicated DS control messages. A ranging mechanism in which the CMTS instructs the CM on the time shift and power level to use in US transmissions is constantly active for every connected CM. This mechanism ensures that all CMs transmissions are aligned to a time base controlled by the CMTS and that all signals are received at the CMTS at approximately the same level, ensuring the ability of the CMTS to identify collisions.

The US channel is divided into time slots. A transmission interval is a group of continuous time slots. The CMTS allocates transmission intervals for different needs, including transmission requests, packet transmission, and ranging messages, and transmits the allocation to the CMs using a dedicated control message in the DS. Generally, transmission request intervals are not allocated to a specific CM. These allocated intervals are considered multicast and may result in a contention. Some of the intervals are unicast, such as a packet transmission interval. The US interval allocation messages, MAP messages, are transmitted in the DS by the CMTS in a timely manner. To illustrate the US transmission mechanism, consider a CM wishing to transmit a packet in the US. The CM will analyze the MAP messages in the DS until a multicast request interval is allocated by the CMTS. The CM will transmit its request, which contains the required transmission length, in the specified interval and will wait until a MAP message containing the requested allocation is received. Once the requested allocation or grant is received, the CM transmits the packet in the allocated interval. If more than one CM transmitted a request in the same interval, a back-off algorithm is implemented to solve the contention. To overcome the possible contention of subsequent requests, a CM may transmit a request embedded or piggybacked in a packet transmission.

While the best-effort scheme provided by DOCSIS 1.0 was sufficient for basic Internet access, it fell short to provide the needs of more sophisticated services that are unable to operate in the absence of guaranteed QoS. The QoS framework of DOCSIS 1.1 was targeted at exactly those types of services.

Four main service categories are supported by DOCSIS 1.1: unsolicited grant service (UGS), real-time polling service (rtPS), non–real-time polling service (nrtPS), and best effort (BE) service.

In a UGS flow, the CM is assured to receive from the CMTS fixed size grants at periodic intervals without the need to explicitly send requests, hence the service name. In addition to the grant size and the period, the tolerated grant jitter is also negotiated at service set-up. The main advantage in using a UGS is the reduced latency achieved by eliminating the need to go through the request-grant cycle for every packet. However, using a UGS is inefficient for applications that don't require a constant data rate over time. A flavor of UGS—unsolicited grant service with activity detection (UGS–AD)—is targeted at those exact applications (e.g., voice with silence detection). In a UGS–AD, once the CMTS detects flow inactivity through non-usage of grants by the CM, it starts sending unicast request opportunities at periodic time intervals. The CM can use the unicast request opportunities or polls to send requests once the flow resumes, avoiding the latency incurred by contention at multicast request intervals.

In a rtPS flow, the CM is assured to receive from the CMTS unicast request opportunities at periodic intervals. If the CM does not use the request opportunities, the CMTS allocates the reserved bandwidth to other flows, thus overcoming the inefficiency of UGS. In a nrtPS flow, the bandwidth is not guaranteed to the flow. The CM, however, is also allowed to use multicast request opportunities for the flow. The last QoS category, BE, defines the minimum traffic rate, which the CMTS must reserve, and the maximum allowed rate as the main service parameters.

Multiple data flows, each flow corresponding to a service and identified by a service ID (SID), may concurrently exist in a CM. A transmission request in the US and the corresponding grant includes the SID as the flow identifier. The CM and the CMTS negotiate the QoS for each flow upon allocation and dynamically as the service requirement changes in dedicated procedures. The QoS is then achieved by the implementation of sophisticated scheduling mechanisms in the CMTS. A classification function is applied to every packet. The flow in which a packet is transmitted is based on the content of the ethernet and IP header fields, allowing every application to receive a different service flow. The classification function may also indicate the suppression of the packet header payload header suppression (PHS), a mechanism that is useful for packets with semi-constant headers and short content, such as voice packets.

The DOCSIS framework includes some other mechanisms (e.g., privacy, secure software download, SNMPv3, etc.) that will not be discussed here and are not essential to the ideas presented in this paper.

In what follows, the set of APIs exposed by the DOCSIS 1.1 library is presented.

Dynamic Quality of Service (DQoS)

To support the establishment and configuration of the aforementioned QoS–related mechanisms, a set of media access control (MAC) management messages and procedures is defined. Service flows and the related classification parameters can be dynamically added, modified, or deleted through the use of such dedicated DQoS messages. However, as the DOCSIS 1.1 library is the only component that uses native DOCSIS 1.1 MAC messages, applications running on top of the DOCSIS 1.1 library, or users, are provided with a dedicated API that allows them to dynamically control the DOCSIS 1.1 QoS settings.

The DQoS API, through an abstraction layer, hides the DOCSIS 1.1 implementation details from the user. The challenge in defining the API is to balance the tendency to minimize the exposed complexity with the resulting limited control. For example, a decision has to be made regarding the way to expose the data structures that are internally used by the DOCSIS 1.1 library to represent the settings of a service flow (e.g., lists of classifiers, PHS rules, etc.). The API includes functions that enable the user application to initiate the establishment and configure the parameters of service flows, thus interacting with the CMTS through the CM, and also includes mechanisms for the user application to receive indications regarding asynchronous events (e.g., notification when a new service flow was established by the CMTS, indication of the successful acknowledgement by the CMTS to a service-flow addition request, etc.).

A packet cable application may use the DQoS API to establish UGS flows for phone calls. Indications regarding flow-establishment request status or requests initiated by the CMTS are also provided to the packet cable application through this API.

Performance Enhancements

According to the DOCSIS 1.1 specifications, every packet to be transmitted in the US should go through a classification process. The purpose of this process is to decide on the appropriate service flow, or the QoS parameters, that apply to the packet. However, sometimes the appropriate service flow is already known in advance, and bypassing the redundant classification process can result in better performance (i.e., less central processing unit [CPU] load, shorter delay, etc.).

Another example of a possibly redundant mechanism is the PHS expansion in the DS. In cases where the packet is to be immediately handed over to the embedded user application, it might not be required to expand the packet header, unless the user application needs some of the header information. In that case as well, bypassing the PHS expansion can result in improved performance.

The DOCSIS 1.1 library provides an API to support those types of performance enhancements, among others. In the US, the API includes a scheme to semantically identify the service flows that should be used in this special manner and a dedicated set of functions and supporting mechanisms inside the library that enable the user application to make use of those mechanisms. In the DS, the API allows the user application to indicate for every received packet whether it should be processed in the normal path or directly consumed by the user application.

By bypassing the US classification, a packet cable application can achieve lower delay on voice packet processing, hence at service-flow creation the required handles are set in order to enable such expedited handling by the DOCSIS 1.1 library. Also, PHS can be avoided for voice DS packets, as those packets are to be immediately consumed by the embedded voice processing entity, achieving an additional performance improvement.

Another improvement on the voice-processing delay is achieved by a packet-synchronization mechanism that is implemented in the DOCSIS 1.1 library and exposed by a dedicated API. The DOCSIS 1.1 library enables a user application or the packet cable application to get an indication on the actual timing of the US packet transmission grants. This allows the packet cable application to optimally schedule the voice sampling in order to achieve minimal voice delay.

Packet Processing

Some user applications implement a sort of packet filtering or manipulation (e.g., network address translation [NAT] or firewall). Those types of applications require that packets be handed over to them upon arrival through a network interface and prior to being sent through a network interface. To support such applications, a dedicated API is provided. The API enables the user applications to be notified with every incoming or outgoing packet. Note that there might be more than one application requiring notification. The user application may manipulate the packet content, indicate to the DOCSIS 1.1 library that the packet should be dropped, or allow further handling of the packet according to the DOCSIS 1.1 filtering specifications.

Shared Persistent Storage

User applications usually require a method to store persistent operational parameters. The DOCSIS 1.1 specification also requires that some parameters are persistently stored, and therefore a supporting mechanism is implemented as part of the DOCSIS 1.1 library using a flash-memory–based file system.

The persistent file system is made available to user applications through an API that allows them to allocate storage areas for private use. Storage-area content can be retrieved by the user application at start-up for initialization and may be updated upon a configuration change.

Logging

Local and remote logging mechanisms are defined as part of the DOCSIS 1.1 specifications. Those mechanisms allow the DOCSIS 1.1 library to report events to a logging server and to locally store recent events in persistent storage for later diagnosis.

Those mechanisms are made available to user applications through the library API. By utilizing this existing mechanism, the user applications can leverage the sophisticated logging options defined in DOCSIS 1.1 (e.g., error levels, throttling, etc.).

Management and Control

The operation of the user application may depend on the status of the DOCSIS connection and the DOCSIS operational parameters. To support such needs, an API to indicate changes in the cable link status is provided. This API allows any interested user application to register for such notification.

Another set of APIs allows the user application to retrieve the DHCP configuration as established by the DOCSIS 1.1 library as part of the DOCSIS 1.1 initialization mechanisms and to use the DOCSIS 1.1 trivial file transfer protocol (TFTP) client (e.g., for retrieval of user application configuration files).

A packet cable application uses the APIs to retrieve the MTA IP configuration parameters from the DOCSIS 1.1 DHCP client. It also uses indications regarding the cable interface link status, as this may affect ongoing phone calls.

Conclusion: The Benefits a DOCSIS 1.1 Library

Throughout the paper, the APIs of a DOCSIS 1.1 library were presented, with packet cable as an example of a user application. By encapsulating the DOCSIS 1.1 framework as a set of services provided by a library, user applications can utilize the DOCSIS 1.1 mechanisms and implement reliable and high-performance delivery of content over the cable infrastructure. The use of a library also enables efficient sharing of system resources (e.g., persistent storage and cable bandwidth) in case of concurrent user applications.

RPR Infrastructure for the Delivery of Deterministic Ethernet in the MAN

Bob Schiff
Senior Director, Marketing
Lantern Communications

This article examines resilient packet ring (RPR), an emerging technology and architecture for packet-based metropolitan-area networks (MAN).

Carriers' Services Portfolio—A Network Outlook

Service providers offer a range of bandwidth services to customers who need to connect multiple locations. A service provider's portfolio includes a mix of private-line, frame-relay, asynchronous transfer mode (ATM), wavelength and Ethernet services. The charts shown in *Figure 1* show the distribution of these services today and in four years. Looking ahead, we can expect growth in all of these services, but we believe the largest growth will be in the newest entrant, Ethernet. Scaling from kilobits to gigabits and being the most widely deployed data transport technology in the world, Ethernet has all the makings to become a core service offering for carriers worldwide.

Already a well-established fixture in corporate networks, Ethernet is quickly becoming the standard communications interface outside the enterprise as well. For example, hotels offer Ethernet modems in guest rooms supporting high-speed Internet access. At home, Ethernet is the standard interface between the home computer and the broadband (cable or DSL) modem. Home computers are now sold with Ethernet ports as part of their standard configuration. With so much momentum, it is only a matter of time before Ethernet becomes a strategic service offering for network operators.

Once we accept the premise that Ethernet services will be successful in the public network, it is then important to consider the network architecture that is best suited for its delivery.

The Importance of Ethernet

Why all the fuss about Ethernet? For one, it has an amazing lifecycle. When you consider the lifecycle of Ethernet to that of synchronous optical networks (SONET) and ATM, it dwarfs them both—and no one knows when the innovation will stop.

There are few technologies that can compare to Ethernet in its ability to evolve and adapt. Ethernet's longevity and durability are a testament to the elegance of the original concept and the effectiveness of the industry to evolve the technology to meet the needs of its newest users while preserving compatibility with its enormous installed base.

Ethernet has changed significantly from how it began over 20 years ago when it was introduced to the market as a shared, half-duplex 10 megabits per second (Mbps) local-area network (LAN) technology. It is now a full duplex technology that supports speeds from 10 Mbps to 1000 Mbps over copper and fiber media to distances of over 60 kilometers. The standardization of 10 Gigabit Ethernet is well underway, scaling this adaptable technology yet another order of magnitude.

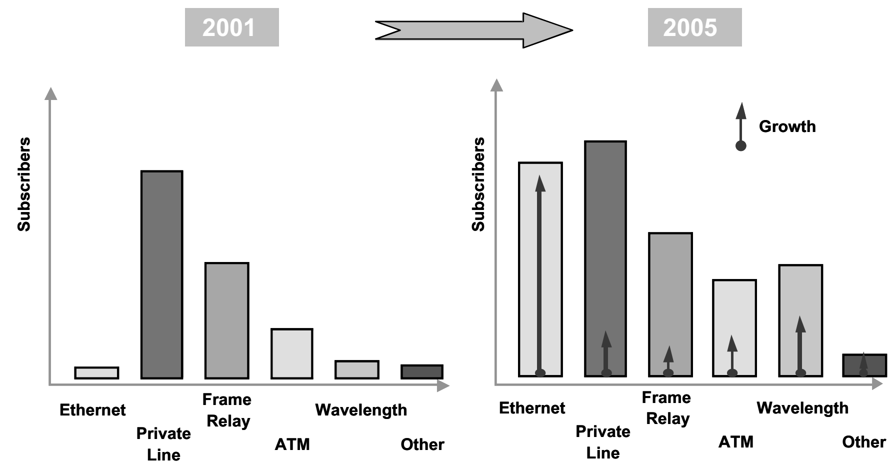
Ethernet's flexibility and low cost, combined with its familiarity and ease of use, have enabled it to dominate the LAN landscape (over 95 percent). We expect this success to spill over into the wide area, and we expect that Ethernet-based services will be the successor to ATM and frame-relay services in MANs.

Figure 2 charts the innovation that has occurred over the past 25 years, starting with Bob Metcalf's patented invention back at Xerox PARC and moving forward to full duplex Ethernet, optical Ethernet, and Gigabit Ethernet. Standards that are expected in the next two years include 10 Gigabit Ethernet, first-mile technologies (for example, Ethernet over passive optical networks and Ethernet over DSL), and Ethernet aggregation and distribution solutions such as RPR.

Introducing an Ethernet access service is a natural choice for service providers. More than 95 percent of all data traffic originates and terminates as Ethernet. An Ethernet access service will seamlessly connect to a customer's access device that already supports Ethernet ports. This will greatly simplify the access solution by eliminating the cost and complexity of introducing another technology such as SONET, ATM or frame relay. Another factor in Ethernet's favor is its economies of scale. When thinking of Ethernet, you should not think in terms of hundreds of thousands of interfaces

FIGURE 1

The Changing Services Landscape



sold; you should think in terms of hundreds of millions of interfaces sold per year. These volumes translate to a large cost advantage over other networking technologies. Lastly, we must not overlook Ethernet's ubiquity and uniformity.

Ethernet is a universal technology that is defined by the same standards worldwide. Ethernet ports on equipment used in North America operate identically to Ethernet ports used on equipment used in Europe, Latin America, and Asia. This is a refreshing change from traditional telecom technologies that are defined by different standards in different parts of the world. Indeed, we believe that when life is found on other planets, they, too, will be using Ethernet!

Ethernet access is a scalable service offering that, when delivered over the right infrastructure, will permit the customer or the service provider to adjust the speed of the connection remotely. For example, an Ethernet access service delivered using a fast Ethernet port can be configured to support 20-Mbps throughput at one time and be quickly reconfigured to operate at 80-Mbps throughput at another time. This flexibility will allow customers to tune their access services on-demand to match their real-time traffic demands.

Ethernet will become the universal service jack for the 21st century. Once a service provider offers Ethernet access services with quality of service (QoS) capabilities, there are many revenue-generating possibilities. As shown in *Figure 3*, a provider will be able to offer integrated access solutions similar to the integrated access service provided today, but using all-packet techniques rather than time division multiplexing (TDM) schemes. Instead of using TDM timeslots to separate traffic and services, the differentiated Ethernet offering will use virtual LANs, Internet protocol (IP) addresses, and/or application port numbers to separate services and applications.

FIGURE 2

Continuous Innovation

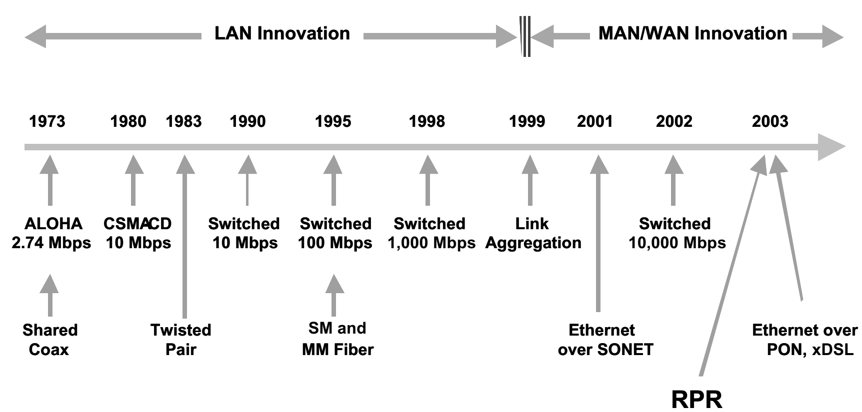


FIGURE 3

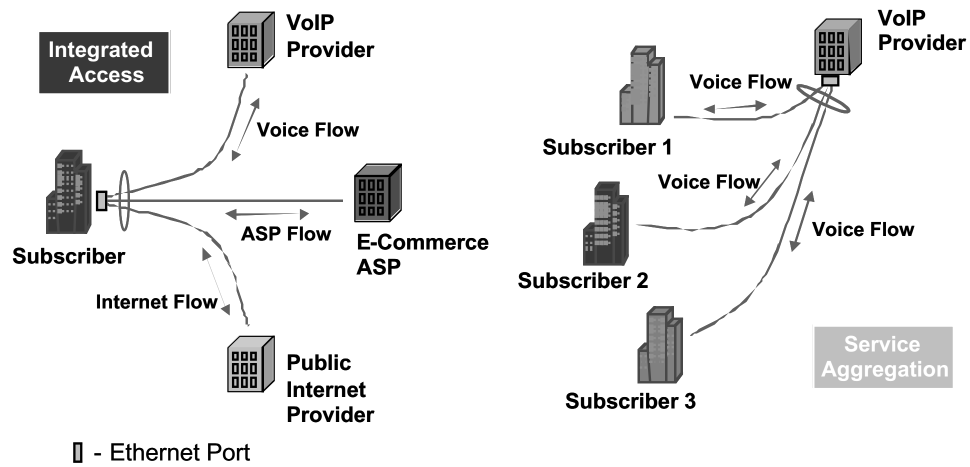
Enabling New Services



Service providers will use Ethernet as the interconnect technology of choice between networks, taking advantage of its capacity, low cost, and ubiquity for distributing and aggregating services to and from their end users.

Ethernet Service Infrastructure

But how best to deliver this Ethernet service? There is certainly no shortage of options—and this is the source of much confusion for customers and carriers. They hear from Ethernet-switch vendors, from packet-over-SONET vendors, Ethernet-over-SONET vendors, dense wavelength division multiplexing (DWDM) vendors, and now RPR vendors. It's very difficult for these customers and carriers to sort through all the marketing fluff and hype to identify what really makes sense in their given situation.

Figure 4 examines Ethernet delivery using SONET and DWDM. SONET's underlying TDM technology is not designed to accommodate the bursty and dynamic nature of packet applications. SONET's full-period circuit services have rigid boundaries that do not lend themselves to bandwidth sharing and dynamic bandwidth adjustment, both of which are important attributes of a flexible packet-switch network. Many of these next-generation SONET equipment add/drop devices use proprietary techniques for supporting or improving their data capabilities.

Metro DWDM systems that simply map Ethernet services to wavelengths are expensive and inefficient. Much like SONET, these metro DWDM systems lock up bandwidth and do not dynamically share unused capacity with other network users. This fixed allocation of network bandwidth results in stranded capacity and low utilization of network bandwidth. Indeed, there is much that can be done over a single wavelength of light before a service provider needs to consider introducing DWDM. DWDM systems often incorporate proprietary techniques for mapping data (e.g.,

FIGURE 4

Circuit-Based Solutions for Ethernet Service Delivery

— Proprietary techniques for data support

Metro DWDM

— Not bandwidth efficient

— Expensive

— High operations overhead

— Proprietary

Ethernet) to their wavelengths. It is unlikely that the equipment of two DWDM vendors can talk to each other and pass Ethernet streams.

Figure 5 examines the Ethernet-switch solution set. For example, a provider may use Layer-3 Ethernet switches (i.e., routers). However, routers do not support an edge-to-edge Ethernet service and are complex and difficult to manage. Also, routers do not maintain QoS across multiple devices, a key requirement in a carrier-class metro infrastructure. Service restoration in a routed network can take tens of seconds—far slower than the 50-millisecond performance required of carrier-grade solutions.

Using Layer-2 Ethernet switches, the provider must still be concerned with the cost and complexity of managing multiple bridges. Ethernet switches, like routers, do not provide a mechanism for ensuring QoS across multiple hops. Service restoration in an Ethernet-switch network, again, can take tens of seconds—the convergence time for the spanning-tree protocol. The spanning-tree protocol actually breaks the ring, forcing a linear topology that does not take advantage of the ring for optimal path selection.

When we look at the different ways of delivering Ethernet service in the MAN shown in *Figure 6*, we see that there is only one architecture that incorporates a Layer-2 media access control (MAC) technology designed for the MAN. This architecture is RPR. RPR is an emerging technology being developed specifically for packet-ring environments to achieve maximum bandwidth utilization while preserving QoS commitments for packet applications such as Ethernet services. Neither SONET nor Ethernet switching addresses the need for a MAC layer designed for the metropolitan area environment (*Figure 4*). SONET employs Layer-1 techniques for bandwidth management and service protection. Ethernet switches rely on Ethernet bridging or IP routing for bandwidth management and service protection. Consequently, the network is either underutilized, in the case of SONET, or non-deterministic, in the case of Ethernet switches.

RPR addresses these shortcomings by defining a MAC layer optimized for metropolitan area networks that provides the resilience, deterministic service and manageability required of next-generation access networks.

Resilient Packet Ring Solution

RPR networks will be used as feeder rings in the MAN. These feeder rings, also known as collector rings, will be used in much the same way as SONET rings today, but for

FIGURE 5

Ethernet Switch Solutions for Ethernet Service Delivery

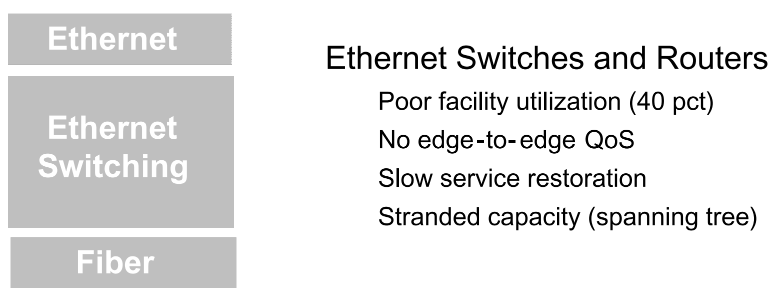

FIGURE 6

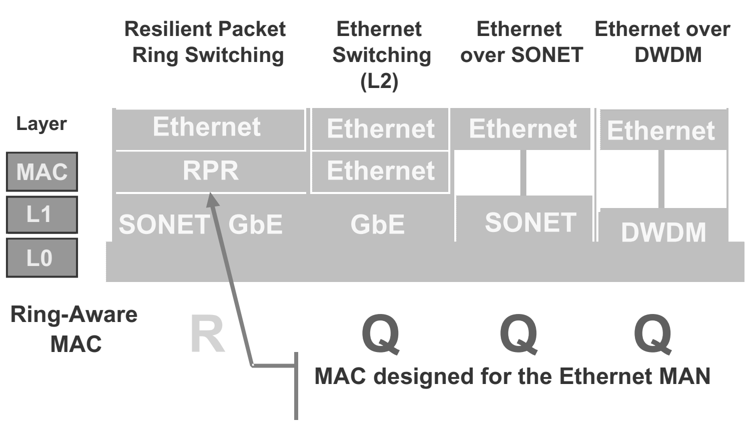
Ethernet in the MAN



packet traffic. Packet access networks such as cable-modem systems and fixed wireless networks will feed RPR networks as shown in *Figure 7*. The RPR network aggregates the packet traffic from around the ring onto one or more highly concentrated links connecting to the network edge. At the network's edge, these links are the handoffs to the DWDM and router networks that switch the traffic to its final destination.

RPR standards are currently being worked on within the Institute of Electrical and Electronics Engineers (IEEE) 802.17 RPR Working Group. The time line for the first draft to be available is January 2002, with an adopted standard in March 2003. The RPR Alliance is a marketing alliance created by a number of RPR companies to promote RPR applications and to accelerate interoperability testing and deployment of RPR solutions.

Several key features distinguish RPR solutions from SONET and Ethernet switch solutions. RPR provides a ring-aware solution for MAN packet networks. It supports a bandwidth-management mechanism that ensures bandwidth commitments at a node or subscriber level. RPR incorporates a service-restoration method that guarantees service protection within 50 milliseconds of a fiber cut. RPR also defines a closed-loop congestion-control technique that enables maximum utilization of the ring capacity while preserving service-level commitments.

The end result is a packet-optimized solution that fully utilizes fiber capacity, provides SONET-class resilience, and supports thousands of packet applications, including metro Ethernet services, each backed by service-level commitments. To illustrate this advantage, *Figure 8* contrasts the number of metro Ethernet services, each configured with a

FIGURE 7

Using RPR for Traffic Distribution and Aggregation in the MAN

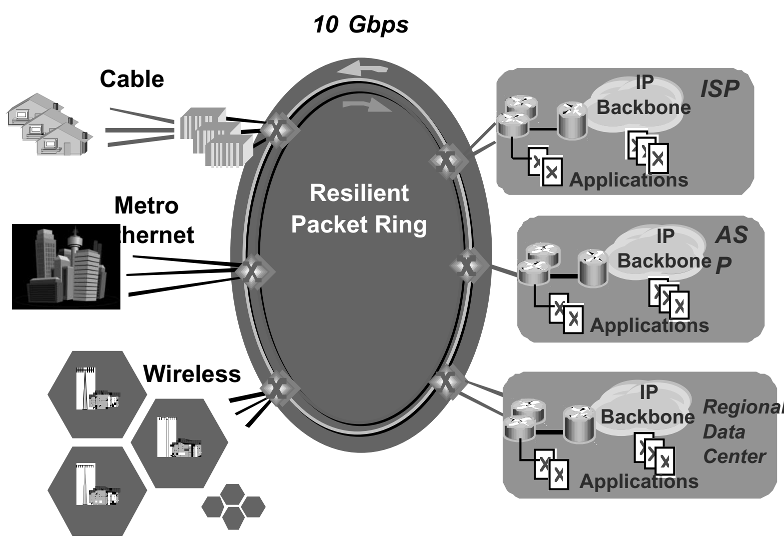


FIGURE 8

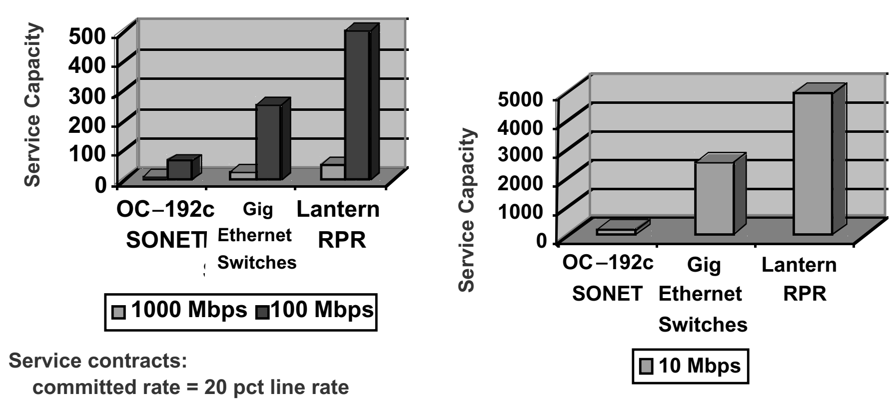
RPR's Disruptive Advantage: Ten times the service at half the cost



committed bandwidth equal to 20 percent line rate (e.g., 20 Mbps for an Ethernet service delivered using a 100 Mbps Ethernet port), that can be provisioned on a SONET OC-192c 2-fiber ring, a dual 10 gigabit Ethernet ring (Ethernet switches), and a dual 10-Gbps RPR.

The RPR solution supports over double the number of Ethernet services than Gigabit Ethernet switches, and over 10 times the number of Ethernet services than OC-192c SONET systems.

Perhaps most important is the solution cost. A network model consisting of five add-drop locations (four tributary sites and one hub site) was priced out for SONET and RPR. The service contract used in the example is a Gigabit Ethernet-based offering with a 500-Mbps committed bandwidth—i.e., a 500-Mbps committed rate and a 1,000-Mbps peak rate (see *Figure 9*). The SONET on the left prices out at approximately $900,000 for a dual OC-192c ring with four add/drop multiplexers (ADM). The RPR solution—with the same number of service contracts, but only utilizing 40 percent of the ring capacity—prices out at approximately $500,000, or nearly half the cost of the SONET.

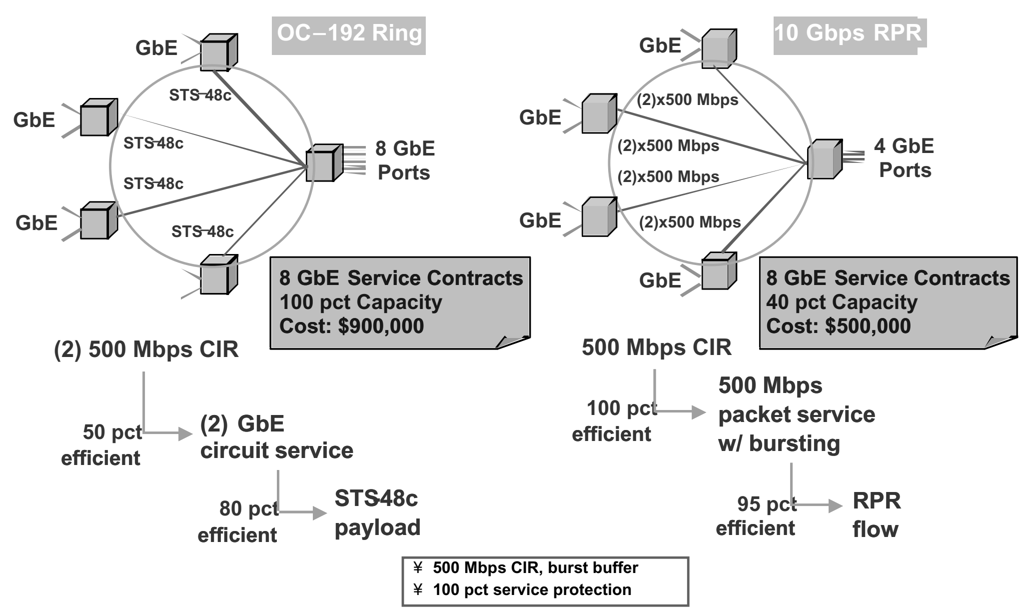
Conclusion

In this paper, we have contrasted several approaches to delivering Ethernet services in the MAN. Circuit-based solutions, characterized by their static-full period, TDM-based connections, are neither cost-effective nor bandwidth efficient for Ethernet service delivery. Ethernet-switch solutions are not designed for the carrier environment and do not provide the edge-to-edge QoS or rapid restoration required of metro infrastructure.

RPR is a technology and architecture that is being developed for packet-based MANs. Leveraging the efficiencies and economics of packet technologies and designed to deliver SONET-class performance and reliability, RPR is the most scalable and cost-effective architecture on which to deploy Ethernet and other packet services on metropolitan fiber rings. RPR networks will play an important role in the evolution of the public network, providing a reliable, scalable, and efficient packet edge for the emerging optical Internet.

FIGURE 9

Economic Advantage of RPR



Fibre-Channel Extension Services

Paul Schoenau
Enterprise Product Marketing Manager
Akara

Today's optical-services market is characterized by what has become known as the "optical chasm"—the barrier that is separating enterprise need for services and the ability of service providers and carriers to deliver cost-effective, business-critical offerings. This paper explains how emerging technologies can bridge this optical chasm, finally delivering cost-effective storage services while reducing capital and operations costs.

As today's enterprise marketplace continues to demand 24/7 data-center operations, information technology (IT) managers are under increasing pressure to support the networking of more and more high-availability applications such as disk mirroring, remote tape backup, and server clustering across the optical metropolitan-area network (MAN) and wide area network (WAN). To support these applications, many enterprises have created storage-area network (SAN) architectures built from various combinations of servers, disk arrays, tape silos, switches, and networking equipment, typically connected with Fibre Channel links.

Current solutions to network Fibre Channel have relied on link extenders (LE) and dense wavelength division multiplexing (DWDM) (see *Figure 1*)—transparent solutions that meet only the basic connectivity requirements of carrying the 1s and 0s of data-center protocols.

Connectivity alone, however, does not meet the networking requirements of today's data centers. To deliver a truly efficient, high-performance data-center operations solution, Enterprise chief information officers and network managers are increasingly demanding full, turnkey services with capabilities that go beyond today's solutions and provide seamless integration of the SAN and MAN networking environments. These capabilities include the following:

- Support of data-center applications over distance, including support of Fibre Channel and the problems that distance introduces;
- Detailed optical-service visibility, control, and security; and
- Scaling of optical networks to accommodate growth.

To address the emerging needs of data-center networking, service providers and carriers are turning to protocol-aware optical platforms that surround the optical network, providing reduced costs and opening the door to diverse new service offerings. The use of these types of protocol-aware platforms can equip the optical layer for the delivery of storage networking traffic by providing the following benefits:

- Optimized use of networking resources:
  - Up to 90 percent more efficient use of the network;
  - Bandwidth delivered that matches the application's requirement; and
  - Zero packet loss.
- Enhanced optical services networking:
  - Improved service visibility;
  - Service security; and
  - End-to-end service management.
- Interoperability with existing equipment:
  - Non-intrusive Fibre-Channel interoperability;
  - Improved Fibre-Channel transport performance; and
  - Easy integration into existing synchronous optical network (SONET) and DWDM infrastructures.

Also, By using native-protocol flow control to combine packet-based flows of Fibre Channel and Gigabit Ethernet into a standard SONET payload that can be carried on dark fibre, SONET, or a DWDM optical network, these platforms can bridge the data center and the optical MAN and WAN, providing:

- Optimized control of the optical network according to individual application requirements, such as latency and throughput;
- Visibility of performance metrics and usage statistics; and
- Efficient, overhead-free data multiplexing.

Time division multiplexing (TDM) technology can deliver deterministic performance and security isolation demanded by enterprises' storage applications. A clear demarcation point between the enterprise and the network will result in greater service reliability, network accountability, and lower operational cost. The result is services beyond simple optical connectivity.

Key Benefits

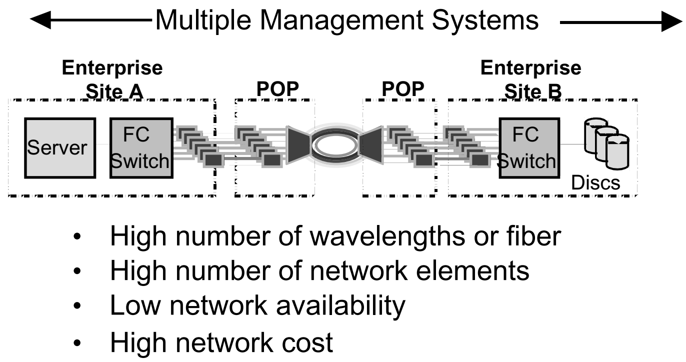
Optimized Use of Networking Resources

Up to 90 Percent More Efficient Use of the Network

A protocol-aware platform can eliminate the need to forward unnecessary protocol "white space" which, in a typical application, could consume as much as 90 percent of the

FIGURE 1

Current Solutions to Network Fiber Channel



available bandwidth (see *Figure 2*). By replacing white space with control and data packets from multiple services, more "real data" is carried per unit of fiber deployed, and bandwidth use is optimized.

Bandwidth Delivered to Meet Application Requirements
When bandwidth is provisioned to support the actual application requirements, the need to over-provision the network is eliminated. This process simplifies network engineering, provisioning, and management, and unused bandwidth can then be allocated for additional revenue-generating services.

Zero Packet Loss
The allocation of a specific amount of bandwidth end-to-end specifies a deterministic path through the network per service, without any loss of data.

Enhanced Optical Service Networking
Improved Service Visibility
End-to-end visibility of Fibre-Channel optical data-center services can also provide detailed end-to-end service information including the following:

- Performance metrics;
- Latency measurements;
- Flow control monitoring; and
- Link statistics.

Protocol error checking at each stage in the service circuit enables rapid fault isolation. Enhanced service-level agreements (SLA), with detailed statistics that can be measured and reported, can also be created (see *Figure 3*).

Deterministic Security
Data-center traffic needs for guaranteed security and high performance require the network to provide end-to-end service isolation with no sharing or contention for bandwidth resources.

End-to-End Service Management
By collecting, processing, and correlating detailed service information, and by consolidating that information into a single, end-to-end service view, interoperability with other network operational support systems can be achieved. The ability to manage and control high-speed storage services can also result from this form of network management.

Leveraging Existing Assets

Non-Intrusive Fibre Channel Interoperability

By interoperating with the data-center protocols at Layer 2, the values of efficient multiplexing, protocol error checking, and native flow control can be leveraged without impacting performance and operation of the link.

Improved Fibre-Channel Transport Performance

A flow-control system can be set to smooth and pack frames into the provisioned line bandwidth, maintaining the utilization at nearly 100 percent. For latency-sensitive applications, flow control can be set to "wire speed" latency, making the packet latency equivalent to a piece of wire with the tradeoff of less efficiency on the line utilization.

Easy Integration into Existing Optical Infrastructure

By multiplexing packet-based flows into a standard SONET, the payload can be designed to interoperate with existing infrastructure, whether SONET, DWDM, or dark fiber.

Summary

Together, these benefits—optimized use of networking resources, enhanced optical-services networking, and interoperability with existing equipment—will enable today's enterprise data centers to quickly and cost effectively meet rising demand for high-availability storage networking applications, and implement solutions that maximize the performance, security, and efficiency of carrying Fibre-Channel links across the MAN and WAN.

The Carrier-Class Gateway in the Voice over Broadband Access Evolution

Mike Schroeder
Vice President, Technical Services
General Bandwidth

Issues with Initial Deployment of Voice over Broadband Access

Initial deployment of voice over broadband access focuses on broadband loop emulation services (BLES), a joint standard from the ATM Forum and the DSL Forum. BLES is based on asynchronous transfer mode (ATM) virtual circuits over digital subscriber line (DSL) between a customer premises integrated access device (IAD) and a voice gateway. The gateway, in turn, interfaces to a Class-5 switch.

BLES provides no routing intelligence or call features, all of which come from the Class-5 switch. BLES, therefore, facilitates early deployment of voice over DSL (VoDSL) by reducing the functionality required in the IAD, thus reducing the unit cost of the IAD—an important early-deployment feature, considering an IAD is required for each customer premises.

The following sections describe issues that can arise in the evolution of a BLES architecture to a distributed voice over Internet protocol (VoIP) architecture.

Limited Intelligence in IADs

Over time, the deployment of VoDSL using low cost, limited intelligence IADs results in an installed base of IADs with limited processing power, limited memory, and no VoIP call signaling capabilities for providing softswitch-derived plain old telephone service (POTS).

Although these IADs successfully provide BLES capability, they cannot function in a VoIP–based softswitch architecture and must be upgraded or replaced—a very expensive proposition in a large-scale BLES deployment.

Customer Use of VoIP

BLES uses voice over ATM (VoATM). However, voice can enter the protocol stack at three different points: VoIP, VoATM, and channelized VoDSL (CVoDSL) (see *Figure 1*). CVoDSL does not take advantage of bandwidth savings resulting from silence removal since it uses fixed bandwidth DSL channels. Additionally, it requires the carrier to continue to expand the time division multiplexing (TDM)–based Class-5 network and is therefore less likely to be used. Internet protocol (IP) is the dominant technology in the customer premises and is the technology that carriers view as a better fit for their long-term strategy for service delivery.

Deployments of IP phones, IP private branch exchanges (PBXs), and VoIP functionality in desktop computers, laptop computers, and personal digital assistants (PDAs) require signaling capabilities such as session initiation protocol (SIP), media gateway control protocol (MGCP), and media gateway control (MEGACO)/H.248 that are not available in Class-5 switches.

The incumbent local-exchange carrier (ILEC) network must provide access to call-control servers (softswitches) that implement these protocols in order to avoid losing revenue from customer-premises implementations.

This is the old Centrex/PBX issue revisited. VoIP allows great flexibility in its distributed architecture for call control, allowing either the customer or the carrier to provide the necessary functionality. Carriers seek to provide as much functionality and network intelligence as possible in order to offer a wide range of revenue-generating services and to prevent their networks from being used for low-margin bit pipes, leased lines, and virtual private networks (VPNs).

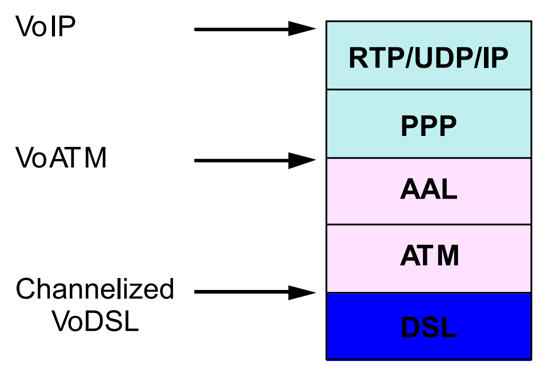
It is important that carrier-based gateways can transport VoIP traffic from both the IP PBX and VoIP Centrex scenario.

Routing of Voice and Data Traffic

When customer traffic arrives over the DSL access network, an ATM switch aggregates it. The voice traffic is forwarded to the voice gateway, and the data traffic is forwarded to one of several networks.

FIGURE 1

Alternatives for DSL Transport of Voice



- An ATM switch for transport to an Internet service provider (ISP) or for access to the carrier's public ATM service
- A router providing access to the public internet or a managed IP network
- A frame-relay switch for transport to an ISP
- A label-switched router (LSR) for transport over a multiprotocol label switching (MPLS) backbone

This results in multiple pieces of data switching equipment in the central officer (CO), resulting in issues of the following:

- Equipment footprint, power, and physical space in the CO
- Interoperability among equipment possibly coming from different vendors
- Management of multivendor equipment resulting in several different element-management platforms
- Increased cost associated with purchase of many different pieces of equipment
- Routing delay resulting in end-to-end quality of service (QoS) issues and poor voice quality

Interworking between Class-4 and Class-5 Softswitches and Gateways

Class-5 switches implement Class feature software, whereas Class-4 switches do not need that capability. Class-5 switches need a range of interfaces to the customer, including POTS, integrated services digital network (ISDN), xDSL, T1/E1, T3/E3, STS–3/STM–1, whereas Class-4 switches generally just need a range of STS–n/STM–n interfaces. As the software-intensive functionality and the diversity of physical interfaces of a Class-4 switch is less complex than that of a Class-5 switch, it is the Class-4 switches that are being replaced by softswitches and gateways before Class-5 replacement. Moreover, the vendors specializing in Class-4 replacement are different from the vendors specializing in Class-5 replacement.

During an evolution to an end-to-end packet voice architecture, it is imperative to ensure interworking between Class-4 and Class-5 softswitches and gateways.

Evolution from MGCP to MEGACO

Initial deployment of softswitch architecture in the public network is using MGCP, primarily due to the simplicity of its implementation. This raises issues of functionality that is not available in MGCP or is provided more flexibly by implementing the MEGACO standard.

Interworking with Customer-Premises H.323

At the customer premises, the H.323 packet voice technology has the largest installed base. In the public network, MGCP currently is the most prevalent packet voice technology. As a result, it is imperative that H.323 and MGCP/MEGACO interwork in public network softswitches.

Provision of Emergency Services

There are two issues related to provisioning of emergency E-911 service: customer-premises equipment (CPE) and network equipment.

Customer-Premises Equipment

Current POTS lines provide power to customer premises analog phones, and PBX customers generally incorporate UPS backup to ensure that the subscriber can make emergency calls in the event of a loss of electrical power.

Packet voice at the customer premises and in the public network must also ensure that the customer can continue to make emergency E-911 calls in the event of a power loss at the customer premises.

Network Equipment

Network equipment must be able to provide a number of features specific to E-911 calls, including the following:

- Emergency ringback if the call is disconnected
- Calling party on/off hook status provision to E-911 operator
- Route diversity
- Multifrequency tone provision as required by tandem switch from which emergency service is provided

Provision of Wiretap Capabilities: CALEA

The 1994 U.S. Communications Assistance for Law Enforcement Act (CALEA) requires carriers to provide wiretap capabilities in cases authorized by court order, and reimburses them for the associated cost. CALEA implementation for packet voice is described by the Federal Communications Commission (FCC) in 97-213.

Wiretaps authorized by law enforcement authorities are implemented in Class-5 switches for analog POTS lines and TDM access facilities. Packet voice must provide equivalent functionality.

Conclusion

There are still significant issues related to the migration of voice services from a Class-5/BLES architecture to a fully packetized distributed softswitch architecture.

The ideal gateway platform is designed to allow carriers a graceful migration path from a Class-5 derived service, such as BLES, to a fully packet-based softswitch by supporting both services concurrently. Additionally, as new access architectures are deployed, such as ATM passive optical network (APON), Ethernet passive optical network (EPON), and LRE, the G6 platform can continue to provide both Class-5 and softswitch-derived services. The key features that allow the platform to provide this migration are as follows:

- Concurrent support of VoIP and VoATM
- Support of MGCP and MEGACO standards for softswitch deployments
- Support of softswitch control of BLES–based IADs
- IP routing and MPLS support for IP–based deployments
- QoS interworking between IP, ATM, and MPLS
- Scalable ATM/IP switching architecture for access aggregation

A graceful evolution is a complex undertaking, and the carrier-class gateway is at the center of that evolution.

Deploying All-Optical Access Networks

Shane Shaneman

Market Manager, Access Solutions and Business Development

Corning Cable Systems

This article examines the emergence of the passive optical network (PON) cloud and the dynamics and drivers behind the deployment of fiber further in the access network. It will examine the primary PON architectures deployed to date, discuss the advantages and disadvantages that each represents to a carrier's network strategy and business case, and concludes with a detailed cost analysis of passive-infrastructure cost drivers for PON deployments.

Emergence of the PON Cloud

Over the past 12 to 18 months, much attention has been given to the development and deployment of all-optical access networks to meet the continually growing demand for bandwidth in the local loop. Many active equipment vendors have developed equipment that is focused on enabling the delivery of broadband services and applications such as fiber-to-the-home, fiber-to-the-building, and fiber-to-the-business. These companies are leveraging many different protocols, including asynchronous transfer mode (ATM), Internet protocol (IP), and gigabit Ethernet.

In order to highlight the role of their active equipment, many equipment vendors represent the access network by showing the optical signal being generated in the central office or head end, passing through the PON cloud (that represents the outside plant), then somehow "magically" appearing at the customer premises (see *Figure 1*). From a carrier's perspective, it is imperative to realize that anywhere from 50 to 70 percent of the cost and a great deal of the complexity of deploying an optical access network are contained within the bounds of the "PON cloud."

Growing Bandwidth Demand

Over the past few years, it has been determined that the Internet has grown by as much as 100 percent every 100 days. Given this growth and the emergence of broadband applications, carriers are looking for ways to increase the capacity of their access networks and capitalize on incremental revenue-enhancement opportunities. The following dynamics and drivers are motivating carriers to consider optical access networks now more than ever:

- Carriers' desire to offer converged voice, video, and data services over a single network;
- Innovations and cost reductions in optical infrastructure and components;
- And evolving need for a protocol-ubiquitous, future-proofed access network.

At the same time, carriers will not deploy an optical access network simply to increase their network capacity or available bandwidth—it must enable the carrier to offer differentiable services and generate incremental revenue. Given the high cost of network installation and deployment, carriers do not want to deploy a broadband network with the anticipation of replacing it within several years; they want to build something that is going to enable them to be more competitive and increase their incremental revenue base over the long term.

The chart below depicts historical bandwidth demands, calculated by plotting the year that residential dial-up modem technology was introduced in the Americas. Given this development in dial-up technologies, America has experienced a historic annual increase in bandwidth of 60 percent per year.

If this historic trend is projected forward, it is anticipated that residential bandwidth demands will rapidly exceed 32 megabits (Mb) in the next decade. Given the networking technologies that are available (and in development), carriers will need to consider leveraging new technologies and deploying fiber deeper in their access networks to meet the ever-increasing demand for bandwidth and enable the delivery of revenue-generating broadband services.

PON Active Equipment Market

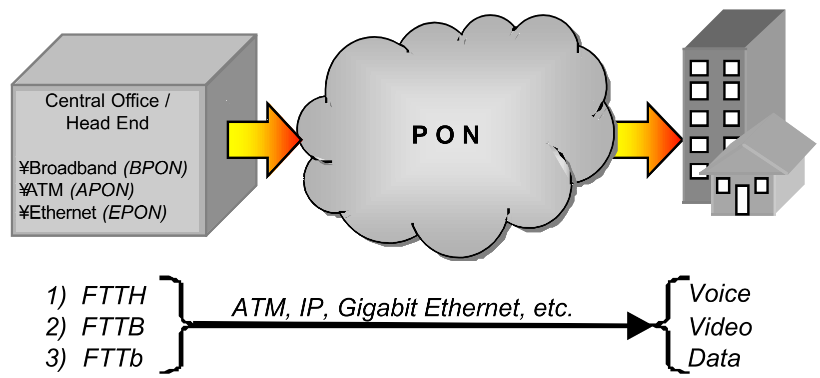
As PON technology continues to mature, many analysts and carriers alike are seeing tremendous opportunities for optical access networks to overcome the limitations of a copper-based access network and the traditional "bandwidth bottlenecks" that exist in last-mile networks. As the chart below depicts, CIBC World Markets forecasts tremendous growth in PON equipment sales over the next several years—with fiber-to-the-business representing the near-term growth opportunity and fiber-to-the-home representing more of a long-term growth area.

PON Architectural Considerations and Design Objectives

Carriers considering the deployment of a PON do not want to make that level of an investment only to be faced with the

FIGURE 1

The Emergence of the PON Cloud



dilemma of redeploying or replacing segments of that network in the next several years in order to capitalize on the next generation of active equipment and broadband services. Carriers should plan and design their optical-access network deployments carefully to ensure that they create a network architecture that can be leveraged for the next 15 to 20 years—providing them with a ubiquitous approach to protocol and an infrastructure that will seamlessly support future technologies while minimizing initial capital expenditure requirements.

When designing a PON network, the carrier should carefully consider the advantages and disadvantages of the various PON architectures and ensure that their design includes or addresses the following objectives:

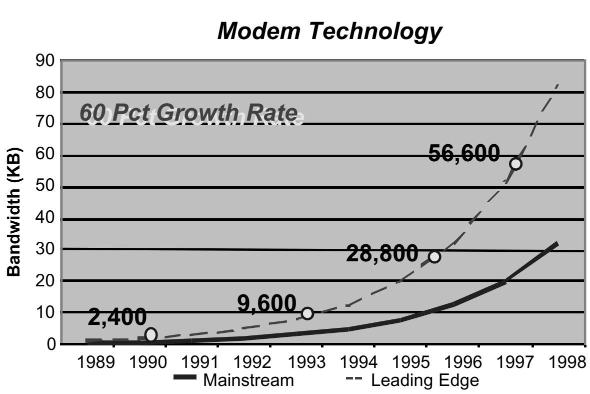
- Adaptability: ensuring that the physical plant will support different transport protocols, technologies, and emerging applications.
- Flexibility: enabling a highly configurable network through the deliberate placement of connectors, couplers, and splitters in strategic locations throughout the network design.
- Reliability: achieved by minimizing active equipment in the outside plant and limiting requirements for network powering and battery backup.
- Scalability: facilitating the incremental addition of subscribers over time and the ability to address new growth areas as they emerge.
- Low initial cost: enabling incremental infrastructure costs and deployment to be delayed until subscribers request service and/or revenue generation is ensured.

PON Architecture Designs

The generic architectural model (see *Figure 5*) below provides the general network layout and key infrastructure points in optical access networks. The network is generally comprised of three distinct network segments: feeder, distribution, and drop. The central switch is usually a central office or head end, which houses the active equipment (optical line terminal) for the optical access network. The local convergence point is the interface point between the feeder and distribution networks; whereas the network access point serves as the interface between the distribution and drop cable networks.

FIGURE 2

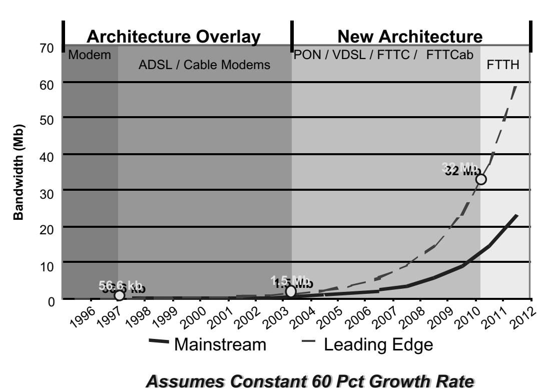
Growing Bandwidth Demand: Modem Technology



Source: TeleChoice

FIGURE 3

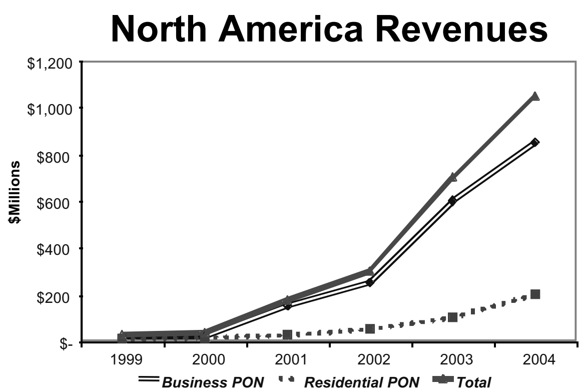
Growing Bandwidth Demand: Architectures



Source: TeleChoice

FIGURE 4

PON Active Equipment Market



Source: CIBC World Markets

In general, there are three primary architectures being considered and/or deployed in access networks to date: central switch, local convergence, and distributed splitting.

Central Switch Architecture

The central switch architecture is the ultimate access network for every network operator—as the architecture provides for a dedicated fiber to connect each subscriber to the central switch (see *Figure 6*). There are numerous advantages to using the central switch architecture:

- It provides a dedicated optical path from the central switch to each subscriber,
- It provides the greatest upgrade potential with an almost unlimited bandwidth capacity,
- And it allows for subscriber configuration to be accomplished directly from the central office without a truck roll.

However, because of the fiber requirements of the central switch architecture, this architecture is very cost prohibitive—requiring extensive up-front capital expenditures that do not prove out for a majority of business cases. There are some applications where the central switch architecture is being used cost-effectively—mainly in Europe. In Europe, central offices are decentralized—making the central-switch location much smaller and closer to the end, and reducing the lengths of fiber required to reach the end subscribers.

Local Convergence Architecture

An emerging architecture—with a particularly strong potential in the United States—is the local convergence (LC) architecture (see *Figure 7*). LC leverages a single tier of couplers and a splitter to lean out the feeder segment and provided a dedicated optical path from the link control protocol (LCP) to each subscriber. The LCP is a very powerful point in the network because the carrier can actually run multiple PON extensions—with, for example, one extension providing service at a 1x8 split, while another is at a 1x32—and provide for extensive subscriber configurability. The LCP can also be a point in the access network that houses active equipment for a point-to-point network architecture (which does not include coupler/splitters).

The LC architecture provides carriers with the following benefits:

- It provides the best balance of capital expenditures and long-term scalability, and
- It eases subscriber configuration by reducing the number of network-interface points and providing a dedicated optical path from the LCP to each subscriber.

On the down side, if the LC architecture is deployed in a dense area, it may cause fiber density and footprint issues at the LCP.

Distributed Splitting Architecture

Up to 75 percent of most residential deployments today are deployed using the distributed-splitting architecture because of its low cost and lean fiber infrastructure (see *Figure 8*). The advantages of the distributed splitting architecture include the following:

FIGURE 5

Generic Layout

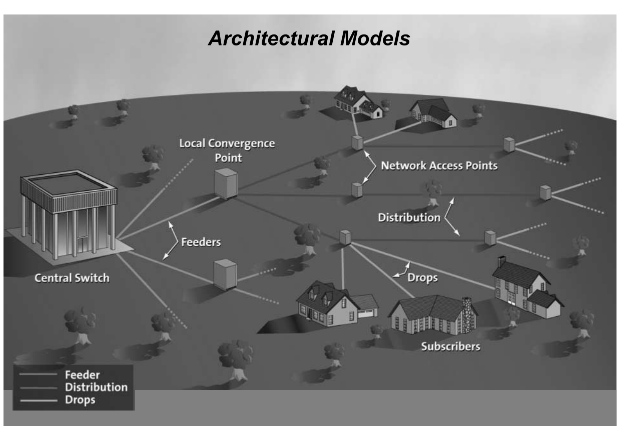


FIGURE 6

Central Switch Model

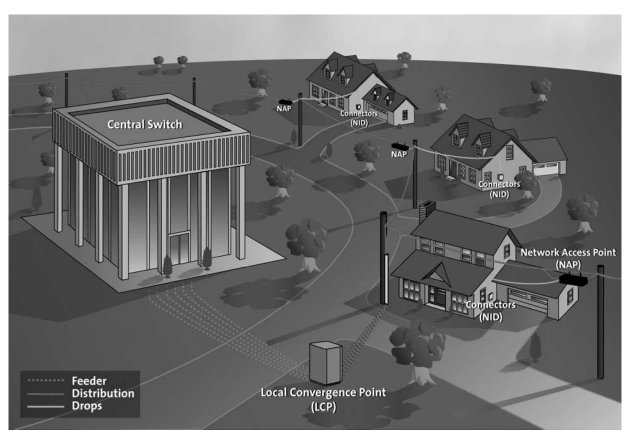

FIGURE 7

LC Model

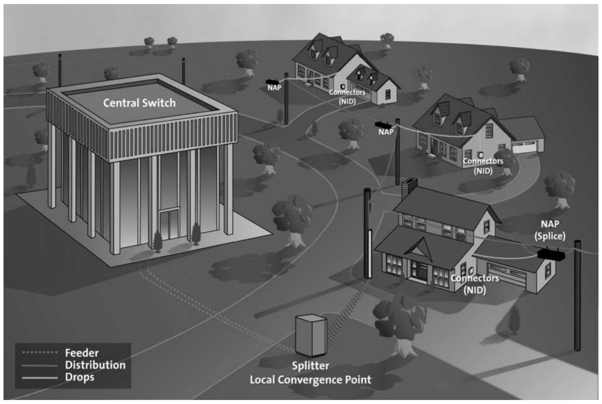

FIGURE 8

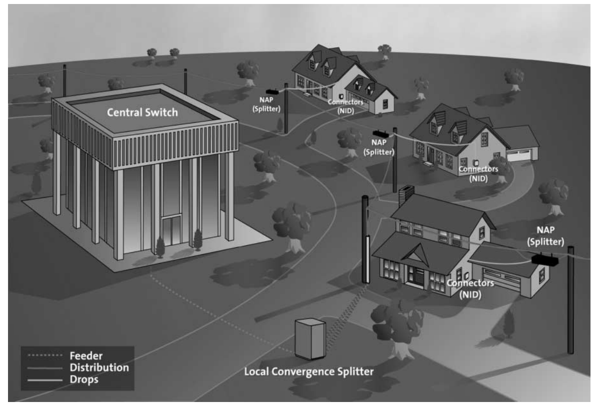
Distributive Splitting Model



- It leverages the cumulative benefits of two tiers of couplers/splitters—one at the LCP and another at the network access point (NAP), and
- It is the least expensive PON architecture to deploy (for penetration rates > 30 percent).

However, the distributed splitting architecture may limit the long-term adaptability and scalability of the PON—particularly in its ability to support Lambda services. It is impossible to know today what active equipment or services will be available or required over the next 10 to 20 years. If at some point in the future the carrier decides it wants to migrate toward a dedicated optical path to each subscriber (LC or central-switch architectures), it literally has to recable its entire feeder and distribution-network segments—which would be extremely costly.

Network Migration Strategies

Anytime a carrier is deploying an access network, it is imperative that it develops and establishes a network-migration strategy. It must think past its current deployment and project the requirements of the next five to 10 years, expecting continual change and new technology, determining how to capitalize on these changes and increase revenues, and understanding what this will mean for its overall network design and architecture.

There are two of different ways to provide for network migration: physical infrastructure and active equipment. By focusing on migration through the physical infrastructure, a carrier can simply decrease its split ratio in the access network (1x32 to 1x16, 1x16 to 1x8, etc) or migrate from one architecture to another (distributed splitting to LC, LC to central switch) (see *Figure 9*).

By approaching network migration through active equipment, the carrier should plan to continuously upgrade its active equipment or purchase and install new equipment or remove any splitters that were installed at the central office or head end (see *Figure 10*).

Network Cost Modeling

When considering an optical access-network deployment, it is important to understand the various costs associated with

FIGURE 9

PON Cloud

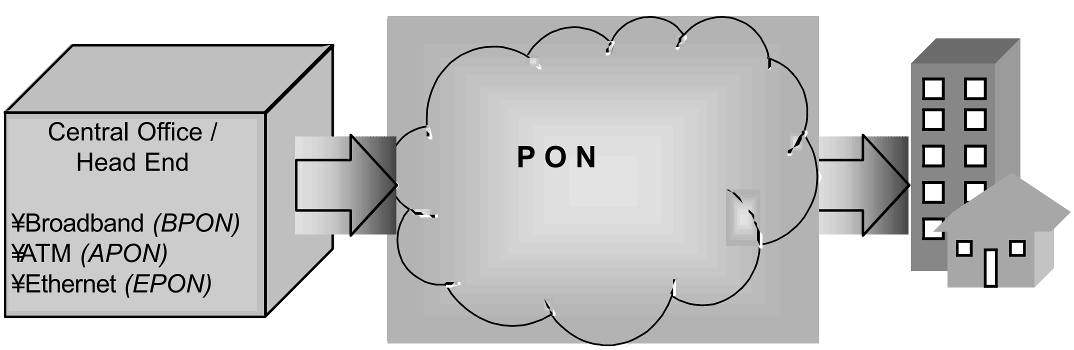


FIGURE 10

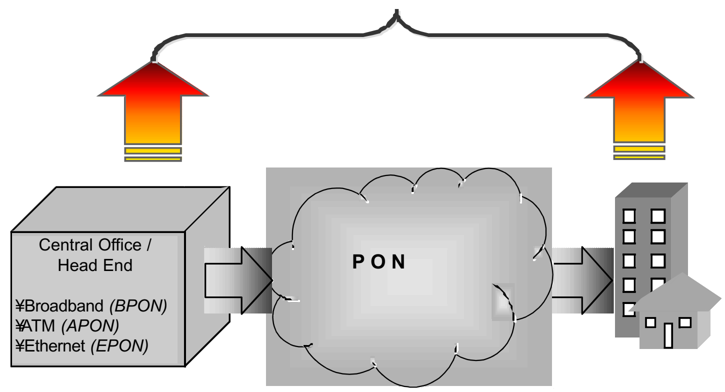
Active Equipment

1. *Decrease Splitter Ratio at Central Office/Head End*
2. *Upgrade Capacity of Existing Active Equipment*
3. *Purchase and Install New Active Equipment*



purchasing the passive infrastructure and how the infrastructure will be deployed and installed (see *Figure 11*).

A carrier must explore the immense number of deployment variables to gain a detailed understanding of how much a specific access-network deployment will cost (see *Figure 12*). Questions that address these network variables include *"How long is the feeder segment?,"* *"How many homes are going to be serviced?,"* and *"What is the anticipated take rate?"*

Labor and installation is a key piece of the deployment cost puzzle (see *Figure 13*). If a carrier deploys an optical access network that is complex or requires a high degree of craft skill, it is going to cost the carrier considerably more money than if installation complexity had been minimized. The carrier must be sure that it is looking at the deployment holistically and that it understands and is addressing each of the key variables towards minimizing the cost of deploying the network and reducing the return on investment period.

Depending on the deployment area and the associated business case, different PON architectures may be more advantageous in certain scenarios than in others. For example, many clients have gravitated toward distributed splitting as their PON architecture solution, believing it will be the least costly. In actuality—for certain scenarios—distributed splitting can actually prove to be more costly than LC architecture because of the high cost of couplers and splitters and potential for a low-port utilization in low-penetration areas (< 30 percent).

Conclusion

As the telecom industry continues to experience tremendous innovation in optical components and infrastructure,

FIGURE 11

Network Cost Modeling

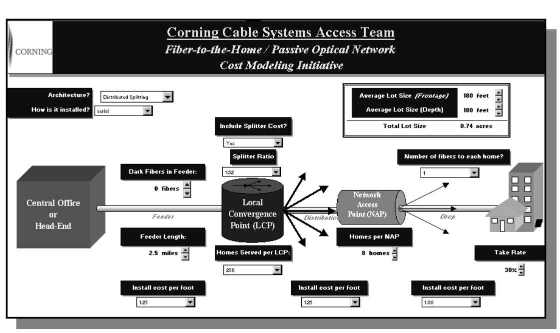


FIGURE 12

Access Deployment Cost Variables

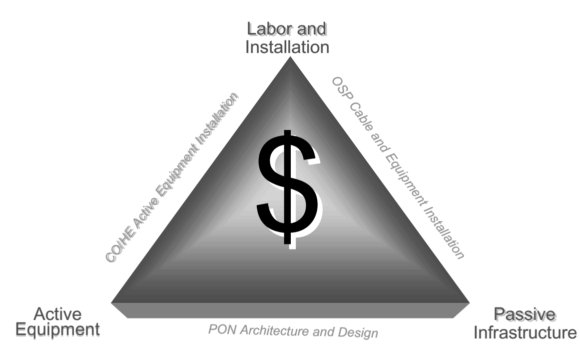

FIGURE 12

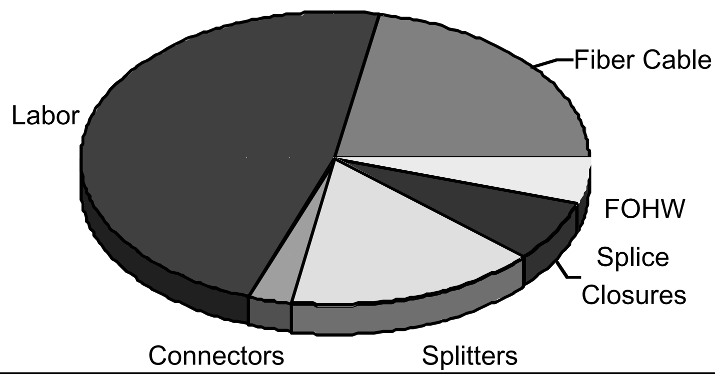
LCP Architecture



Relative Costs		
Fiber Cable	$1.00	22 Pct

Splitters	$0.73	16
Connectors	$0.13	3
Labor	$2.12	47

carriers are looking to deploy fiber deeper and deeper into the local loop; deliver differentiable, broadband services; and capitalize on incremental revenue enhancement opportunities. Prior to beginning *any* deployment, it is imperative that carriers gain a detailed understanding of the various cost drivers and dynamics that could positively or negatively impact the deployment of their optical access network and the resulting success or failure of their associated business case.

VoDSL for ILECs

Why RBOCs and IOCs Should Undertake In-Region Deployment of VoDSL Services

Steve Shaw
Director, Marketing
Jetstream Communications

Introduction

While the justification for the deployment of voice over digital subscriber line (VoDSL) services by competitive local-exchange carriers (CLECs) is clear to most in the industry, the same cannot be said for incumbent local-exchange carrier (ILEC) deployment of VoDSL. A number of ILECs, in fact, have only expressed the potential downsides of deploying VoDSL, such as the cannibalization of existing services. However, in-territory deployment of VoDSL can provide tremendous tactical and strategic benefits to both the marketing and operations organizations within ILECs. This white paper more closely examines the ILEC VoDSL opportunity.

For most CLECs, VoDSL represents the only profitably method for delivering a compelling bundle of voice and data services to the large and growing small-business and upscale residential markets. By enabling the delivery up 24 telephone lines and speed data services over a single leased copper off a single, centralized Class-5 switch, the economic drivers behind CLEC VoDSL deployment are quite clear.

Since ILECs already own the copper plant as well as Class-5 switches, or remotes, in every wire center, their motivations for deploying VoDSL services are not immediately apparent to many. However, upon closer examination, VoDSL can be shown to solve a number of near and long-term ILEC operational challenges. From a tactical perspective, VoDSL can immediately be leveraged to solve the growing copper exhaust challenge faced by many ILECs. From a strategic perspective, VoDSL provides ILECs with a graceful path for migrating their networks to a more efficient pure packet-switching architecture. From a marketing perspective, VoDSL can immediately begin to grow an ILECs average revenue generated per subscriber as well as provide a long-term method for mitigating the overall effect of competition.

VoDSL Dramatically Increases Operational Efficiency

By enabling ILECs to leverage their existing DSL broadband access networks and Class-5 local digital switches to deliver up to 24 telephone lines and a high-speed data service over a single copper pair, VoDSL can significantly improve the overall operational efficiency of ILEC local networks.

Single-Pipe Service Delivery

One of VoDSLs most significant contributions to operational efficiency is that it enables ILECs to maximize the value of every copper loop in their plant. Today, the vast majority of copper pairs are used to deliver a single analog telephone line. With VoDSL, an ILEC can now deliver up to 24 telephone lines and high-speed data services over a single copper loop. In other words, VoDSL enables ILECs to move to a single-pipe delivery method for all services delivered to subscribers (see *Figure 1*). Single-pipe service delivery can dramatically lower an ILECs overall capital and maintenance costs, and thereby significantly improve the profitability of all services delivered.

Today VoDSL Enables Single Pipe Delivery

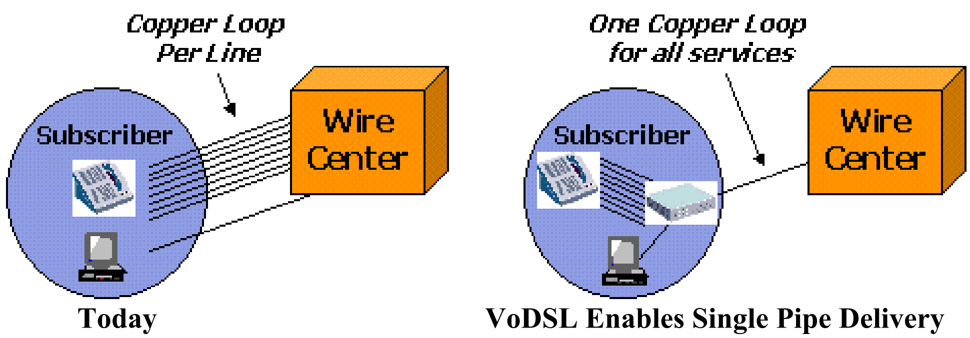
More and more small businesses and consumers are ordering additional lines to accommodate growth and to receive new services such as high-speed Internet access. According to IDC, small businesses alone were expected to add 5.2 million new lines in 2000. While this is great news for ILECs, many of them are running into severe copper exhaust challenges and are being forced to run new copper loops to meet this demand. Unfortunately, the high capital and maintenance costs associated with running new copper can significantly impact the overall profitability of the service delivered. According to one major ILEC, they expected their second largest capital expense in 2000 to be maintenance of their copper plant. Running new copper pairs can also greatly increase the time it take to fulfill line orders, which can negatively impact an ILECs perceived service quality.

Since VoDSL can liberate more than 20 copper pairs per subscriber served, an ILEC can free up a tremendous amount of its copper plant by converting even a small percentage of subscribers to VoDSL service. With VoDSL, an ILEC can cap the size of its copper plant in existing markets and possibly reduce the overall size of its plant that must be maintained.

One other benefit of VoDSL is that it provides a key missing element for ILECs toward reaching of their goal of subscriber self-provisioning. Many ILECs can envision how to enable

FIGURE 1

The Single-Pipe Delivery Method



subscribers to activate various custom calling features on their existing lines, as it requires only software provisioning of the Class-5 switch. However, enabling subscribers to self-provision additional lines is much more problematic, as it requires physical activity at the wire center and often at the subscriber premises. With VoDSL, the activation of additional lines (i.e., integrated access device [IAD] ports) for a subscriber becomes solely a software-provisioning effort. By removing any physical provisioning required to activate an additional line, VoDSL takes ILECs one large step toward achieving their goal of subscriber self-service.

Centralized Switching

By leveraging ILECs existing digital subscriber line (DSL) broadband access networks, VoDSL enables them to begin the transition to a more efficient centralized Class-5 switching model. Instead of growing and maintaining the smaller Class-5 switches deployed today in every wire center (see *Figure* 2), VoDSL enables the use of fewer, larger, Class-5 switches housed in centralized regional switching centers (RSCs) (see *Figure* 3). These RSCs often serve today as tandem offices as well MegaPOPs that house the asynchronous transfer mode (ATM) and data switching equipment to which the digital subscriber line access multiplexers (DSLAMs) deployed in every wire center backhaul their traffic.

In addition to requiring fewer Class-5 switches, VoDSL also enable the use of "lineless" Class 5s. While the Class-5 switches used in today's network are filled with line cards that directly terminate copper pairs from subscribers on a line-by-line basis, the Class-5 used in VoDSL service do not require expensive line cards, since the VoDSL gateways that enable the service terminate directly into the concentrated GR-303 interface of a Class-5 switch.

Since VoDSL enables the use of fewer, and lineless, Class-5 switches, it can dramatically reduce an ILECs overall capital and maintenance costs. In addition, it enables the rapid introduction of new features, as there are fewer switches to upgrade or update with software releases.

A Logical Path to Pure Packet Switching

While most ILECs believe that the transition from circuit to pure packet switching is inevitable, there is much debate as

FIGURE 2

Today's Decentralized Switching Network

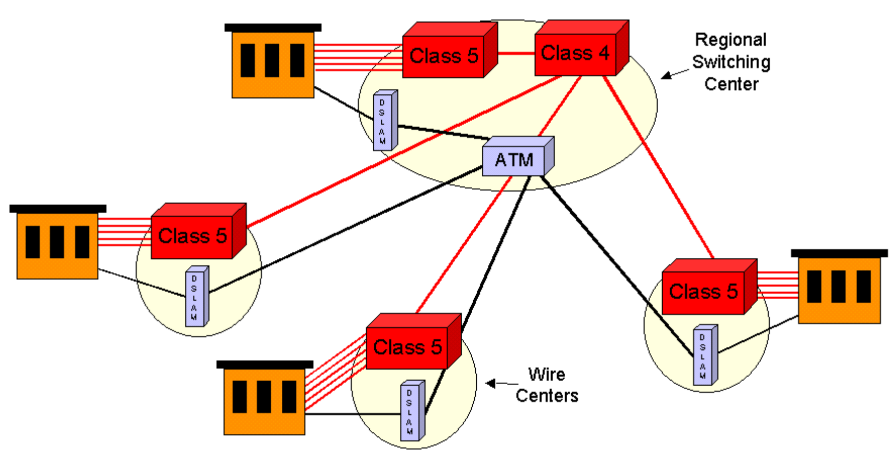


FIGURE 3

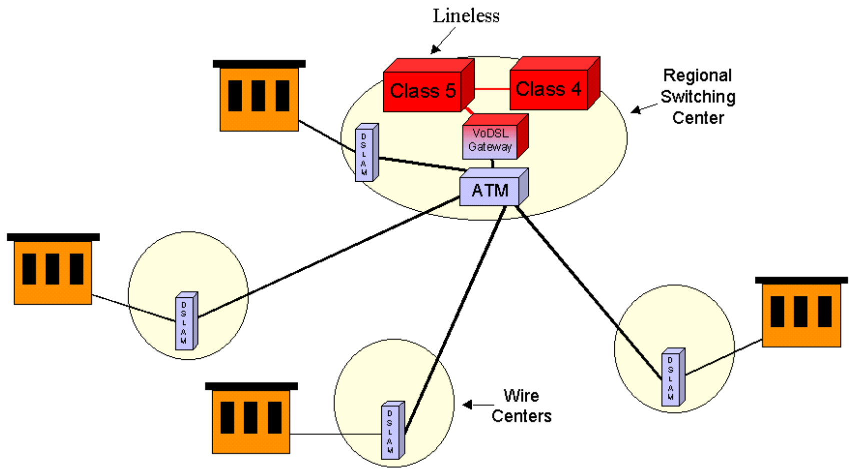
Centralized Switching Network Using VoDSL Broadband Access



to when and how the transition will take place. In addition, there has been much discussion as to where VoDSL fits in the overall transition. However, it has recently become clear to many ILECs that VoDSL is directly on the path to soft switching. In fact, VoDSL is a necessary next step that must be taken in reaching that goal.

VoDSL enables ILECs to take the critical next step of using their broadband access networks to deliver voice services. VoDSL allows ILECs to continue to leverage the feature and reliability strengths of their existing Class-5 switches while immediately begin to realize the cost and service flexibility benefits of using their new DSL broadband access networks. Rather than a short diversion on the way to softswitching, VoDSL represents an absolutely necessary next step that ILECs must take in transitioning to a pure packet-switching model.

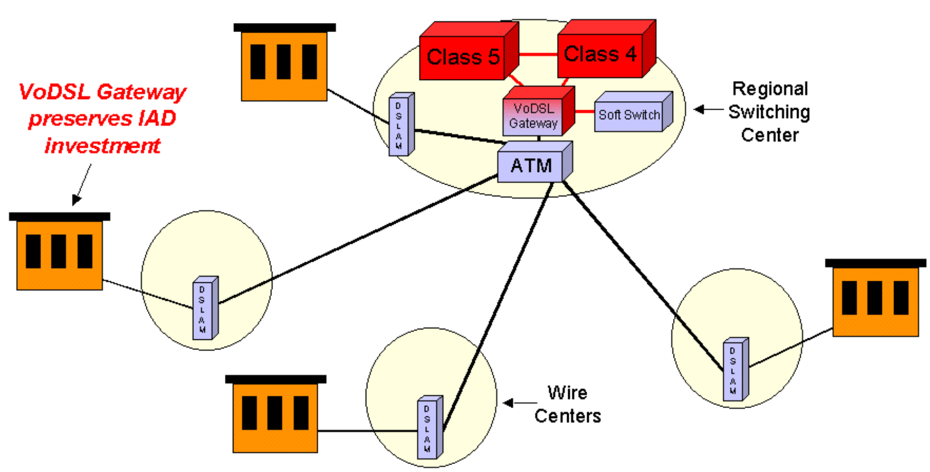
In a few years, when softswitches are better able to meet the feature and reliability expectations of the ILECs, they can be implemented in conjunction with the installed base of VoDSL gateways and IADs. The VoDSL gateways will be able to communicate directly with the softswitches and function as proxy servers that manage communications out to the IADs (see *Figure 4*). This hybrid model allows ILECs to continue to serve the majority of subscribers off of their existing Class-5 switches while slowing transitioning certain user groups over to more cost-effective softswitches.

VoDSL Provides Additional Near-Term Revenue

Some ILECs have viewed VoDSL solely as a means of overcoming operational challenges, such as copper exhaust. Other ILECs have viewed it as a method of mitigating the impact of competition by entrenching key

FIGURE 4

VoDSL Gateway Working with Softswitch



subscribers through service bundles, which is discussed further in a later section. However, VoDSL holds tremendous promise as a means of quickly growing the average revenue per subscriber by increasing the penetration of existing voice and data services as well as by enabling compelling new services.

Increases Penetration of Existing Voice and Data Services

VoDSL enables ILECs to further the success that they have experienced with service bundling. A number of ILECs have discovered that bundling enhanced features such as caller ID, call waiting, and voice-mail along with local service is a successful way to profitably increase their average revenue per subscriber. However, to date, service bundling has been primarily restricted to the delivery of various voice features. Recent end-user research has now shown a strong desire among target VoDSL subscribers to sign up for service bundles that include both voice and data services.

The theory behind service bundling is that an ILEC includes items in the bundle (in this case additional lines and features) at an effective price that is lower than the à la carte price. The subscriber is happy because they are getting services "cheap." The ILEC is happy because they are selling services that have a very low cost (much lower even than the discounted effective price) and that they would not have been able to sell (because the subscriber wouldn't have bothered to take them) if they were offered only at the regular retail price.

For example, say an ILEC subscriber currently has one phone line ($20) plus call waiting and caller ID ($3+$6). They receive their long-distance service from a different company, with which they are satisfied, as the subscriber believes they are getting a good deal at 7 cents per minute. They typically use 300 long-distance minutes per month. The subscriber by "default" would take a DSL service ($40) in addition to their current spending ($29). The total monthly revenue paid to the ILEC by the subscriber would be $69.

Now say the ILEC offers the subscriber a package for $129 per month (only available in package form) that includes DSL and three phone lines, all with call waiting, caller ID, and voice-mail, and 500 minutes of long distance. The indicated "value" of this package would be $180[1]. The ILEC's cost of the additional capabilities would be $20[2]. The ILEC has now taken their revenue up by $60 (with $40 of profit), so they are happy. And the subscriber is content, as they perceive they are saving $56. The subscriber has purchased more than they would have without the bundle.

Through targeted marketing of service bundles that include a specific number of telephone lines, an ILEC can significantly grow their overall line count. For example, targeting single-line DSL subscribers with a package that includes two feature-rich phone lines or targeting two- to three-line business subscribers with a bundle that includes four lines, or targeting five- to seven-line business subscribers with a bundle that includes of eight lines. The key point is that while such service bundles do have the potential to cannibalize some existing service revenue, there is much larger opportunity to grow total line count and service revenue through targeted selling.

Enables New Service Opportunities with Broadband Centrex

Small-business Centrex service continues to be one of the most significant unrealized ILEC revenue opportunities. According to Research First Corporation, there are more than 7.5 million small businesses in the United States, which, in total, utilize more than 38 million telephone handsets. However, more than 77 percent of these handsets (or 29.5 million) are served off of key telephone systems (KTSs). Since KTSs typically oversubscribe handset-to-analog trunks by more than 2:1, ILECs are providing approximately 14 million telephone lines to this subscriber group. If ILECs were able to go back into this installed base and successfully displace the KTSs with more reliable and feature-rich Centrex services, they could deliver approximately 15 million new telephone lines. In addition, while lines that service KTSs are typically feature poor, Centrex lines that service individual end users represent a significant additional source of revenue through the selling of custom local-area signaling services (CLASS), custom calling, and voice-mail features.

However, despite all its feature, growth, and reliability advantages, traditional Centrex service still faces a number of technical and business challenges that have prevented its widespread adoption within the small-business market. Largest among these hurdles has been the price of Centrex service. Due to the high costs associated with delivering traditional Centrex services, which requires a copper loop per telephone line as well as a lack of feature differentiation with standard business telephone service, ILECs have been unable to lower the price of Centrex service to the point where it is truly cost competitive with today's advanced KTSs and hybrid private branch exchanges (PBXs).

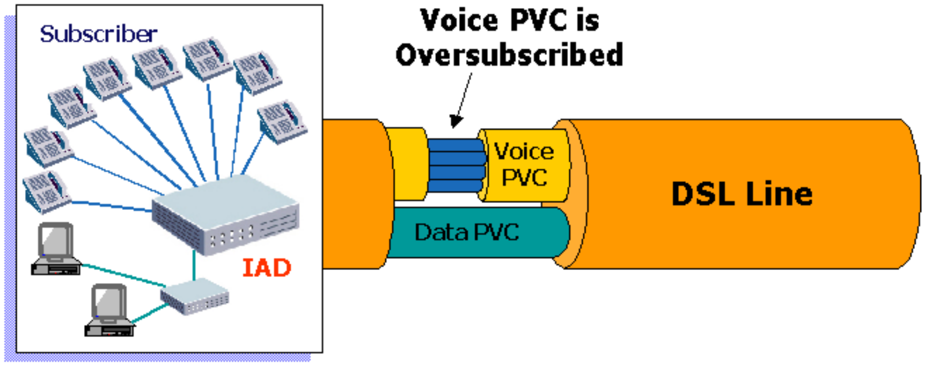
Fortunately, by using Jetstream's VoDSL solution to deliver Centrex services (a.k.a. Broadband Centrex), ILECs can overcomes these remaining hurdles and begin to successfully penetrate this 15 million new-line opportunity.

Since Jetstream's VoDSL solution enables ILECs to deliver up to 24 Centrex lines over a single copper pair, it dramatically reduces the cost of service delivery. Second is the unique and important feature of Jetstream's solution that enables ILECs to provide an oversubscribed Centrex service. With Broadband Centrex, a subscriber can now order telephone service using the same terms that they might use when buying a KTS, by specifying the required number of trunks and stations. For example, an ILEC could offer a 3x8 Centrex-over–DSL service, where eight Centrex lines would be provided, but only three lines could be simultaneously active. The eight lines delivered are standard Centrex direct inward dialing (DID) lines off the Class 5, supporting all available CLASS and custom calling features as well as meridian business sets, or P-Phones. The only, and key, difference is that the service is oversubscribed in manner similar to that of a KTS or PBX (see *Figure 5*).

By allowing for oversubscription, Jetstream's Broadband Centrex solution provides the key feature differentiation that now enables service providers to differentiate their Centrex pricing relative to standard business telephone service. In addition, since a Broadband Centrex service is delivered over the same DSL line, or pipe, as data service, it

FIGURE 5

Broadband Centrex Supports Line Oversubscription



opens opportunities for voice and data service bundling, enabling further feature and price differentiation.

Another side benefit of Jetstream's Centrex oversubscription feature is that it can prevent the use of less expensive Centrex lines by ISPs looking to terminate a large number of dial-up connections.

VoDSL Mitigates the Impact of Competition

As competition continues to heat up in the local service arena, ILEC revenues are beginning to take a hit. CLECs have made tremendous progress in the few years since the Telecommunications Act of 1996. As of late 2000, there were more than 170 facilities-based CLECs competing in the United States, which, in total, generated annual service revenues of more than $39 billion. Together, they have more than 990 voice switches and 2,000 data switches installed. They have 9 percent of the access lines in the United States (more than 19 million lines), which is up from 3 percent in 1998. While the CLEC market has been experiencing some shakeout during the last six months, it continues to be a vibrant market and a real threat to ILECs.

Potential Loss Is Significant

While a number of early CLECs focused on serving the large enterprise market, the vast majority now targets small to mid-sized businesses as well as high-end consumers. While the monthly revenue contribution from individual subscribers in these markets may appear low, many CLECs have realized that the present value of each subscriber remains quite high ($200,000+ for a small business and $35,000+ for a high-end family) and that they constitute the largest and fastest-growing market opportunity for competitive service. In addition, these markets have traditionally been underdeveloped by the ILECs, and it has been relatively easy for the CLECs to get to the price-sensitive decision maker in these organizations. All in all, the CLECs represent a significant potential near-term and long-term revenue loss.

However, while the potential revenue loss may be large, the potential profit loss to ILECs is tremendous. Like all new competitive market entrants, the CLECs are first targeting the ILECs most attractive subscribers. In regulated markets such as telecom, this can have a profound effect on the overall profitability of the incumbent provider. This is especially true within the consumer market, where there are a large number of subsidized subscribers. In fact, one major ILEC indicated that less than 20 percent of their consumer subscribers contribute more than 100 percent of the overall profit in that market. And, it is exactly those 20 percent that the CLECs are targeting and into which they are beginning to make serious inroads.

VoDSL Entrenches Their Most Attractive Subscribers Today

VoDSL represents one of the best methods for ILECs to go back into their installed base and quickly entrench their most attractive subscribers. While CLECs are making tremendous progress, they have a long way to go before they have universal market coverage and the marketing resources by which to take full advantage of this opportunity. With VoDSL, ILECs can rapidly assemble, and profitably market, a compelling set of bundled services that would allow them to attract and retain their key small-business and consumer subscribers before the CLECs can cause more serious, long-term damage to their businesses.

Summary

Deployment of VoDSL represents a tremendous opportunity for ILECs. Not only does VoDSL solve a number of near-term tactical challenges, including copper exhaust and shrinking revenues per subscriber, but it also helps ILECs to solve a number of critical strategic challenges, including the difficult migration of their networks over to pure packet switching as well as the mitigation of the overall impact of competition to their businesses.

Notes

1. $40 + 3x$20 + 3x($3+$6+$6) + 500x$.07 = $180
2. Two VoDSL derived telephone lines with features: (2x$4) + (400 [actual long-distance minutes used] x $.03) = $20

Synchronizing Deep Fiber Baseband Access Network Design with Traditional HFC Infrastructure

Donald Sorenson
Manager, Advanced Access Planning, Transmission Network Systems Sector
Scientific-Atlanta, Inc.

Abstract

Increasingly, optical network technologies are being evaluated for their suitability as a residential access network platform. Clearly optical networking holds promise for the distant future as networked applications evolve to demand greater transport capabilities. However, today and for years to come, hybrid fiber/coax (HFC)–based access systems, with their low-cost structures and evolving performances, will remain the dominant access network of choice for delivery of interactive multimedia services in the majority of the served residential markets. In a contemporary context, it is quite likely that an all-optical access platform could be best utilized as a strategic tool tailored to delivering high-value business class services to 10 percent or less of a residential serving area and a much larger percentage of the small to medium-sized businesses presently passed by HFC feeder fiber. A low first-cost optical access network may be an ideal strategic/offensive overlay to an existing or new HFC network.

This paper explores the key applications engineering issues associated with such an overlay and proposes a methodology for synchronizing key optical access and HFC network elements. The paper concludes with a detailed analysis of how optical split ratios and cable sheath fiber counts can impact plant first costs. This work is focused on the engineering issues associated with layer 1, the physical layer, of the seven-layer open systems interconnection (OSI) network model. Commentary on upper-layer requirements and protocols are limited to issues that impact the logistics of an overlay deployment and subscriber provisioning.

HFC and FTTx Architectures

The overlay of contemporary deep fiber architecture on an existing or new HFC plant is facilitated by effectively coordinating the location and functionality of key network elements. A brief review of each access method's legacy and contemporary structural fundamentals will serve as a useful point of reference as various design and cost sensitivities are explored later in the analysis to follow.

Hybrid Fiber/Coax

Routinely, the architectural details of HFC plants are varied to meet a host of constraints associated with factors such as geography, home density, upgrade logistics, and costs, as well as many other details. However, fundamentally most plants adopt a variant of a ring(s)—star(s)—bus configuration, as illustrated in *Figure 1*. Typically, one or more fiber rings interconnect primary head-end and hub facilities, in some cases secondary rings link head ends with secondary hubs or optical termination nodes (OTNs) that commonly serve tens of thousands of subscribers. In turn, fiber nodes are typically linked to hubs, OTNs, or head ends in a star configuration.

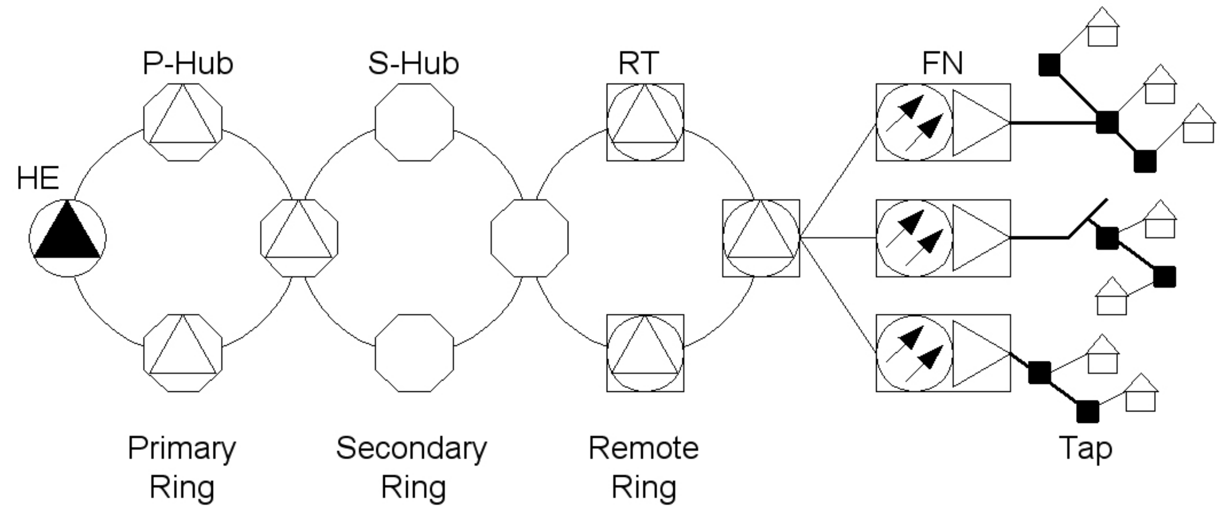
Ring and meshed configurations offer physical path diversity and associated enhancements in plant reliability. As high-performance service and business models stimulate the need to extend fiber deeper into the plant, a greater use of rings is anticipated at deeper levels. Within this trend, network functionality is also on the move—network process functions are migrating to the edge of the plant where they can be better tailored and incrementally scaled to meet subscriber and new business demands. A third ring extending from a secondary hub through a series of smaller serving areas to remote star locations at the "1,000 to 4,000 homes passed" level effectively enables the deployment of advanced video and cable data services [1] and is a logistical requirement for the deployment of an all-fiber access overlay, as will be shown later in this paper.

Optical Access Network Overlay

Various all-optical access networks are increasingly seen as the following:

- The enabler of high-value services to a large under-served population of small business and home offices

FIGURE 1



- A low-risk infrastructure enhancement that has the potential to extend a plant's useful life well beyond that of copper-based technologies

A contemporary all-optical access architecture must be optimized to cost-efficiently deliver advanced services to a small percentage of a wide subscriber market base being passed.

To insure the integrity of these services and an extended useful plant life, the network must be reliable and easily scaled with increasing take rates without major upgrade or modification.

By contrast to most copper-based networks, all-optical access networks do not utilize active amplification or signal-processing elements in the transmission path and are referred to as passive optical networks or PONs. Ideally, the active elements at both the subscriber and service-provider ends of the network are safely housed in conditioned facilities, and only passive components such as fiber cable and splicing devices suffer the environmental rigors of the outside plant, as shown in *Figure 2*.

Rarely would a dedicated fiber connection, between the service provider's internal network and a residential or small-business subscriber, be cost-effective. To distribute costs a means of allowing multiple subscribers to access a network, fiber is implemented through the use of a multi-port optical splitter or coupler (see *Figure 3a*).

FIGURE 2

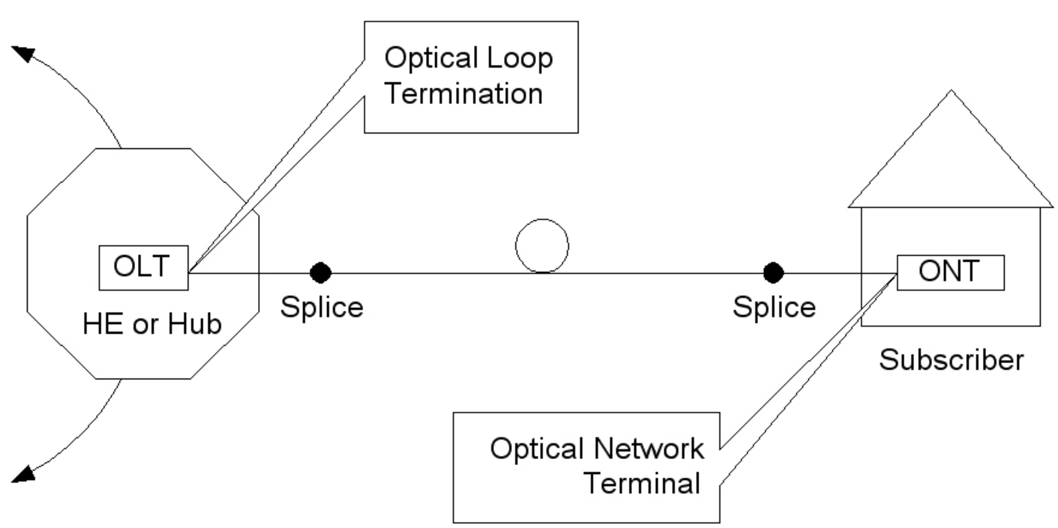


FIGURE 3A

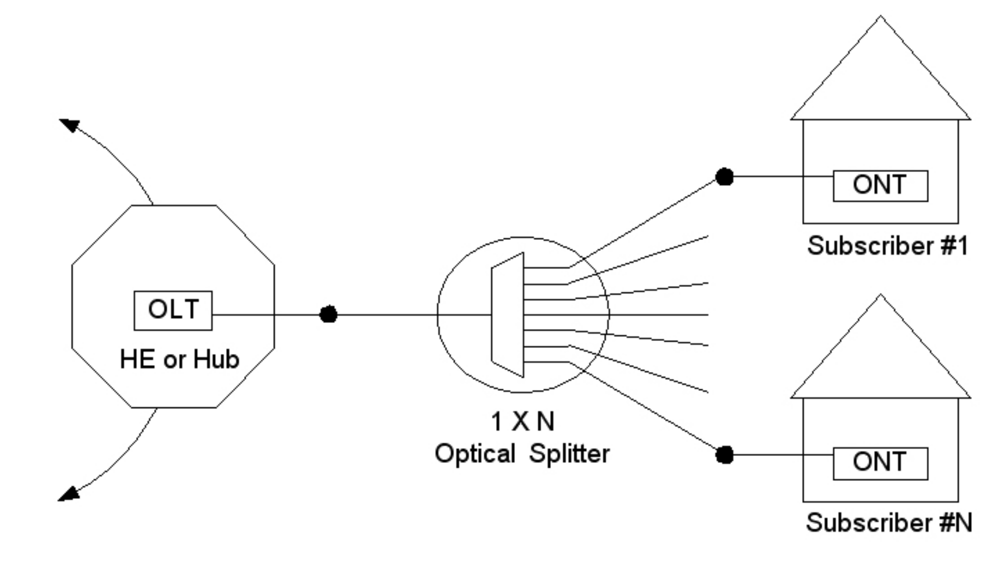

FIGURE 3B

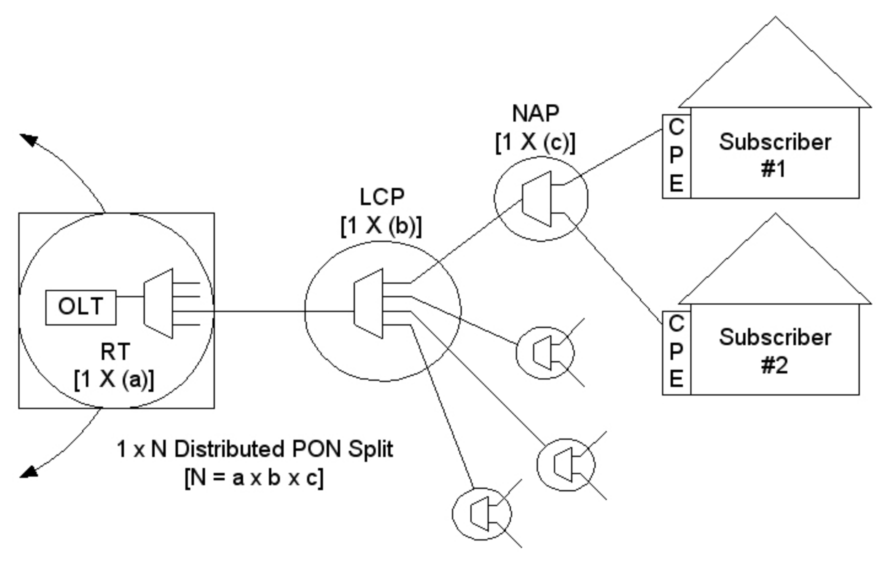


In this instance, each PON fiber becomes a shared media. If the PON is used in conjunction with dense wavelength division multiplexing (DWDM) or course wavelength division multiplexing (CWDM), each subscriber is allocated a dedicated wavelength, or subchannel carrier on a wavelength, for their dedicated use. Using a time division multiplexing (TDM) approach, the downstream traffic is broadcast to all of the subscribers served by a splitter, and upstream access is controlled via a suitable media access control (MAC) protocol, a number of which are competing for industry acceptance. For reasons relating to cost and operational logistics, it is often not desirable to lump the splitting function into one physical location [2,3]. As shown in *Figure 3b*, the splitting function can be divided between multiple locations along the fiber path. The product of the split ratios at each location becomes the PON's overall return fiber to subscriber ratio.

The sizing and distribution of the PON splitter function is the principal tool used to synchronize an optical access network's elements with an existing or new HFC plant.

As previously mentioned, ideally a PON's active elements are housed in conditioned environments. However, the realities of applying an optical network design to a wide serving area typically demand that active electronics be placed in the outside plant. At the subscriber side of the network, the logistical realities of service activation place the ONT [4] outdoors on the exterior of the subscriber premises as customer-premises equipment (CPE). On the network side, construction costs and operational issues typically demand a high degree of fiber aggregation deep in the design. Without such measures, fiber counts quickly become difficult to manage with even the highest of PON split ratios. Splicing costs escalate dramatically while network reliability and scalability suffer. Typically, it is not practical to provide path redundancy on one or a few PON fibers; however, when hundreds of fibers collect on their way to a network facility, the failure group size and recovery time from a fiber cut become unacceptable. Furthermore, high fiber-count head-end or hub runs are very likely to exceed existing fiber inventories and subsequently adversely impact plant first costs.

The location of an optical loop termination (OLT) [4] synchronizes quite well with the evolution of the third-ring nodes or remote terminals (RTs) [1] in advanced HFC architectures.

Commonly, an OLT or RT location will service a 1,000 to 4,000 home area. Construction practices demand the consolidation of fiber cable sheaths as they route to the RT. These local consolidation points (LCPs) [2] (see *Figure 3b*) provide another physical location to easily distribute a portion of the network's total split ratio.

The proper allocation of PON split ratio to the LCP can be used to synchronize its physical location in the network with that of each physical HFC fiber node, thus providing a convenient fiber path for the HFC node and common physical point of equipment access.

Access to the PON fibers passing a subscriber premises is achieved in manner similar to an HFC coax tap—the principal difference being that the equivalent PON tap is fed by a dedicated PON fiber that is not shared by other upstream or downstream PON taps (see *Figure 3b*). To logically clarify this difference, the PON fiber tap point is referred to as a network access point or NAP [2]. Fundamentally, a NAP is composed of a suitably sized ground or aerial mounted fiber splice enclosure near a small group of subscribers. The optical service drop to the subscriber is terminated at the CPE using an optical splice or connector. At the NAP, the drop will be spliced either directly on one of the PON fibers passing through the NAP or onto a port of an optical splitter located in the NAP.

The installed first cost and service-activation cost of a PON are quite sensitive to the fraction of the total PON split ratio allocated in the NAP. In general, a higher split ratio at the NAP yields a lower first cost of construction and slightly higher cost per subscriber served should the take rate at the NAP exceed 50 percent of its capacity.

Another challenging issue regarding PON architectures is that of remote active element powering. Historically, remote network device power has been supplied via the metallic signaling media. Without such a media, a PON must either include some form of copper-based powering network, or its remote actives must be locally or subscriber-powered. Both alternatives have their advantages and difficulties, a selection between which will largely be determined by business and public-policy issues.

The issue of powering remote PON equipment in an HFC overlay is facilitated by utilizing the powering signal commonly available from the underlying cable television (CATV) distribution coax.

By including a light gage twisted pair with the subscriber's optical drop network, power can be provided to the CPE using industry-standard power passing tap devices. In those cases where spare power capacity is not available from the HFC network, other twisted pair powering alternatives exist that can be implemented at the time of plant construction at a modest percentage of total PON overlay cost.

Network Design Constraints

The practical objective of a design is the implementation of a serviceable network that meets near- and long-term needs for the lowest possible cost. Compliance with this objective in legacy copper-based technologies is strongly enforced by well-understood and refined engineering practices. In part, the scope of these practices must be expanded when new technologies, such as PON, are adopted. The following material outlines key engineering, construction, and operational considerations that will act to constrain the design variables associated with implementing a PON overlay.

Serving as a reference point for the following discussion, *Figure 4* is a simplified illustration of a PON overlaying an HFC fiber node with a physical size of 256 homes-passed (HP). In turn, the physical node (PN) is fed by a 1,000 HP logical node (LN) or RT.

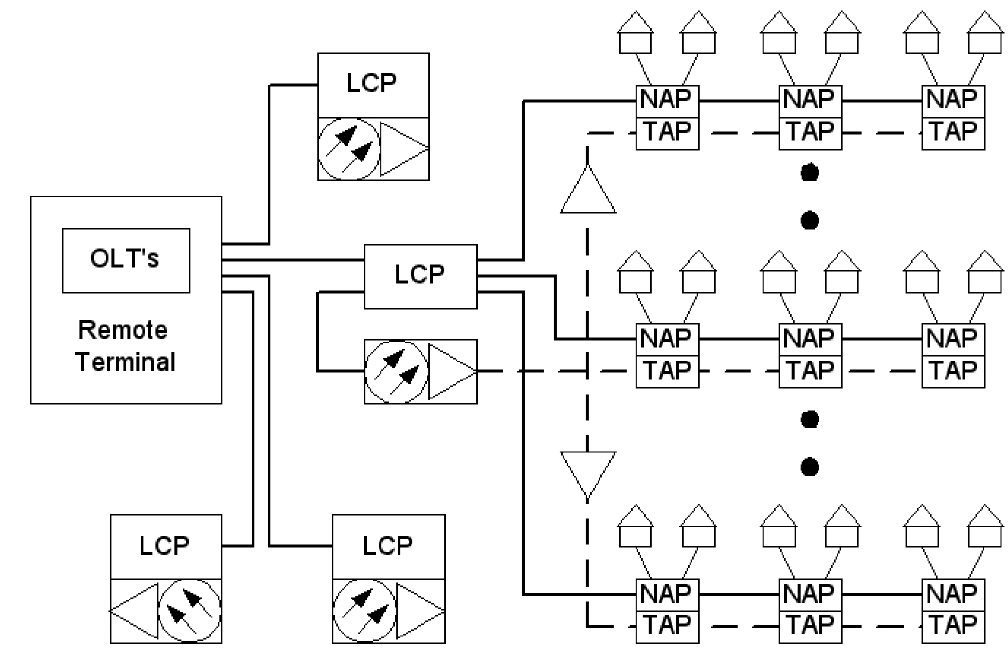
Network Engineering Considerations

Routinely, more than one communications service provider serves a residential or commercial market area. This implies a reduced initial service activation rate as market-share is obtained. Accordingly, new plant designs of any type are commonly engineered for a lowest possible first cost that enables the network to physically address the market area. This condition is particularly true with regard to PON deployment. It is anticipated that early take rates for PON–based services will be quite low—less than 10 percent of HP. This condition is likely to remain until the value of service portfolios, exclusively deliverable via an optical network, increase and construction costs associated with PONs decrease.

With a lowest possible first cost, a PON overlay must address 100 percent of a market service area, and with minimal provisioning or manipulation. the network can be made available to any one of the subscribers passed.

In keeping with a low first cost and take-rate assumptions it is anticipated that PON split ratios will be under-subscribed by as much as 50 percent and that initial RT data-processing capacity will be over-subscribed by as much as 10:1. These two factors substantially lower first costs with regard to OLT ports, associated packet switching and fiber counts, and/or advanced optical wavelength provisioning in the upper network transport rings. A 50 percent under-subscription of a PON split ratio implies that less than 50 percent of a PON's available optical splitter ports will be terminated and in service at any one time. Dedicated wavelength division multiplexing (WDM)–based PONs inherently provide this ability. However, when using a shared access TDM PON control method, this engineering option is enabled by the selection of a MAC protocol that has the ability to dynamically allocate access to the PON over a specified range of possible subscriber counts. This capability greatly simplifies provisioning and record keeping while allowing the network to provide bandwidth to customers based upon the terms of their subscription agreements without regard to the number of subscribers terminated on a given PON. Conversely, and based upon optical budget limits, which as

FIGURE 4



discussed later, under-subscription allows the network engineer to pass lit fiber by all of the homes in a given serving area without excessive OLT costs.

The use of WDM or the selection of the proper TDM MAC protocol and the planned under-subscription of a multi-port PON allows the network to distribute lit fiber past 100 percent of the subscriber base without encumbering excessive OLT provisioning cost or degrading subscriber data throughput.

If the PON is to be under-subscribed, it is advisable to take measures that help ensure the under-subscription through the life of the network. This can be achieved by distributing a portion of the PON split ratio to the LCP. By doing so, each of the PON's ports can be spread across multiple distribution branches or NAP locations that are not geographically adjacent. Routinely, subscription rates in small clusters of homes passed can reach 100 percent. By spreading a PON's ports across multiple distribution branches, the likelihood of 100 percent utilization is diminished.

The PON must be capable of supporting the eventual migration of standard services delivered today via copper media. This requirement principally impacts optical budget limits that in turn drive PON split ratios and passive device performance limits. Large PON split ratios, such as 1:32, demand optical physical interface (PHY) transmitter power levels of up to +20 dbm. Elevated levels such as this are achieved at a cost premium and bandwidth penalty over more common PHY transmit levels of +10 dbm or less.

In the years to come, the need to operate the PON at multi-gigabit speeds is almost certain. Large PON split ratios and the associated elevated PHY transmit power levels are likely to delay the point in time where an existing network can be easily upgraded to multi-gigabit operation.

Thus PON splits such as 1:8 or 1:16 are attractive from the point of keeping CPE PHY–device costs down and ensuring early migration to higher data rates. It may also be advantageous to allocate some portion of the PON split ratio to the OLT side of the network. For example, a four-port directional coupler can facilitate insertion of overlaying ls to support additional services in the future.

Construction Engineering

Minimizing construction first costs are key to the financial success of a PON overlay. Low first cost enables early economic business models that rely on the delivery of high-value services to a selected few of the subscribers passed by the network. Unfortunately, only a small number of PONs have been deployed, and related experiential knowledge is limited at best. The following points address construction issues impacted directly by PON architecture decisions.

Through the analysis to follow, it has been found that PON construction costs are reasonably insensitive to actual fiber counts. However, costs are particularly sensitive to the labor associated with fiber management, termination, and optical splitters, along with related outside plant enclosures and places to locate them. Again, the size and distribution of PON split ratios can be optimized to minimize these initial costs.

Analysis has shown that poorly designed 1:32 or 1:16 PON can be significantly more expensive than an optical network based on a dedicated home-run fiber for every home passed!

PON fiber counts at a single location in the network can easily escalate to levels that are exceedingly difficult and costly to manage. Additionally, in the event of a fiber cut, a large count represents a correspondingly large failure group size. For example, 200 – 1:16 PON fibers under-subscribed by 50 percent still represents 1,600 high-value paying subscribers that will lose service when a pole falls or a cable is dug up. With cable restoration time in mind, it is advisable to keep individual fiber sheath counts below 50 if possible and fiber aggregation point (LCP and RT) counts well below 150. This can be achieved by adjusting the amount of PON split ratio performed at the NAP and LCP.

Increasing NAP split ratios reduce fiber counts at the LCP and move the LCP into the network, which can be used to synchronize the LCP location with an existing or planned HFC fiber node. Correspondingly higher LCP split ratios have the same effect on the RT.

A uniform bill of materials composed of industry-standard elements that are frequently reapplied throughout the construction footprint enforces cost control and reduces construction-schedule delay risks. The selection of one standard cable sheath fiber count for all distribution branch runs and another for feeder runs between the LCP and RT is beneficial. The variables involved in selecting a distribution branch fiber count are NAP split ratio(s), anticipated home density range, HFC distribution branch length (typically on a per active basis), and an allocation for spare fiber. *Table 1* illustrated how NAP split ratios can be selected based upon home density and branch length. In this case, higher NAP port counts are implemented using two smaller optical splitters. Such an approach allows the deferral of the optical splitter and its associated cost.

A generous allocation of spare fiber throughout the design will insure restoration and application flexibility in the future and possibly aid in addressing legislative issues associated with equal access. Adding individual fibers to sheath counts has a relatively minor impact on first cost. Later, these fibers can be used to deliver high-value multi-gigabit services via dedicated port connections from facilities remote to the subscriber, such as a primary head end or hub.

At the time of this paper's authorship, the industry does not provide a selection of low-cost standard NAP enclosures suitable for co-location with standard and power-passing cable television taps. This condition will change as PON deployments become more routine.

Operations Engineering

Easy PON subscriber provisioning and low or no PON equipment maintenance are key operations cost-control objectives. To meet these, objective measures must be taken at the physical layer of the PON as well as at the MAC protocol layer if TDM is used.

Installation of a subscriber service drop and CPE must be executable by a technician with a relatively low craft skill level and without the need of advanced tooling or diagnostic equipment.

Turn-up of the CPE must be a plug-and-play event, with the MAC protocol automatically handling provisioning and network access issues in much the same way as done today by cable modems via the data over cable service interface specifications (DOCSIS) protocol. Dedicated WDM approaches will be challenging in this regard, due to the inherent need to manually manage or allocated wavelengths and WDM filters to individual subscribers. For this reason, WDM solutions are likely more appropriate for high-bandwidth services to small and medium-sized businesses.

Optical budgets, noise, and return loss margins must allow the use of industry-standard mechanical fiber splice devices at both ends of the service drop. Experience has

TABLE 1

Distribution Branch Cable Sheath Fiber Count Scaling

Length	900' Typical		
Homes Passed	8 HP	16 HP	32 HP
CATV Tap Size	2 Port	4 Port	8 Port
Taps / Branch	4	4	4
NAP Split	1:1	2x1:2	2x1:4
PON Fibers	8	8	8
Spare Fibers	4	4	4
Total Fibers	12	12	12

shown [3] that cable drop damage due to bending or dirty connections can occur during the installation process. The ability to easily open connections for optical time-domain reflectometer (OTDR) measurements at the NAP and below the last optical splitter is convenient. Additionally, the PHY receivers at both ends of the PON must provide a dynamic input range that can tolerate the initial exclusion of the NAP's optical splitter.

The ability of the PON to tolerate the exclusion of the NAP splitter for the first NAP subscriber is more difficult to achieve when high optical split ratios are applied at the NAP.

The service technician cannot be required to access or open adjacent NAP or LCP enclosures to establish to which PON fiber the subscriber's NAP has been allocated nor to activate or light the PON fiber. Having to access other devices during the provisioning process can be logistically difficult and is certain to significantly drive labor costs up on a per-home-served basis. Again, this objective is directly influenced by the allocations of splitter ratios at the NAP and LCP, as well as cable sheath fiber count.

The LCP must be affordably provisioned such that each distribution cable sheath has at least one dedicated fiber for each NAP on the sheath.

This fact coupled with a desire to keep first costs down encourages higher branch cable sheath fiber counts and lower LCP split ratios. During plant construction, the appropriate fiber color for each individual NAP is tagged with a color marker on or in the NAP, or alternatively the appropriate fiber can be ring-cut from the sheath and stored ready for use.

PON Overlay Synchronization

The proposed methodology of synchronizing a PON overlay with an existing or new HFC plant is driven by the objective of having the PON's key functional elements closely located, both physically and logically, with the corresponding HFC devices. Practically, direct physical co-location is required at the CPE, tap, and RT levels. Strict co-location of the LCP with a HFC fiber node may be desirable but is not a requirement. The accomplishment of this objective must, of course, align with as many of the previously mentioned engineering constraints as possible.

The PON design is driven by three key parameters: the PON split ratio, the ratio's distribution through the network, and the sheath/enclosure fiber count limits. These three parameters narrow the field of alternatives such that final selections can be made based upon specific performance or functionality objectives and first-cost reduction measures.

PON Split Ratio Analysis
All possible ratio distributions between the NAP, LCP, and RT were explored for the combined split ratios of 1:1, 1:2, 1:4, 1:8, 1:16, and 1:32. The first three ratios offer limited flexibility with regard to distribution but were explored for comparative purposes. The first column of *Table 2* lists the possible ratio combinations for each overall split ratio.

Limiting the associated fiber counts to a maximum of 136 controls the LCP's position or depth in the network. The LCP fiber counts shown in *Table 2* are inclusive of both inbound and outbound fibers. With regard to split ratio allocation, the LCP's position in the network is dominated by the NAP. For example, a 1:4 NAP ratio favors a 256 HP LCP position.

TABLE 2

Split Combo	LCP / Physical Node		Rermote Terminal		Normalized	
NAP-LCP-RT	Size	Fibers	Size	Fibers	First Cost	Ultimate Cost
1-32 PON Split Ratio

1-1 PON Split Ratio						
1-1-1	64 HP	128 F	128 HP	128 F	2.1	2.1

Alternatives can also be explored, such as creating a four-port NAP utilizing two two-port splitters at the NAP; this will favor a 128 HP position at the expense of doubling the number of fibers in each cable branch. At first, such an alternative may be dismissed as costly, but individual fibers are relatively inexpensive compared to optical splitters. Having two fibers available at each NAP further delays the purchase of NAP splitters until three or more NAP ports are in service, which may never happen. The measure also reduces the dynamic range requirements imposed on the CPE and OLT PHY receivers.

Strategies that postpone the use of a splitter at the NAP significantly impact the average subscriber provisioning costs, particularly during the early years of plant operation while subscription rates are low.

The RT is positioned in the network by following a process similar to that used with the LCP. The total incoming fiber count is held constant by adjusting the number of LCPs reporting to the RT. As shown in the fifth column of *Table 2*, the total inbound LCP fiber count was held at 128. This quantity was chosen, rather than the previously mentioned 150, to allow for outbound or ring fibers and HFC node fibers that were not included in the analysis.

Both NAP and LCP ratios influence the depth or position of the RT in the network. NAP/LCP ratios of 1:4/1:2 favor a 1,000 HP RT in the 8, 16, and 32 PON splits.

Physical placement of ground mounted 1,000 and 2,000 HP RT cabinets is common, particularly with regard to digital loop carrier (DLC) telephone systems. Small, 500 HP RTs can be pole mounted, but become numerous and pose powering challenges when extended backup times are required to ensure network operation during extreme weather conditions.

The cost data provided in *Table 2* is based on items that generate a relative cost difference between PON split options. For example, the fiber cost for a PON split of 1 – 1 – 32 would be considerably greater than 32 –1 – 1; this along with other associated impacts such as number of RTs required for each combination. The resulting dollars per home passed were then arbitrarily normalized to the 1:4 NAP option. Normalization of the data is appropriate since the cost analysis is gauging relative merits rather than absolute values.

The cost impacts of various subscription take rates are difficult to predict and are not included in the analysis. This is principally due to the cost of an optical splitter at the NAP if it is needed at the time of service provisioning. In many instances, a splitter may not be needed for the early subscriber(s) whose drops can be connected directly to the PON fiber allocated to the NAP. Thus, unless there is a great deal of subscriber clustering, the impact of NAP splitter costs will be negligible until take rates approach 30 percent to 50 percent. Due to this variability, the analysis focuses on the initial relative cost and that of a 100 percent take rate. The 100 percent figure reflects the comparative cost between low and high subscription-rate pockets.

The principal conclusion drawn from the cost data is that from a relative-economics point of view, a plant can be designed by appropriately applying a wide range of split combinations.

This is good news from a plant-engineering point of view, providing the network designer latitude to meet the numerous other non–cost-related engineering constraints such as those previously outlined.

Observations

The key take-away observations from this analysis effort and discussion are as follows:

- Properly executed, PON optical split ratios do not greatly affect network first costs.
- The appropriate allocation of PON split ratios between key network elements can be effectively used to control the physical and logical location of those elements in the network.
- Control of sheath fiber counts can be effectively used to defer optical splitter cost at the NAP and to ease performance demands on PHY receivers and transmitters.
- One or two standard sheath fiber count configurations can be readily adapted to varying subscriber densities and HFC tap configurations.
- Mechanical fiber splice connections at the NAP and CPE are required to keep provisioning costs down and support drop troubleshooting. The network's optical performance requirements must be tailored accordingly.
- The eventual migration of the network to gigabit speeds is likely to occur earlier with lower overall PON split ratios, particularly with regard to TDM–based solutions.
- The planned under-subscription of a PON split ratio can be leveraged to reduce the cost of the RT while enabling lit fiber to pass by 100 percent of the serving area's subscriber base.
- The utilization of a self-provisioning MAC protocol capable of dynamic bandwidth allocation without regard to PON split or subscription is required to maintain high customer satisfaction and low provisioning/maintenance cost.

This analysis was focused on PON split ratios in exponential powers of 2. Clearly, other ratios are equally valid and have been used successfully [3], such as multiples of 3. A significant cost benefit would not be anticipated in alternative ratios; however, they may offer useful alternatives with regard to LCP and RT placement and provisioning.

Summary

Fundamentally, HFC alone is a proven financial workhorse capable of delivering outstanding residential video, voice, and data services. Based upon the work done thus far, it is clear that it will be some time before the PON alone can compete economically in a standard residential market space with HFC. However, in part, this fact is contrasted by three emerging near-term trends:

- The growing utilization of e-business practices by small, under-served businesses—businesses within easy service-provisioning range of an HFC plant.
- The steady demand for advanced data networking and voice services for work-at-home and small branch office employees.
- A strong financial desire to reduce or eliminate the risk of obsolescence in newly constructed plant. Extending

the plant's operation during its positive cash-flow life by as little as two or three years has significant investment repercussions.

Perhaps the optimal migration compromise between the realities of today's economics and the future's service demands may be the strategic application of optical network overlaying a new or existing HFC plant.

Accordingly, this paper has proposed a series of engineering considerations and design methodology for the synchronization of a PON with a modern HFC network. The methodology has been demonstrated analytically to be capable of effectively placing key PON elements at physical and logical locations consistent with an underlying CATV network.

Challenges and Opportunities in Home Networking

Matt Tormollen
Vice President, Marketing
BroadJump, Inc.

Introduction

Home networking has emerged as the leading application for residential broadband, with more than one-third of all current subscribers using some type of home network. The proliferation of inexpensive, plug-and-play network address translation (NAT) routers has given the early adopters of broadband an easy solution for sharing a high-speed connection among multiple machines. Broadband service providers are keenly aware of this trend but have encountered a number of challenges in capturing the value of home networking, which has thus far gone mainly to networking hardware vendors and consumer electronics retailers.

Service providers have, however, absorbed many incremental costs associated with home networking. Provider networks have experienced an increase in average bandwidth utilization, and support-desk phone calls are increasing in volume and length because of the added complexity of troubleshooting connection problems with a NAT router in place. The home-networking story for service providers has largely been one of increasing costs without incremental revenue—not exactly the business model they are looking to achieve.

Beyond this frustration, however, lies a new wave of opportunity. Home networking devices have fallen enough in price that hardware vendors are now looking to bundle data over cable service interface specifications (DOCSIS) and digital subscriber line (DSL) modems into their boxes and begin selling directly to service providers. In addition, less experienced broadband subscribers are more receptive to paying an incremental monthly service charge in exchange for supplying the equipment and supporting the installation and maintenance of a home network. Finally, the profit potential of advanced hardware functionality, such as voice over Internet protocol (VoIP) and home monitoring, can only be realized in conjunction with back-end network hardware and systems. Service providers are now in a position where, armed with the right tools, they can leverage advanced home networking capabilities to create new revenue streams and transform what has been only a source of additional costs into a profit generator.

First Steps in Home Networking

Service providers looking to offer a home networking solution to their subscribers will face a number of difficult decisions. Will they serve primarily as hardware resellers, looking to capture a one-time margin on home networking equipment? Or will they offer home networking as a service, giving subscribers the option of paying an incremental monthly service fee in exchange for free equipment and ongoing support? Finally, what technology solution will they focus on, be it traditional Ethernet, wireless, or some other alternative, such as HomePNA? But regardless of the business model that service providers choose to pursue, the first avenue of opportunity lies in the reduction and limitation of costs associated with NAT home networks. The cost drivers that providers need to focus on first are the expense of helping a subscriber successfully set up a home network, and then allowing the subscriber to self-manage and troubleshoot their network on an ongoing basis.

Automating Installation

Usability studies show that the average broadband subscriber encounters a number of issues when setting up even the most basic form of NAT–based home networks. Ensuring that each machine being connected to the network is qualified for broadband service, setting up each machine for dynamic host configuration protocol (DHCP), and then booting up the NAT device and every machine in the correct order are just a few a the frequent headaches that generate calls to the help desk. Just as service providers need to ensure that all of the computers at different subscriber locations are configured properly to receive service in the wide-area network (WAN), each subscriber needs a means through which to standardize their multiple machines for service in the local-area network (LAN). The answer to this problem lies in giving subscribers intelligent software tools that automate the qualification and installation process. This will help them to quickly configure each machine for broadband Internet access, step them through the appropriate process of connecting their machines to a NAT hub, and then instruct them on how to restart the devices in the correct order to power up the network to a working state.

Home Network Support
While the point of installation represents a large component of cost in offering a home-networking program, subscriber support cannot end there. Once a NAT home network is installed correctly, service inquiries related to the NAT device itself should be minimal, primarily because these devices are typically reliable and simple in their operation. The problem, however, is that the presence of a NAT device makes diagnosing and resolving problems with computer configuration and network connectivity far more difficult and complex. Support-call duration is often greatly extended because a representative must ask a series of probing questions to determine the root cause of problems in the subscriber environment. In addition, simple tools, such as a PING test, are unusable in a situation where the subscriber's computer is invisible behind a NAT router. Providers often have no record of the machines that have been installed in a home network, which further extends the process of gathering the necessary information. To cost-effectively manage the support of residential home networks, providers need to deploy an application that allows subscribers to self-diagnose potential problems within their network and, if they are unsuccessful, allows customer-service representatives (CSRs) to quickly upload information on each machine and its status.

Home Networking As a Service

The broadband providers that will achieve the greatest success in deriving new revenue streams from home networking components will view these hardware devices as the enabler of new, paid-for services. The opportunity to transform NAT functionality into a revenue-generating service is now emerging—primarily because the subscribers that are just now adopting broadband service are less sophisticated in managing their own customer-premises equipment (CPE) and will pay an incremental fee for provider support. And beyond the revenue potential of NAT lies the next generation of services that advanced home networking devices will help to create. Linking multiple types of devices, adding secondary VoIP phone lines, and offering home monitoring and home-security functions will all depend on a centrally located gateway device in the home that the service provider can interact with and maintain control over. Today's home networking devices give subscribers the ability to change configurations and activate new services, but they do not rely on head-end systems to coordinate the delivery of new, Internet protocol (IP)–based services. Ultimately, service providers will look to combine home networking hardware with intelligent software applications that make these incremental services available to subscribers in a secure, reliable, and paid-for format.

Promoting and Selling Home Networking
The most fundamental aspect of transforming home networking into a service is the ability to sell the service to a new subscriber at the appropriate touch point. Once subscribers have already installed their services, demand for a home networking device will likely lead them to a retail outlet, rather than back to their broadband service provider. For this reason, providers must be able to anticipate the demand for home networking services and make these offers intelligently and efficiently during initial contact with a new subscriber. By allowing subscribers to upgrade their service plan with home networking equipment, and then helping them to install their home network quickly and easily, service providers will establish themselves as the first source of both networking hardware and associated services.

Silent Functionality
To create multiple revenue-generating services through a piece of home networking hardware, service providers must be willing to subsidize the deployment of devices with embedded functionality over and above their baseline capability. This "silent functionality" becomes the enabler of services for which subscribers will pay incrementally on top of their basic access plan. To allow for this process to take place, however, the provider must deploy a layer of software intelligence that presents these advanced capabilities to the subscriber in the form of service offerings and allows the subscriber to activate the services by agreeing to the associated surcharge. In addition, the software interface with which the subscriber interacts must be able to communicate with back-end systems, coordinating the adoption of new services with the provisioning of network elements that work with home networking CPE to deliver services to the subscriber in the manner specified.

Integrated Billing
The creation of new, paid for services through home networking necessitates that providers have the ability to efficiently and cost-effectively bill for incremental offerings. Just as subscribers will view home networking hardware components as services, they will expect to be billed for these services in a logical and accurate manner. To ensure that this happens, providers must have intelligent software within their network that registers the activation of a new, paid-for service and initiates a corresponding event within the provider's billing system. This is made possible only by a client-server architecture that gives subscribers control over service selection, while at the same time, a layer of abstraction from the critical back-end systems must register and bill for these services.

Home Networking Solutions

Broadband service providers looking to transform home networking hardware into profitable, revenue-generating services will have several key decisions to make in defining their approach to this opportunity. At the most basic level, providers will need to select a business model. Proposed home networking models vary widely in terms of upfront investment and potential return, so providers will ultimately have to determine how strategic home networking is in reference to their long-term objectives. Second, any home networking program will involve the deployment of home networking hardware, but the control layer can be either hardware or software-based, so providers will need to define a network topology that maximizes their overall investment. Finally, providers must consider the various services that they want to leverage from home-networking capabilities. Advanced gateways promise to deliver a host of advanced services to the residential broadband subscriber, but each category of service involves significant investment in the face of uncertain market potential.

Choosing a Business Model
Given the multitude of potential models that exist for deriving value from home networking, it would seem that identifying one particular program with a high degree of success

would be next to impossible. Service providers have only to look at their basic access priorities, however, to select a generic model that holds out the most promise. First, a service provider will want the payback period of a home networking service to be as short as possible, and second, the provider will want to align revenues with expenses. Since these factors eliminate the possibility of either selling equipment at retail prices (a one-time gain with long-term costs) or fully subsidizing the cost of all hardware components in exchange for a monthly fee (an unacceptably long payback period), it is logical that the best approach is a hybrid model.

As a hypothetical example, consider a home-networking program that involves a choice of three CPE devices: a simple modem, an integrated Ethernet router/hub and modem, and an integrated 802.11b wireless router/hub and modem. In this program, subscribers choose one of these three devices at the time of ordering broadband service and pay incremental monthly fees for more advanced functionality. The service provider offers network interface cards (NICs) at retail price and supports these cards accordingly. By adopting this model, the service provider earns enough additional revenue on networking CPE devices to cover their incremental cost in a matter of months, and they earn a margin on the sale of each NIC. Subscribers, in turn, derive value from this model in that the incremental monthly charge saves them the cost of paying for the router/hub up front (which would cost them at retail much more than the price at which the provider can purchase these devices), and they pay the same price for NICs that now come with comprehensive support at installation and on an ongoing basis. In this model, the service provider has a modest upfront investment on each subscriber, creates a sustainable stream of service revenue, and sets the stage for future cash flows derived from advanced services.

Control—Hardware or Software?

To create and sustain profits from home networking, the service provider must have a control mechanism through which services can be provisioned, managed, billed for, and finally, deactivated. While every home-networking program will necessitate the deployment of an integrated system, the provider can allocate different levels of control between the hardware and software elements within the network. Hardware-based control, in the form of integrated circuit (IC) functionality, has the benefit of being stable and preintegrated, while software-based control, in the form of embedded agents with server-side applications, has the benefit of being more cost-effective and remotely updateable. The key issue for a service provider, however, is that a hardware-centric approach requires a single source solution, which in turn exposes the provider to a number of additional risks from a pricing and technology advancement standpoint. For this reason alone, the service provider will find that intelligent software provides both advanced functionality and control, along with the flexibility to manage several hardware platforms, in a model that is economically advantageous.

Enhanced Services

Without question, the first application of home networking is NAT. While NAT holds the promise of significant revenue streams, the true long-term potential for home networking lies in services that go beyond personal computer (PC)–based data transmission. With this potential for reward comes risk, and service providers will need to carefully evaluate the services that they are willing to subsidize in the short-term to create an installed base of devices waiting to be unlocked for the delivery of enhanced, next-generation services. VoIP, home monitoring, and security, as well as gaming and entertainment services, are all potential add-ons that providers can build into their home-networking program. What services will justify the cost? Many industry reports, especially when analyzed collectively, would seem to indicate that all of these services hold enormous revenue potential and that service providers should focus on all of them, lest they miss out on the true "killer app" for broadband. What service providers need above all else, however, is a home networking platform that is flexible enough to deploy these services cost-effectively yet can be updated with more advanced capabilities should a robust market for any of these particular services start to emerge. With this goal in mind, service providers will find that a minimal amount of added hardware components, in conjunction with a software platform that can manage the remote update and activation of services, will give them this type of flexibility.

Summary

Broadband service providers are experts at deploying new systems in their network to enable the delivery of additional, paid-for services. With the onset of home networking, a host of new services can be made available to subscribers in this same manner. Service providers will be constrained by the economic realities that they faced in deploying their traditional service offerings and accordingly will need to make investment decisions in home-networking programs with the same level of consideration. The right business model, combined with the appropriate combination hardware elements and software intelligence, will equip service providers with the means to fully capitalize on the emerging home-networking market opportunity.

Scalability of the Optical Core Network

Lord Uva

Product Manager, Photonics Business Unit

Cisco Systems

This paper will discuss the need for scaling the optical core, as well as the scalability trend in general. It will also talk about scalability of the optical core in terms of capacity, reach, and speed (CRS). Finally, it will review some of the emerging optical technologies, at a very high level, that are enabling the scalability of optical networks.

Scalability Drivers

What is driving scalability? A couple of years ago, if a manager needed to get in touch with an employee after hours, he had to wait until the next day. These days, he can send him an e-mail at 2 am and expect him to respond. The Internet has changed everything—the way we work, live, play, and learn. Now people are working 24 hours a day. They cannot just work eight hours and go home and relax until the next day. People are sending e-mails to them and sending their files across continents. We have seen the emergence of Internet protocol (IP) applications in voice and wireless, as well as the continued expansion of e-business. Essentially, we are experiencing an exponential increase in Internet traffic. All of this is putting increased pressure on the core of the optical network. In other words, to be able to accommodate all these changes, the core of the optical network needs to be very scalable. It needs to be able to scale in channel capacity, reach, and speed and at the same time lower the cost per transmitted gigabit.

Figure 1 is a look at pre-Internet traffic patterns. Before the Internet, enterprise networking was essentially a local-area phenomenon in which about 80 percent of the traffic was maintained within an enterprise campus or building. Only about 20 percent of the traffic actually left the enterprise environment, as applications such as e-mails and file transfers. The challenges of the pre-Internet era were mainly scaling local access network (LAN)-type equipment such as Ethernet and fiber distributed data interface (FDDI) switches.

With the Internet traffic pattern, the 80/20 percent rule still applies. The difference is that now 80 percent of the traffic actually leaves the enterprise campus or building and only 20 percent stays within. This means that there is more traffic coming out of enterprise environments and onto the optical core or backbone of long-haul networks. This is one of the reasons the optical core needs to be scaled to meet growing bandwidth demand.

The Internet has changed the world. The role of a service provider (SP) is to provide a seamless extension of Internet applications, not just within the enterprise but beyond it as well. A scalable infrastructure is needed to support all of this. In the Internet economy there are suppliers, partners, and customers all over the globe trying to conduct business at any time of the day. SPs have to find ways to build scalable networks to handle this unpredictable Internet traffic crossing their networks.

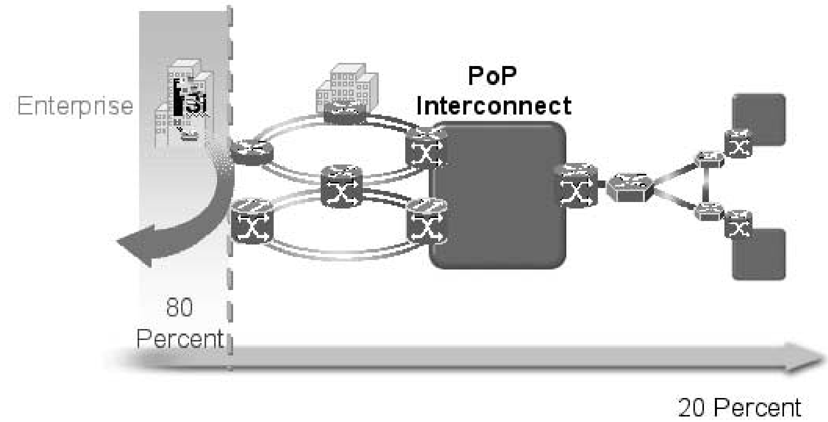
There are essentially three ways to scale an optical network. First, the optical core can be scaled by increasing the channel capacity of optical systems. This is accomplished by utilizing tighter channel spacing in the conventional (C)-band and/or migrating to long (L)-band or, in the future, to short (S)-band. Second, the optical core can be scaled by upgrading to higher bit rates through faster transponders. Third, optical-core networks can be scaled by increasing span distance or reach. However, there is always a tradeoff between speed, reach, and capacity. These issues are constrained by amplifier bandwidth and optical power budgets.

Scalability Trends

What is the biggest challenge for the optical core network? How can it be scaled? *Figure 2* shows the scalability trends in the core optical network. A few years ago, when dense wavelength division multiplexing (DWDM) first came out, people were talking about systems with 200 Gigahertz (GHz) channel spacing. Right now, there are systems out there with 100 GHz and perhaps 50 GHz channel spacing. We have seen DWDM systems go from 2.5 gigabits per second (Gbps) to 10 Gbps in the last two years, and there are 40-Gbps systems being developed in various labs across North America. With the preponderance of data/IP traffic in carrier networks, we now see systems moving from long haul to ultra-long haul (ULH), the latter being those systems with longer span reach than conventional systems that require regeneration, reshaping, and retiming (3R) every 500km or so. This reduces equipment cost by more than 30

FIGURE 1

Pre-Internet Traffic Pattern



percent. *Figure 3* shows the projected market for ULH; as you can see, it is projected to be about $3.6 billion in 2004.

Basically, all these trends are being driven by the use of the Internet, as the SPs need to be able to scale their networks to accommodate bandwidth demand brought about by exponential increase in Internet traffic.

Technologies

The emerging technologies for scaling optical networks are being made possible by smart engineering and a better understanding of physics, with most of the innovation taking place at the component level. For example, Raman amplifiers have now made it possible to increase the channel capacity of networks by tapping into L-band and, eventually, S-band.

Some companies are using dispersion-managed solutions to go longer distances, and there has also been an increase in the use of out-of-band forward error correction (FEC) transponders for extended long reach. In the next couple of months, we should have available better-performance, high-speed modulators for 40-Gbps systems. Right now, there may not be any commercially deployed 40-Gbps out there, and one of the problems is that polarization mode dispersion (PMD) is a very big issue for 40-Gbps systems, especially for old fiber types. Because of the stochastic nature of differential group delay, dynamic PMD compensators will be needed.

In summary, the Internet is changing everything. There is a lot of pressure on the core of the network, and the next-generation Internet will require a scalable optical core.

The Evolution of Wavelength Switches

Ian Viney
Senior Director, Product Marketing
Luxcore

Introduction

Dense wavelength division multiplexing (DWDM) networking is evolving at a phenomenal pace, particularly in the area of wavelength switching. This paper examines the evolution of wavelength switches, comparing today's first-generation architectures with soon-to-be-released second- and third-generation alternatives. This information will assist service providers in making more informed network decisions, thereby avoiding stranded capital and loss of their competitive edge.

A New Unit of Capacity

Since the first deployment of DWDM technology in the mid-90s, the capacity of optical fiber has increased by a factor of nearly 200, with no signs of a slowdown. In addition to enabling this astounding bandwidth growth, DWDM also introduced the wavelength (or lambda) as a new unit of network capacity. As shown in *Figure 1*, situated between the multiple-terabit capacity of a single fiber and the relatively small 50 megabit-per-second (Mbps) building block of the synchronous optical network (SONET) hierarchy, the wavelength is a perfect addition to the grooming hierarchy.

Unfortunately, today's switching equipment is unable to groom at the wavelength level, and so operators are forced to use traditional SONET cross-connect equipment as an expensive stopgap. As a result, the development of an all-optical switch capable of cost-effectively grooming signals at the wavelength level has become a major thrust in the telecommunications industry. This paper examines the evolution of wavelength switching and compares alternative architectures, both in service and being proposed in the marketplace.

The Ideal Wavelength Switch

Before comparing alternative switch architectures, it is worth defining the "ideal" wavelength switch as a basis for evaluation. In this paper, the term "wavelength switch" refers to a device that terminates multiple optical fibers, each carrying multiple wavelengths (see *Figure 2*).

From a grooming perspective, a wavelength switch can transfer the entire contents of any wavelength on any incoming fiber to any wavelength on any outgoing fiber. Wavelength connections are established on the order of tens of milliseconds under the direction of provisioning staff.

Wavelength switches do not groom traffic at the sub-wavelength level (e.g. synchronous transport signal [STS]–1). Instead, STS–level traffic are aggregated onto dedicated fibers and passed to a lower-level SONET switch to be groomed.

In many respects, the high-level requirements of a wavelength switch are identical to those of an electronic switch—non-blocking, scalable, automated, cost-effective, etc. In addition, however, DWDM has opened up an exciting new possibility—transparent wavelength switching.

A transparent wavelength switch grooms individual wavelengths carried by a DWDM fiber without imposing restrictions on either the rate or the format of signals carried on those wavelengths. The benefits of transparent routing are enormous. For example, signal rates can be upgraded (optical carrier [OC]–48 to OC–192 to OC–768), and new protocols deployed (e.g., 10 Gigabit Ethernet [GbE]), without any hardware changes to the switch. In contrast, optical-electrical-optical (O–E–O) switches are not rate or protocol independent (referred to as "opaque") and require a forklift upgrade to achieve the same results.

In an era when subscribers expect service changes and upgrades to be instantaneous, and in an era when service-provider competition is at the highest level ever, many of the benefits of instant-rate and protocol change are obvious. Maybe not so obvious, though, is that transparent wavelength switching also enables a wide range of new offerings such as:

- New services: wavelengths-on-demand, time-of-day service, native-rate local are networks (LAN), 10 GbE, etc.
- Service-level agreements: type of service (ToS), class of service (CoS), and quality of service (QoS).
- Network protection: varying degrees of dynamic wavelength protection and restoration.

Another important capability that can be offered by a wavelength switch is the ability to broadcast the contents of one wavelength to multiple other wavelengths. This functionality is key in applications such as video distribution, and further serves to distinguish a transparent wavelength switch from an O–E–O switch.

FIGURE 1

The Wavelength

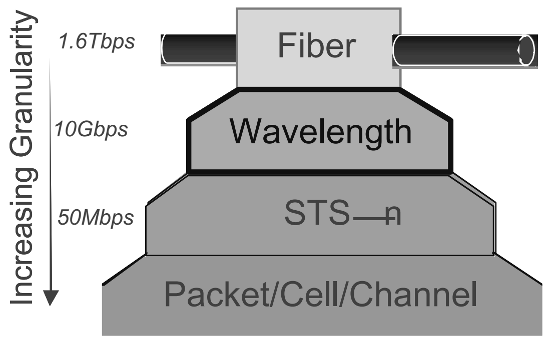

FIGURE 2

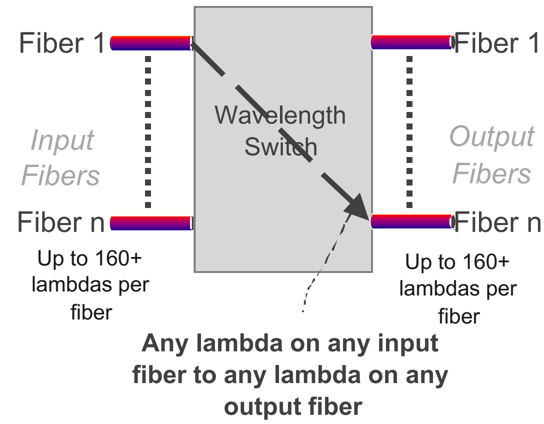
The Wavelength Switch



The Evolution of Wavelength Switches

Many of the components required to build a fully functional, all-optical wavelength switch are based on state-of-the-art technology that is in the process of moving from lab to product. For this reason, the first all-optical wavelength switches will not reach the market until the end of 2001.

In the meantime, a number of interim approaches are being proposed. The following sections compare these approaches with the "ideal" switch described in the previous section.

First-Generation Wavelength Switches

In today's telecommunications networks, the basic functionality of a wavelength switch is achieved by combining multiple discrete products (see *Figure 3*). For simplicity, only one direction of signal flow is represented, and passive optical components such as splitters, combiners and filters have been omitted.

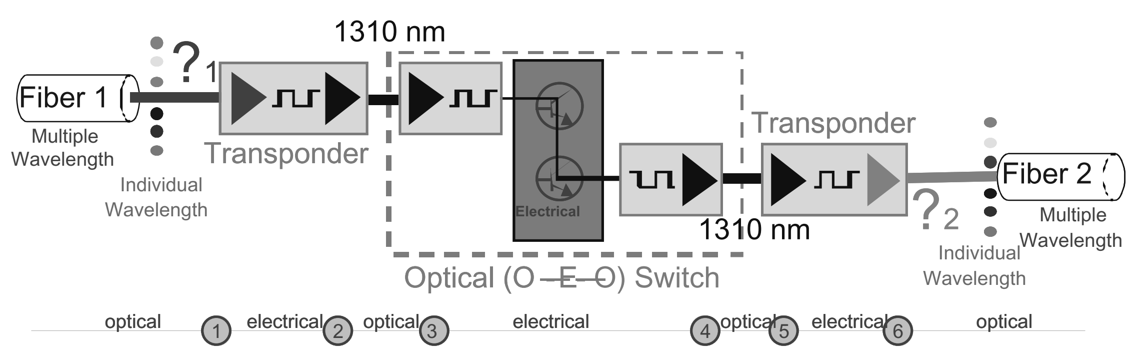
Following the signal flow from left to right, each DWDM wavelength on the incoming fiber is terminated, and then, typically, converted to a generic short-haul 1,310 nanometer (nm) interface by an outboard O–E–O transponder. Because each DWDM equipment vendor uses the International Telecommunication Union (ITU) grid in a different manner, the transponders are vendor specific.

The 1,310 nm optical signal is then passed to the optical switch, where it is converted back to electrical, demultipexed into a stream of sub-rate signals, and cross-connected to the appropriate output port using an n x STS–1 matrix. The signals are then multiplexed back to a higher SONET rate and converted back to the 1,310 nm optical signal—again using an O–E–O device. (The label "optical" here is clearly a misnomer, as the core switch is electrical, and for this reason such switches are often referred to as an O–E–O switches.) Finally, the 1,310 nm output from the switch is passed to another outboard O–E–O transponder, which terminates the 1,310 nm signal converts the signal to the appropriate DWDM wavelength.

Today's O–E–O switches utilize an "n x STS–1" based electrical core, and the O–E–O transponders are clocked at the

FIGURE 3

First-Generation Wavelength Switches



SONET rate; hence neither device provides protocol or bit-rate independence. This architecture is therefore referred to as "opaque" to distinguish it from a transparent wavelength switch.

This first-generation architecture is a very crude attempt at wavelength-switch functionality and suffers from numerous drawbacks:

- Changes in bit rate (i.e., OC–192 to OC–768) require major hardware change outs.
- The architecture is restricted to use with SONET traffic.
- The large number of optical-to-electrical conversions (six per wavelength) makes first-generation wavelength switches expensive, low density, and power hungry.
- Electronic-switch cores do not scale well and require multiple inter-connected matrices to increase capacity. As a result, the cost and footprint of the core increase almost geometrically as the port requirements increase.
- There is one patch cord for each O–E–O transponder, and one transponder for each wavelength. This results in an extremely large number of optical patch cords with the associated increase in cost, reduction in reliability, and administrative headaches.
- Finally, the optical-interface card associated with each wavelength has a different part number and hence one spare transponder card is required per wavelength. Because spares are typically maintained at every office, the result is a huge inventory of transponder cards with the associated cost and administrative headaches, particularly in systems supporting close to 200 wavelengths per fiber.

Second-Generation Wavelength Switches

Proposed alternatives to fully transparent wavelength switches replace the electrical core of today's O–E–O architecture with an optical matrix (see *Figure 4*). Most of these offerings are slated for deployment in the second half of 2001. Based on recent press releases, optical micro-electromechanical systems (MEMS) appear to be the technology of choice for the optical matrix; however, other options are under evaluation, including liquid-crystal and bubble technologies.

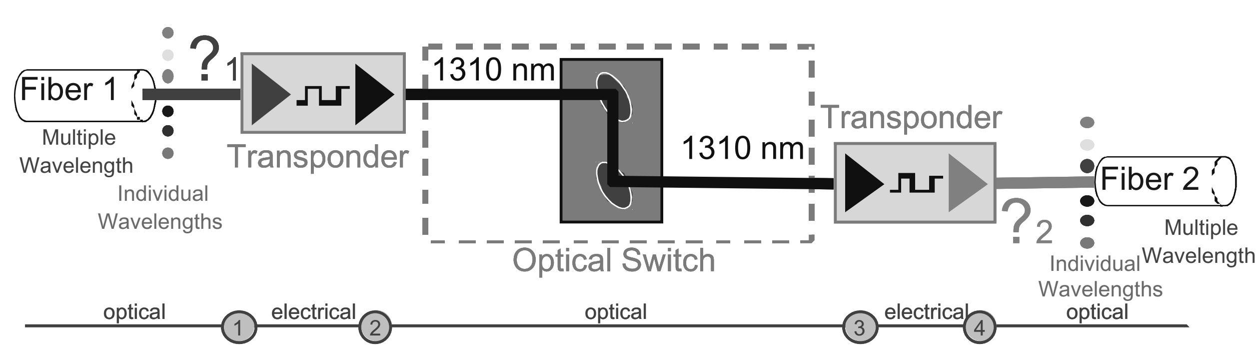
Although the core switches proposed for use in these second-generation offerings are transparent, they have no visibility of individual wavelengths carried by the fiber and hence function as an automated fiber patch panel. In order to switch individual wavelengths, transponders are required in conjunction with the optical-switch matrix.

Second-generation wavelength-switch functionality can be achieved in multiple ways. Depending on the particular configuration, the overall architecture will exhibit some combination of the following advantages and disadvantages:

- All-optical switch cores are in the early stages of development and show promise to scale more cost effectively than their electrical counterparts.
- Comparing *Figures 3* and *4*, the second-generation architecture reduces the number of O–E–O conversions per wavelength from six to four. This simplification is likely to result in improved cost and footprint over the first-generation approach; however, since the improvement came from the removal of low-cost intra-office interfaces and not the more expensive DWDM optics, the overall savings are likely to be modest.
- Changes in bit rate (i.e. OC–192 to OC–768) require major hardware change outs.
- Some architectures are restricted to use with SONET traffic.
- The optical-switch matrix cannot support broadcast capability.
- There is one O–E–O transponder, and one interconnection between the transponders and switch for each wavelength in each direction of traffic. This results in an extremely large number of optical patch cords with the associated increase in cost, reduction in reliability, and administrative headaches.
- The optical-interface card associated with each wavelength has a different part number and hence one spare transponder card is required per wavelength. Since spares are typically maintained at each office, the result is a huge inventory of transponder cards with the associated cost and administrative headaches, particularly in systems supporting close to 200 wavelengths per fiber.

FIGURE 4

Second-Generation Wavelength Switch Architecture



- Direct inter-working with other vendor's ITU grid wavelengths without tunable interfaces is likely to be a major challenge.
- Bundling wavelengths into bands can lead to significant under-utilization of fiber. In some cases over 50 percent of the fiber capacity could be unused.
- Wavelength engineering is a nightmare.
- Switching wavelengths on a band basis is significantly less flexible than switching individual wavelengths.
- The optical switch matrix cannot support broadcast capability.

Third-Generation Wavelength Switches

To meet all the requirements of the "ideal" wavelength switch described earlier in this paper requires a sophisticated combination of tunable optical devices including lasers, wavelength converters, filters, and multiplexers.

The basic architecture of a third-generation all-optical wavelength switch is shown in *Figure 5*. As a wavelength enters from the left a transparent, tunable wavelength translator converts it to a second, fully selectable outbound wavelength. A transparent optical core then directs this new wavelength to the appropriate output fiber thus completing the connection.

In contrast with the first- and second-generation architectures, the third-generation architecture is the first to offer a fully integrated, fully functional solution. In particular:

- The third-generation architecture is 100 percent transparent and hence totally independent of both protocol and data rate.
- Any wavelength on any incoming fiber can be dynamically converted to any wavelength and exit on any other fiber without conversion to electrical.
- All fiber interfaces are at the DWDM level, avoiding the need for the mass of per-wavelength patch cords required to interconnect today's architecture and some second-generation architectures.
- Wavelengths can be switched individually, avoiding the stranded wavelengths associated with the "bundled" approach.
- Tunable optical devices are still early on the technology curve and hence have huge potential for cost reduction and miniaturization.

FIGURE 5

Third-Generation (All-Optical) Wavelength Switch Architecture

× Bad - Average ✓Good * Varies according to switch architecture

- The signal carried by any incoming wavelength can be broadcast to any number of outbound wavelengths.
- Wavelength engineering is simple, even in very large networks.
- The signal carried by any incoming wavelength can be broadcast to any number of outbound wavelengths.

Conclusion

Figure 6 summarizes the relative merits of these architectures. While the second-generation proposals appear to offer some advantages over today's first-generation approach, given the short time until fully functional third-generation wavelength switches become available, these advantages will most likely be short lived and the associated investments stranded.

Perhaps more importantly, in an environment where bandwidth prices are dropping at an astonishing rate (reportedly as high as 50 percent every six months), services providers can no longer compete on price alone. Instead, the ability to introduce new services quickly and effectively will be the key to survival. As described earlier, transparent routing is both bit-rate and protocol independent, providing a sound platform for new-service capability and increased service velocity.

The exciting news is that fully transparent, third-generation wavelength switches are finally viable.

MPLS Applications in Broadband Networks

Anna Wielosz
Associate Director, Broadband Technology, ATM Network Architecture
Bell Canada

Abstract

Switching-based broadband networks represent significant capital investment for many network operators. These networks are used for multiple services and run over multiple protocols. Today, many of them have the possibility of turning on multiprotocol label switching (MPLS) capabilities. This paper analyses the opportunities that the MPLS brings to carriers on the existing networks.

The subject can be divided in two aspects: core and access networks. The core network analysis is focused mainly on the evolution toward a next-generation MPLS–enabled architecture. However, MPLS helps also to improve existing network performances by introducing packet interfaces and label-switched path (LSP)–based management. Access networks are analyzed from provisioning perspective: moving from permanent virtual circuit (PVC) to LSP. An additional aspect for MPLS at the edge is the new service potential that it creates: virtual private networks (VPNs) and voice over MPLS.

Finally, multiple standardization organizations have standard definition works in progress that will allow interoperability between the MPLS and existing Layer-2 technologies. Some of them, such as MPLS user network interface (UNI), may play a crucial role in making MPLS successful at the edge and thus becoming a truly end-to-end protocol.

MPLS Introduction

MPLS has been initially developed to address the following aspects: traffic engineering, quality of service (QoS), and routing performances in Internet protocol (IP) networks. The concept of the MPLS is the following: the IP forwarding based on IP addresses is replaced by label switching. IP routing still takes place, but the label switch routers (LSR) distribute and assign labels, and bind them to IP addresses. Once this assignment is done, no more header look-up is required, but packet forwarding is performed based on label switching. All MPLS packets carry at least one label information.

LSPs are established between label edge routers (LERs) using routing protocols. LSPs introduce a connection-oriented aspect into connectionless IP networks. Moreover, when LSPs are established, resource availability may be verified and the path may be routed according to the QoS requirements. This is a significant improvement of the IP network engineering.

Another important aspect is the underlying protocol independence. MPLS is designed to run over asynchronous transfer mode (ATM), Ethernet, frame relay (FR), and packet over synchronous optical network (SONET), or POS, links. This addresses a crucial challenge in telecom networks: interoperability between technologies.

Today, we see large IP networks deploying successfully MPLS technology and implementing VPN services. For a while now, the MPLS has been considered as a solution for Layer-2 networks. Like ATM a few years ago, MPLS looks promising to be a convergence networks protocol. In addition, today we know that most of the networks carry mainly IP traffic, which eventually should favor the success of the MPLS.

Industry Trends

The first MPLS products on the market were large IP routers conceived for IP backbones. Today, we see more and more ATM and FR switches implementing MPLS protocol as well. MPLS has introduced connection-oriented approach and QoS on IP platforms. The traditional ATM and FR products are by definition connection-oriented. They also have backplanes and switching fabrics supporting hardware implemented QoS. This is a huge advantage for the manufacturers of these products. Well-known QoS mechanisms based on separate queues and exhaustive round-robin algorithms provide very deterministic QoS behavior. A second advantage is the resource reservation algorithms built in traditional switches. The resource reservation constitutes a main tool for traffic engineering and QoS. The starting point toward MPLS for switching platforms is far advanced in comparison to the routers; most of hardware requirements are already implemented and well known.

It should be noted that most of the traditional switches today support IP–over–ATM or FR protocols. Thus, implementing MPLS represents the extension to already existing features. This is effectively the way in which most of the traditional switches evolve today.

Service providers operating large ATM networks and various access technologies realize that today their networks have the capability to implement MPLS. Some of them have already built IP backbones in parallel.

What kind of applications and benefits could MPLS bring to the existing networks? First, MPLS is new services enabler on broadband networks. Layer-3 VPNs can now be created on already-deployed networks and generate new revenue opportunities from already-invested capital. However, the trade-off between service definition on IP–focused equipment and IP–enabled equipment may make this opportunity less appealing. New services based on MPLS standards, such as MPLS Layer-2.5 VPNs or voice over MPLS, will create more attractive service opportunities. Still, the success of the approach depends on the adaptation of MPLS standards by end-user and edge-equipment manufacturers.

There are other appealing aspects for network operators brought by MPLS. A closer look at the access and core networks shows that there are many challenges that network operators are facing today. We will go through some MPLS features and see how they can resolve some of broadband network issues.

Broadband Networks Challenges

Broadband networks (see *Figure 1*) are truly multiservice today. ATM networks carry high-quality video services as well as best-effort Internet services. However, there are still parallel core networks required for Ethernet, Gigabit Ethernet services, and IP services. The reasons behind that? The ATM network did not catch up with required access speeds and is not optimized for best-effort services with Ethernet or IP accesses. Other technologies, such as resilient packet ring (RPR), are adapted better and provide better implementation costs for these types of services.

The second issue is the network scalability. Services such as transparent LAN or Layer-3 services require static PVC mesh. Dynamic protocols, such as LAN emulation, can be applied on small-enterprise networks but are not scalable for large multi-customer networks. The number of PVCs on ATM core grows very rapidly and reaches thousands of connections. Hence, the management of the network becomes a challenge. Any change to a service description may require intervention to multiple PVCs. Similarly, bandwidth allocation on PVC–based networks requires micromanagement. SVCs may address this type of issues. However, because the edge-equipment implementation did not follow this direction, the demand on the SVC type of services has been low.

Bandwidth efficiency is another argument very often used against the ATM network. The 53-byte cells allow deterministic QoS but introduce so-called cell tax, which may reach 30 percent, depending on the packet size distribution. This percentage becomes non-negligible when optical carrier (OC)–48 and higher speeds are concerned.

Additionally, in traditional networks, the interworking functions are required per PVC to adapt FR, Ethernet, IP, etc. This involves extra provisioning efforts for each adaptation circuit.

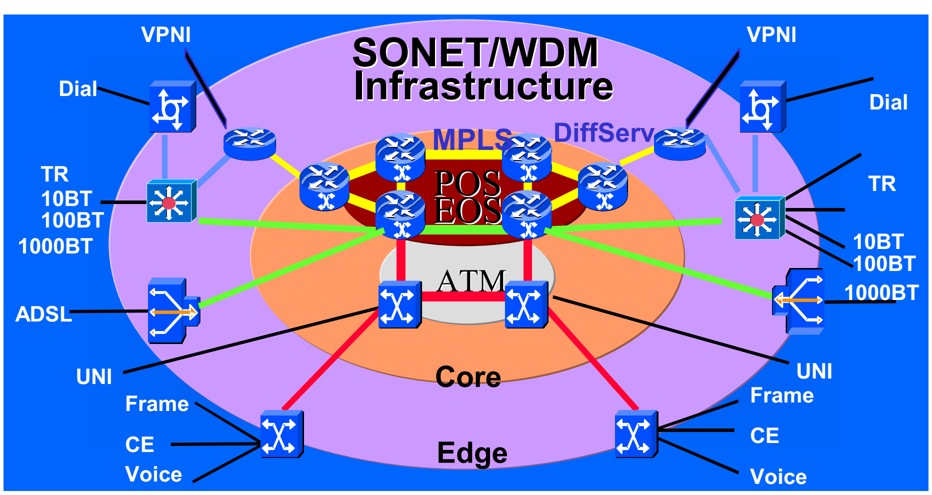
Some of these issues may be improved by MPLS deployment in the core, while others may require applications in the edge. Because core and access implementation can be done independently, both applications will be described separately in the following sections.

Core Network MPLS Applications

MPLS promises the possibility to collapse multiprotocol core networks. Hence, MPLS–based equipment could be

FIGURE 1

Broadband Core Network Architecture



Source: Bell Canada

used as well for IP and for ATM transport. The Internet Engineering Task Force (IETF) and MPLS Forum contributions on Layer-2 mediation and VPNs over MPLS allow adapting the Layer-2 traffic on the Layer-2.5 core. The main advantage is that the convergence is possible without major capital investment in today's networks.

Collapsing multiple networks is driven by investment efficiency requirements. Building parallel backbones result in running two underutilized backbones. This contributes largely to the increase in network costs. Moreover, the return on capital on separate networks is much slower.

Another requirement is the large fan-out to fill network trunks. On average, access links are utilized at 30 percent of the access speed. Because the switches do not allow any backplane oversubscription, the networks need to be, in general, hierarchical in order to provide accurate trunk utilization. On the other hand, the hierarchy also allows the building of less network trunks and thus better fiber utilization (see *Figure 2*).

The hierarchical network architecture gives an opportunity to evolve IP and ATM backbones to a common core architecture. This evolution can be done without significant changes to the existing networks. The new common core should provide high-speed "pipes" with the support of LSPs. Current backbones will perform mediation function and will aggregate traffic into LSPs.

The common MPLS core will have very stringent requirements for QoS functions. ATM backbones should be able to receive the same grade of service satisfying real-time application requirements. With the switching fabrics and queuing mechanisms implemented in next-generation MPLS switches, it becomes a reality.

The constraint-based routing–label distribution protocol (CR–LDP) and resource reservation protocol–traffic engineering (RSVP–TE) protocol, both label-distribution–related MPLS mechanisms, provide the implementation of resource reservation and QoS mechanisms. This way, LSPs are using routes where QoS requirements can be satisfied.

In the MPLS core, traffic-engineering functions will be pushed to the edge. The traffic over an LSP will be admitted according to its QoS and bandwidth requirements (forward error correction [FEC] and connection admission control [CAC] algorithms). The edge will be also responsible to provide appropriate traffic aggregation on an LSP. Thus, all flows will be policed at the edge: IP, ATM, or frame-based rate limiting. Secondly, the number of flows expected over an LSP should be engineered in the access. This approach gives a possibility of intelligent overbooking based on the community of interest.

Once this classification is done at the edge, the core is managed on a "big pipes" basis. This approach should improve network resources provisioning. An LSP bandwidth reflects well the requirements of the community of interests it interconnects. LSPs are then modified as requirements grow or, ideally, adjust bandwidth to traffic in a dynamic fashion (see *Figure 3*).

MPLS promises also performing fast rerouting procedures. The rerouting times are expected to be in the range of 100 ms. This significantly improves the robustness of core networks. Today, Layer-1 robustness does provide link-failure or card-failure but not node-failure recovery. Layer-2 and Layer-3 rerouting mechanisms' performances are in the range of seconds.

With broadband core network growth in the range of 20 percent and 30 percent for the next two years, more links are expected to be at OC–48 and higher speeds (see *Figure 4*). For some time now, the OC–3 component of the total core bandwidth has decreased steadily, leaving a place for OC–12 and higher speeds. Similar behavior will be

FIGURE 2

Hierarchical Network Architecture with MPLS Core

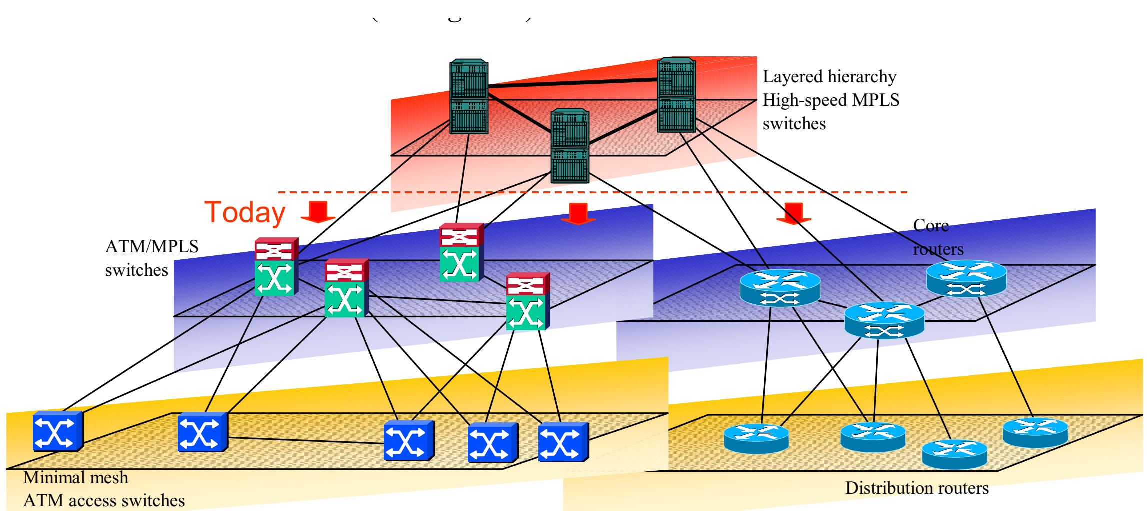


FIGURE 3

LSP–Based Bandwidth Management

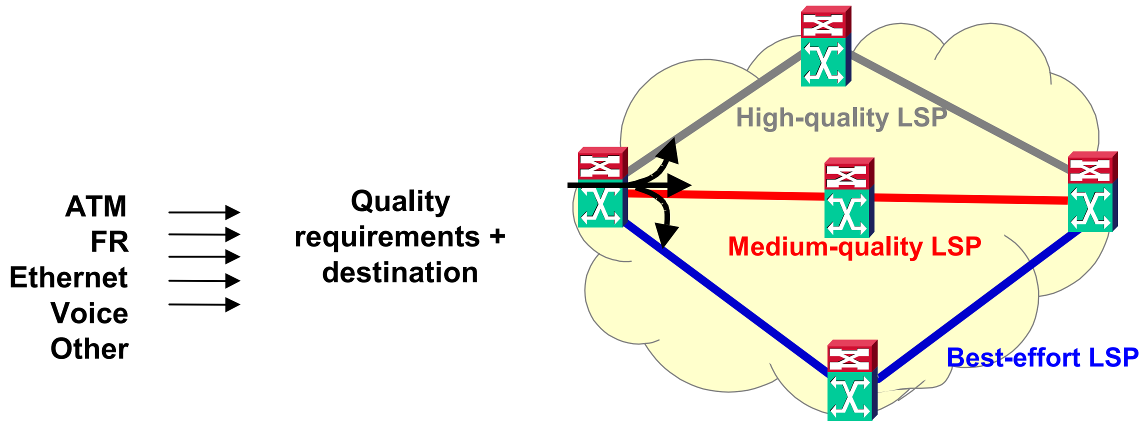

FIGURE 4

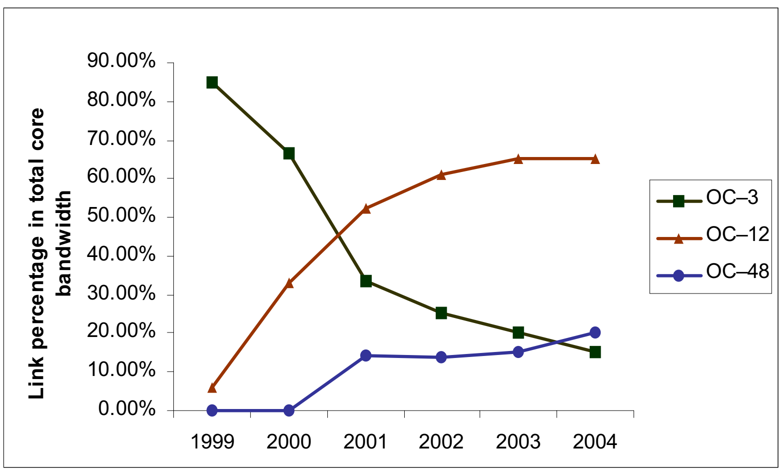
Link-Type Percentage in Total ATM Core Bandwidth



Source: Bell Canada

observed with OC–12 links. The number of higher-speed links is expected to grow. This is the result of growth applied to a total network size and growing bandwidth demand per circuit.

First, it is beneficial to deploy higher capacity as early as possible. Otherwise, the deployment of parallel links grows with capacity requirements. Moreover, redesigning the network with the proper trunk speeds involves significant operational effort. Once again, collapsing the network helps in deploying the right infrastructure at the beginning.

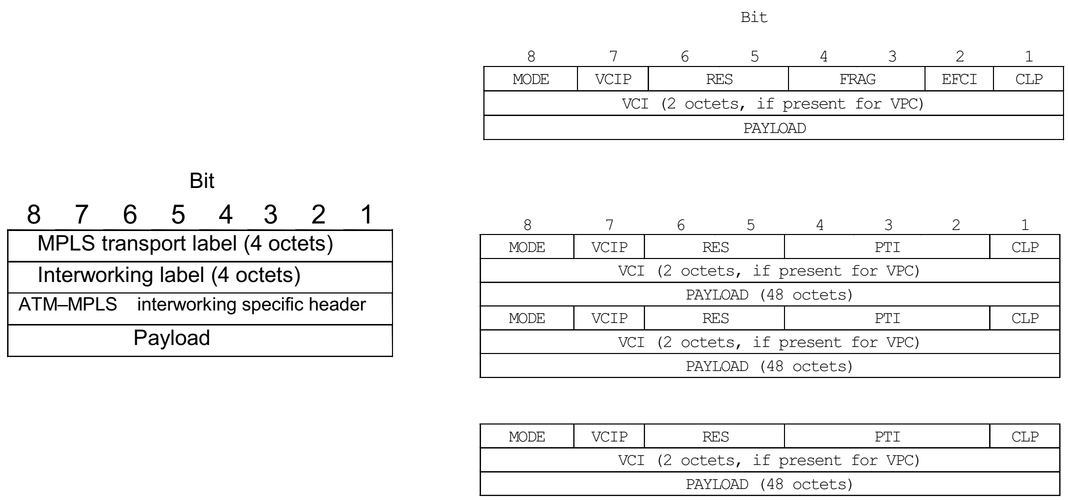
Finally, it is worth to look at the bandwidth savings with packet technologies, especially for high-speed interfaces. Jitter introduced at these speeds is lower, and maximum acceptable packet length becomes higher. A very interesting feature under development by the MPLS Forum is the cell concatenation. Multiple cells are concatenated into an MPLS frame without analyzing any payload information. This allows the reduction of cell tax without performing the complete reassemble at the packet level (see *Figure 5*).

Replacing cell interfaces by packet or frame interfaces, assuming that the headers are implemented as per *Figure 5*, can produce up to 16 percent of bandwidth savings. This is equivalent to 398 megabits per second (Mbps) per OC–48 link. These interfaces can be POS, Gigabit Ethernet, FAST, or other interfaces supporting MPLS.

In summary, implementing MPLS in broadband core networks gives a clear evolution path toward a common core next-generation network. Management on large LSP bases can provide significant improvements in bandwidth management. Finally, the smooth introduction of packet interfaces with QoS support is enabled, which translates directly into significant bandwidth savings.

FIGURE 5

Proposed MPLS Header for ATM Mediation as per....



Edge MPLS Applications

Independently to the core, edge platforms can be deployed with MPLS capabilities. Assuming the broadband core can switch or tunnel the LSPs, the following advantages should be considered: provisioning advantages coming from circuits' aggregation and new services opportunity.

As has been mentioned, multiple circuits in fully meshed configurations must be provisioned today to provide services on ATM networks. MPLS does not resolve the problem completely; routers still need to be interconnected with LSPs. However, LSPs are established automatically according to IP routing protocols, and LSRs are exchanging topology information.

Furthermore, even if the mesh is still required, the degree of meshing is significantly reduced by the aggregation step. Because IP headers are processed at the access switch acting as the LER, multiple access links can be mapped on the same LSP. It reduces significantly operational impacts and time to market for new services. Enabling a new access does not require any intervention in the core network (see *Figure 6*).

The interoperability problem is reduced from any-to-any to IP over MPLS, where IP can be carried over any Layer-2 protocol.

The common IP control plane plays a role in automatically establishing LSPs across a heterogeneous network. Like S–PVC in ATM networks, LSPs are established via signaling (LDP). The topology information is exchanged, and optimal path in the network is selected according to the LSP parameters. Both, CR–LDP and RSVP protocols contain LSP parameters: bandwidth and QoS requirements. For more information on QoS, please refer to [1].

Additionally, MPLS edge implementations will become new service enablers. Today, the MPLS forum is working on a voice-over–MPLS standard. Considering the MPLS QoS capabilities, that could become more successful than voice over IP (VoIP) applications. Another interesting standard under development is the MPLS UNI. The standard is meant to provide VPN capabilities with autoconfiguring edge.

MPLS Standards Development

The standards that are crucial for the success of MPLS in the converged backbones are those defining mediation policies—i.e. ATM, frame over Layer-2.5 networks. Major equipment manufacturers are involved in developing these specifications, and first implementations are available on the market.

Mediation is the technology allowing smooth migration or integration of existing Layer-2 networks with MPLS networks (see *Figure 7*). MPLS networks also promise interoperability with a generalized MPLS (GMPLS) optical core. The ATM Forum, FR Forum, and MPLS Forum work is focused on the transport of ATM or FR over MPLS. At this time, any-to-any Layer-2 interoperability is not considered. However, by definition it is possible with IP routing.

Layer-3 VPNs have been addressed by IETF Internet drafts [2]. Layer-2 transport is first addressed by "Martini" drafts describing Layer-2 MPLS encapsulation—i.e., ATM, FR, Ethernet, point-to-point protocol (PPP), and VLAN over MPLS. These drafts specify what information should be included in the headers and what management information should be exchanged (such as P–NNI, FR link management, etc.). A more complete Layer-2 VPN solution is proposed in the "Kompella" draft and extensions to it. These contributions propose extensions to LDP protocols to carry CE identification information [3] [4].

Another contribution under development is the UNI MPLS. This work may provide an attractive way to provide MPLS VPNs with an autoconfiguring feature for customer-premises equipment (CPE) devices. The CPE discovers LSPs on

FIGURE 6

MPLS Edge Implementation

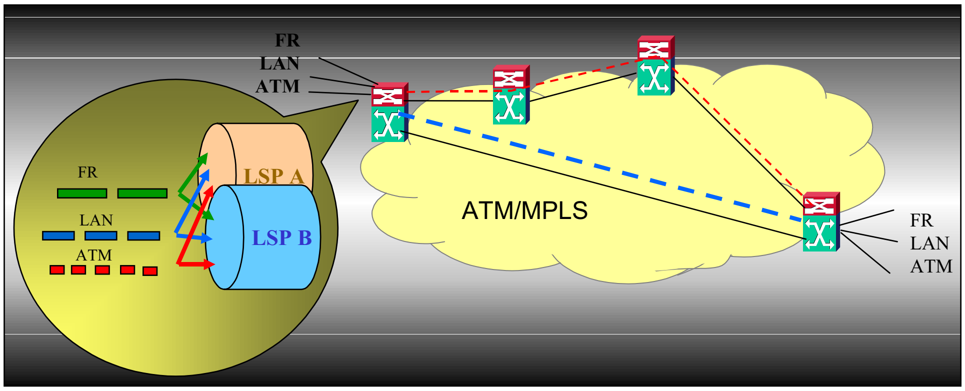


FIGURE 7

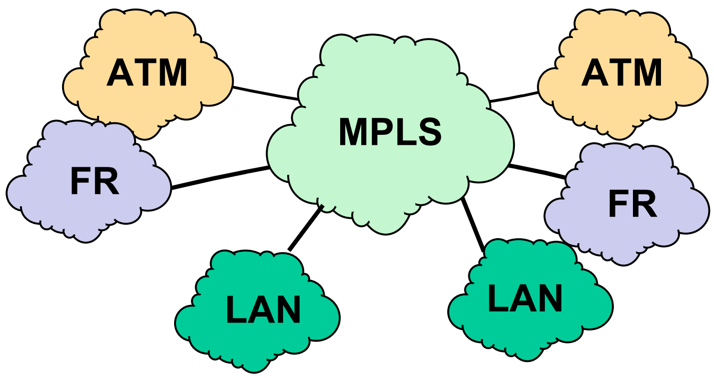
MPLS Mediation



the link to which it is connected and configures its forwarding tables accordingly. VPN information is exchanged between the LER and CPE device over LDP.

The important limitation to note is that LSPs are presently point-to-point and unidirectional connections.

Conclusions

In conclusion, broadband networks can evolve toward convergence with IP technologies by implementing MPLS in the core. MPLS implementation will generate a profit over the already invested capital, as the functionality is incorporated on most of traditional switching platforms.

Multiple advantages appear in the hierarchical structure of a network. It enables almost a seamless implementation of next-generation MPLS cores shared between traditional switching and IP backbones. This, in turn, allows better resource utilization and, therefore, more efficient investment.

Additional advantages are related to operating core networks with a low number of high-speed trunks. The n-square problem of ATM networks, although still present, is reduced to the number of devices necessary to interconnect. The aggregation over an LSP reduces the complexity of new services provisioning.

Finally, MPLS brings new service opportunities to the edge. It also enables a huge installed base of broadband switching networks to carry IP services.

Subcarrier Multiplexing: More Than Just Capacity

Ted Wolcott
Director, Advanced Optical Product Development
Centerpoint Broadband Technologies

Heidi Thelander
Senior Product Marketing Manager
Centerpoint Broadband Technologies

Abstract

Increasing demand for bandwidth in today's networks has driven a rash of optical technology development. Among these new technologies are high-capacity subcarrier multiplexed systems capable of increasing network capacity as much as eight times while dramatically improving fiber bandwidth efficiency. However, this subcarrier multiplexing (SCM) technology does more for the network operators than just provide greater capacity and higher efficiency. This paper describes how the use of higher order modulations together with SCM provide inherent capabilities and features which are highly attractive to network operators when implemented effectively.

1. Introduction to Subcarrier Multiplexing

Demand for more flexible bandwidth creation at lower cost is causing service providers to look at alternative and complementary technologies to traditional time division multiplexing (TDM) and wavelength division multiplexing (WDM) systems. SCM provides an additional dimension of multiplexing to increase the efficiency and flexibility of optical transport networks. It has largely been promoted as an approach for increasing capacity and bandwidth efficiency on a given fiber or wavelength with its use of bandwidth efficient digital modulation and sublambda grooming. However, SCM and the architectures it enables provide many additional capabilities for which network planners are waiting.

SCM, sometimes referred to as frequency division multiplexing (FDM), has been used in radio, satellite, and cable television (CATV) applications at much lower data rates for many years, providing low-cost, highly bandwidth-efficient physical-layer transport. Recent developments in high-rate digital signal processing and radio frequency (RF) component capabilities have enabled application of this technology to optical networking systems, which have just begun to require such high levels of bandwidth efficiency. This optical SCM technology is the result of the combination of several key elements, all considered proven technology in their other applications:

- Higher order modulation for bandwidth efficiency
- Pulse shaping for spectral efficiency
- Forward error correction and coding for bit-error rate (BER) performance
- RF signal multiplexing and demultiplexing
- Broadband optical intensity modulation

The higher order modulation most commonly used in SCM is quadrature amplitude modulation (QAM) wherein multiple information bits are transmitted in a single signaling interval using a mapping algorithm involving both amplitude and phase. An example of this is 16-QAM (see *Figure 1a*), which transmits 4 information bits by transmitting one of 16 locations in the amplitude phase plane or "symbols." The digital clock speed used in timing these symbols is much lower than the pure bit clock speed used in an on-off-keyed (OOK) modulation, translating to lower speed (and cost) electronics and to an ability to transmit more information in a given bandwidth. Thus, these modulation types are often referred to as bandwidth-efficient modulation (BEM).

In addition to transmitting several information bits in each symbol period, digital signal processing is used to shape the spectrum of the transmitted pulses so that most of the modulated signal energy is retained in a minimum frequency band. This reduces required spacing between carriers significantly (see *Figure 1b*), enabling subcarrier multiplexed systems to provide very high bandwidth efficiency. Since having 16 states (symbols) to choose from each period would naturally increase the likelihood of error, techniques to enhance performance are also used with these modulation approaches so that link budgets comparable to or better than alternative approaches can be achieved with similar power. These include linear equalization of the received signal within the demodulator and use of multiple advanced forward-error-correction coding algorithms (see *Figure 1c*).

SCM technology is more than digital processing; the key to many of the performance benefits is actually the RF processing that is performed on the already modulated signals. These individual channels—all output from digital modems at a single intermediate frequency—are frequency converted and filtered to a series of equally spaced offset sub-

FIGURE 1

c) Forward-Error-Correction Coding Improves System BER Performance

carrier frequencies (f_1, f_2, … f_k). The offset subcarriers are combined or multiplexed together, creating a single composite RF signal consisting of *k* independent subcarriers (see *Figure 2a*). This RF signal is then used to intensity modulate the laser, creating a single wavelength optical signal carrying *k* independent subcarrier channels (see *Figure 2b*).

Systems have been developed with these technologies that provide up to 20 gigabits per second (Gbps) of data transmission on a single wavelength in as little as 32 gigahertz (GHz) of spectrum (see *Figure 3*)—equivalent synchronous optical network (SONET) TDM systems require 60 GHz. With linear external modulators, standard International

b) Composite RF Signal Intensity Modulates a Laser to Create a Single Carrier Optical Signal

Telecommunication Union (ITU) grid lasers are used to transmit these signals at any desired ITU wavelength. Systems have been constructed providing 32 subcarriers capable of transmitting 32 optical carrier (OC)–12/OC–12c signals or eight OC–48/OC–48c signals on a single wavelength. In addition, these individual wavelength signals can be fed into WDM systems to provide even greater capacity per fiber.

SCM provides superior bandwidth efficiency and overall capacity to the much simpler OOK systems. However, capacity and bandwidth efficiency alone will not answer many network operators' needs. Many other functions and features that operators require, desire, or hope for are provided by the unique combination of the digital processing BEM and SCM. Some inherent features that provide a new level of flexibility are as follows:

- Linear and ring configurations enable add/drop, drop/continue, regeneration, and broadcast/drop (fanout) of individual subcarriers
- Transparency providing multiple service types in native format—with carrier-class protection
- Highly flexible traffic mix carries any combination of IP, ATM, and SONET signals
- SONET–like protection performance without SONET overhead on each individual channel
- Interoperability with TDM and WDM equipment, creating flexible, scalable, and robust networks

In addition to the features produced by the architecture, a number of performance benefits are obtained through implementation of this type of system. These include the following:

- Straightforward network link design—no optical link budget adjustments with subcarrier provisioning
- Improved system robustness with reduced adjacent channel interference and link performance enhancements due to equalization and FEC
- Lower susceptibility to polarization mode dispersion (PMD) and chromatic dispersion than 10 Gbps TDM systems
- Highly insightful performance monitoring with many valuable metrics from digital signal processing
- Excellent fault isolation capability due to metrics and architecture

2. Functionality Creates Flexibility

The functionality of an optical networking system determines the level of flexibility it provides to both the network designer and the network operator. Subcarrier multiplexed systems can be architected for a high level of functionality in a number of areas. With low-cost RF processing, the SCM system can be configured to support both linear and ring network configurations (see *Figure 4*). Nodes can be configured as linear terminals, ring add/drop multiplexers (ADMs), or regeneration elements, allowing traffic to be set up as add/drop, drop and continue, regenerated, or broadcast and drop (fanout) for individual subcarriers—and be reconfigured as needed. Linear configurations are then easily created to provide 1+1 protection for application to regional point-to-point interconnect, capacity expansion of thin fiber routes, or to supplement capacity on existing long-haul routes where fiber type currently limits the ability to increase TDM speeds. Metro rings can be configured with ADMs (and regenerators as needed) to provide unidirectional path-switched ring (UPSR) protection for the metro core or collector ring applications where capacity growth is rapid, yet service mix difficult to predict.

In addition to supporting a variety of applications with these configurations, the digital and RF processing inherent in SCM provide a level of visibility together with data transparency that is unique. The digital processing performed yields a great deal of insight into the performance of the link on a given channel with metrics ranging from uncoded channel BER to received signal-to-noise ratio (SNR). This enables SONET–level protection to be provided on *any* traffic type carried by an SCM system. Since all traffic is digitally modulated, all traffic can be protected with less than 50 ms switching to a protect channel, including native IP data traffic without SONET framing or digital wrappers.

FIGURE 3

SCM Packs More Information onto an Optical Carrier

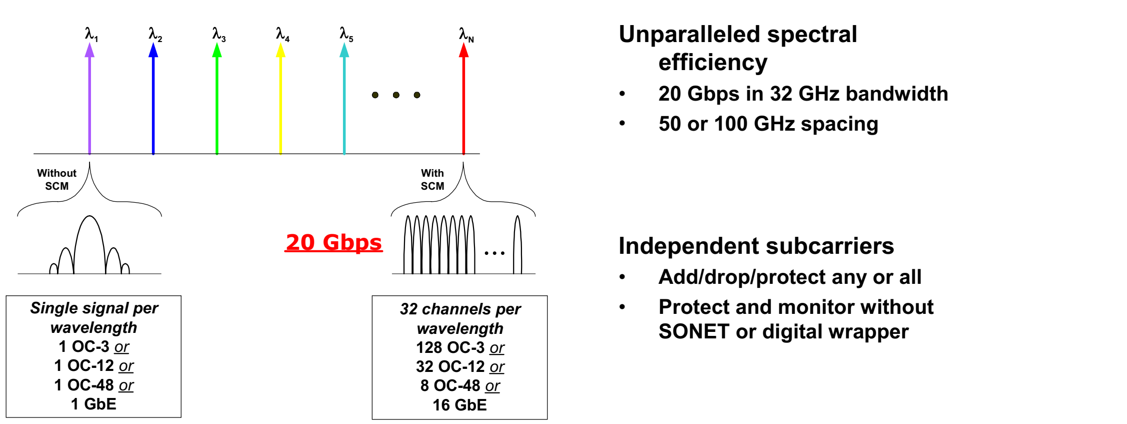

FIGURE 4

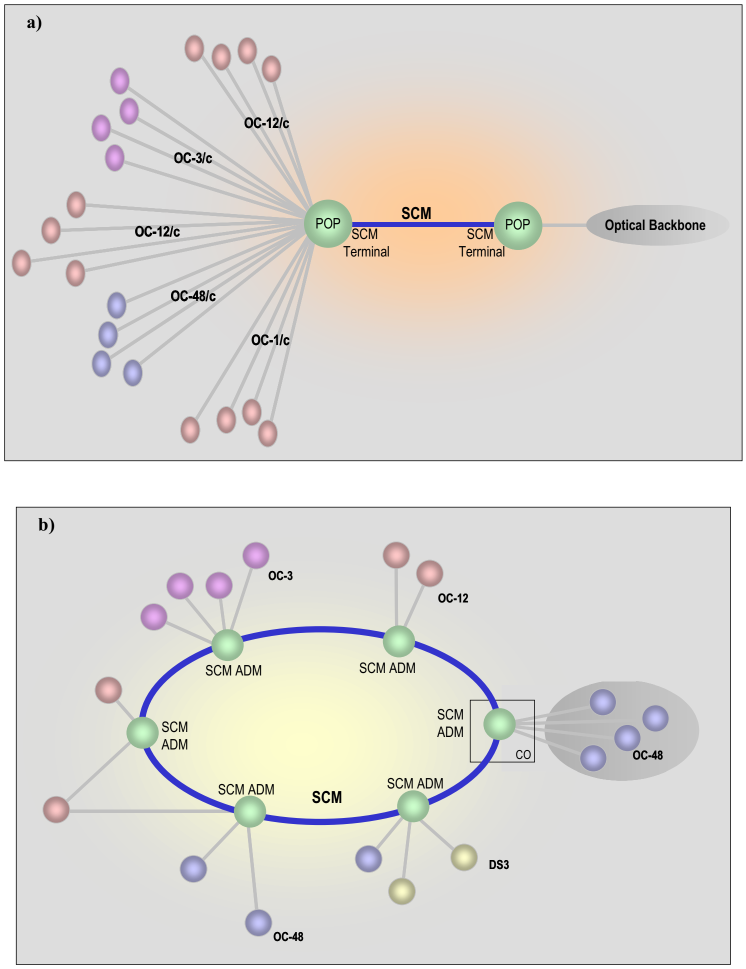

The RF processing performed in the SCM system provides the true transparency sought after by network operators. Each channel can independently carry different traffic operating at different rates (see *Figure 5*). Any traffic type can be carried transparently, and systems have been designed that carry SONET, ATM, and IP traffic seamlessly on the different subcarriers. This transparency provides the network operator with the ability to reconfigure the system easily and quickly as the service mix changes without swapping out a lot of equipment. The rise of Gigabit Ethernet as a service provided by carriers is pushing demand for flexible systems that enable transitions, and SCM eliminates the need for equipment to convert non–SONET signals into SONET signals.

Because SCM is effectively orthogonal to TDM and WDM, the technologies are inherently interoperable (see *Figure 6*). SCM adds another dimension to the space network operators can choose from to implement capacity. On the tributary side, SCM systems can, and indeed must, be designed to provide complete compatibility to SONET TDM signals. The use of standard lasers supporting the established ITU grid wavelengths enables SCM systems to be combined with WDM for very-high–capacity systems with superior flexibility, providing subwavelength granularity while supporting multiple services in their native format.

3. Performance Provides the Edge

With so many technologies being applied to optical networking, traditional notions of performance standards are being challenged and adapted. Network design is more challenging at higher rates, over more wavelengths, for longer distances. Any edge in simplifying network design through enhanced or more robust performance can make a real difference to designers—and to cost. SCM with digital signal processing for bandwidth-efficient modulation provides some significant performance benefits to optical networks.

Optical link budgets can be difficult to maintain through a network that, despite standards used for initial design, has a range of channel conditions across its spans; each change can mean having to take a new look at the link budgets. However, the optical power for an SCM signal remains constant, no matter how many subcarrier channels are in service. By modulating a common light source with the aggregate signal, the optical power is a function of the laser, not the number of channels in the signal. Any power not used

FIGURE 5

SCM Aggregates and Transports Full Mix of SONET, ATM, and IP Traffic Transparently

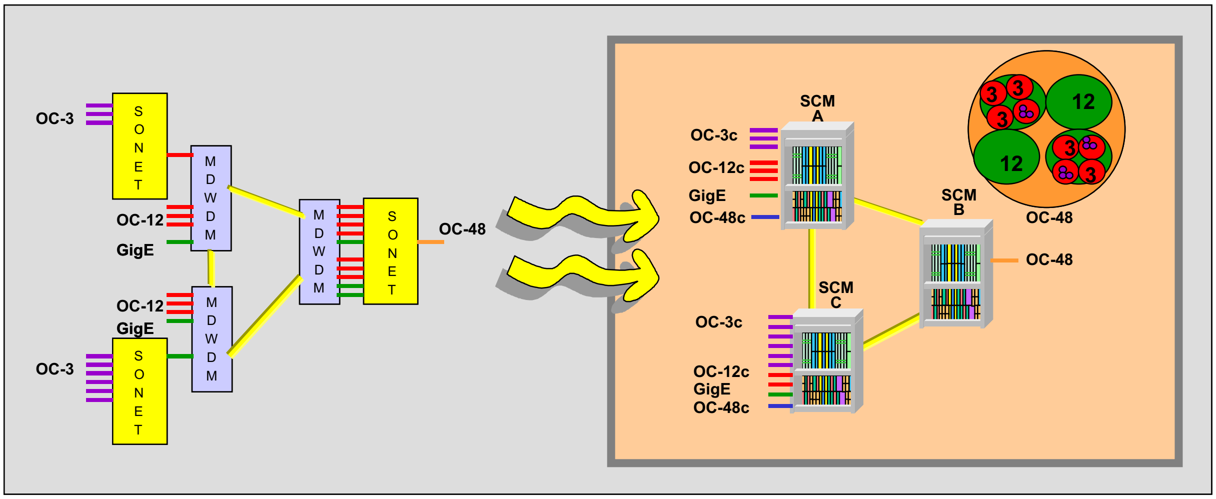

FIGURE 6

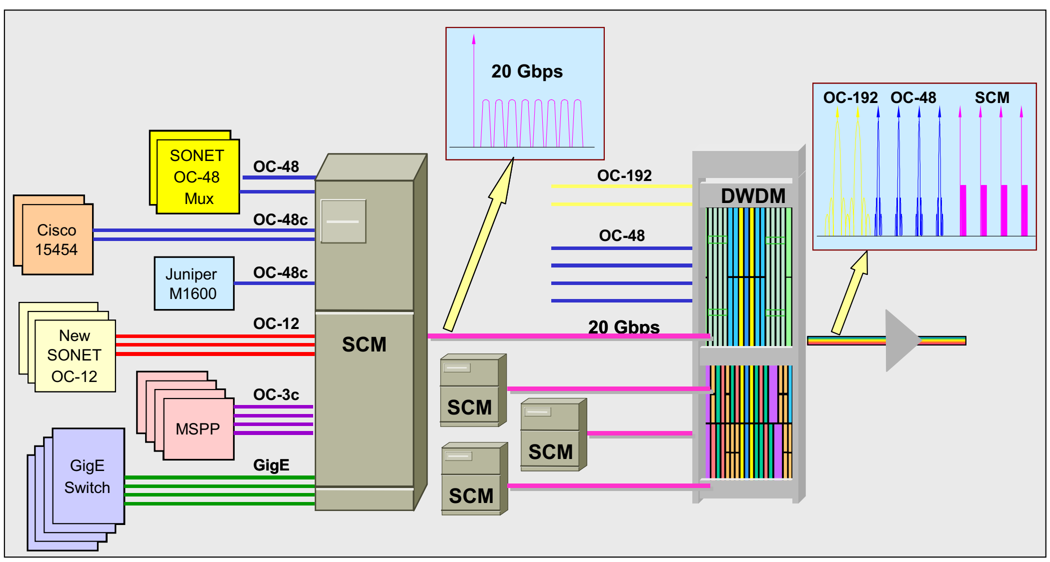
SCM Interoperates with TDM and WDM for Three Dimensions in Multiplexing



by a channel is returned to the unmodulated portion of the SCM waveform. This enables add/drop of subcarriers without re-engineering the link.

The SCM and BEM signal processing combination also provides a high level of robustness in system link performance over a wide range of channel conditions. Because of the pulse shaping and filtering of the subcarriers, SCM signals have very low adjacent channel interference (see *Figure 7a*). Unlike an OOK signal, the spectral sidelobes of an SCM signal are negligible—an ideal SCM signal will have no sidelobes at all, whereas nonlinearities in any practical SCM modulator will produce small sidelobes well below those of an OOK signal. This lack of out-of-band power results in very low adjacent channel interference in dense WDM (DWDM) systems.

The digital signal processing in the SCM modems provides additional robustness with linear equalization to improve signals received through varied channels and with forward error correction more powerful than that used in other optical systems. The relatively low subcarrier clock rate—a 20 Gbps SCM signal made up of synchronous transport signal (STS)–12 rate subcarriers, operating with parallel channels, each running at a clock rate on the order of 200 megahertz (MHz), rather than 20 GHz—allows the implementation of multi-tap, fractionally spaced linear equalizers at each receiver to combat linear distortion in the channel (see

Figure 7b). The improved signal quality results in lower BER in highly distorted channels.

Many optical systems are now employing linear block code based forward error correction, typically Reed Solomon block codes. However, with binary signaling, the full power of forward error correction cannot be tapped. SCM's use of higher-order modulation allows the traditional Reed Solomon forward error correction to be paired with trellis coded modulation (TCM), a form of forward error correction that takes advantage of the modulation format to maximize the coding gains (see *Figure 7c*). Together, these codes provide coding gains of 7 decibels (dB) or more.

A critical performance edge is found in the area of dispersion tolerance. Chromatic dispersion impairs performance of all high-rate OOK signals, and therefore must be compensated for every link and channel in many optical networks. The higher the bit rate, the wider the signal bandwidth, the lower the chromatic dispersion tolerance. Likewise, the longer the fiber span, the greater the chromatic dispersion. To avoid expensive or complex chromatic dispersion compensation, networks must be limited in either data rate or distance.

Single-sideband (SSB) SCM eliminates the need for chromatic dispersion compensation in all but the longest optical networks, even at very high aggregate bit rates. By eliminating the energy on one side of the optical carrier, the chromatic dispersion tolerance is limited only by the symbol rate of the individual subcarriers—not by the aggregate signal bandwidth. Thus, a 20 Gbps SCM signal, operating with OC–48 rate subcarriers, will exhibit chromatic dispersion tolerance far exceeding that of a 10 Gbps OC–192 system (see *Figure 8*).

PMD is another impairment that gets worse with increased bandwidth. Unfortunately, SSB does not help in this case. However, the inherent bandwidth efficiency of an SCM signal limits the impact of PMD. A 20 Gbps SCM signal exhibits greater PMD tolerance than an OC–192 signal. At 10 Gbps, the PMD tolerance of SCM approaches that of an OC–48 signal. In networks where PMD is the primary limitation, an SCM signal can be designed to maximize the PMD tolerance.

Extensive performance metrics provided by the digital signal processing together with a decentralized architecture provide SCM systems with a very high level of performance-monitoring and fault-isolation capabilities on traffic of all types. Use of TCM and Reed Solomon coding allows the monitoring of both channel BER performance (before decoding) and decoded BER performance (see *Figure 9*). The channel BER is much higher in the operating region providing BER degradation information to the operator as gradual or slight degradations occur, well before they accumulate to result in an outage. This provides a valuable maintenance corrective action tool to avoid costly downtime on service-level agreements (SLAs). SCM systems also provide superior fault isolation and correction as compared to other technologies. Together with proper fault correlation, it isolates problems down to the card level as well as corrects and increases the reliability of the various traffic protocols.

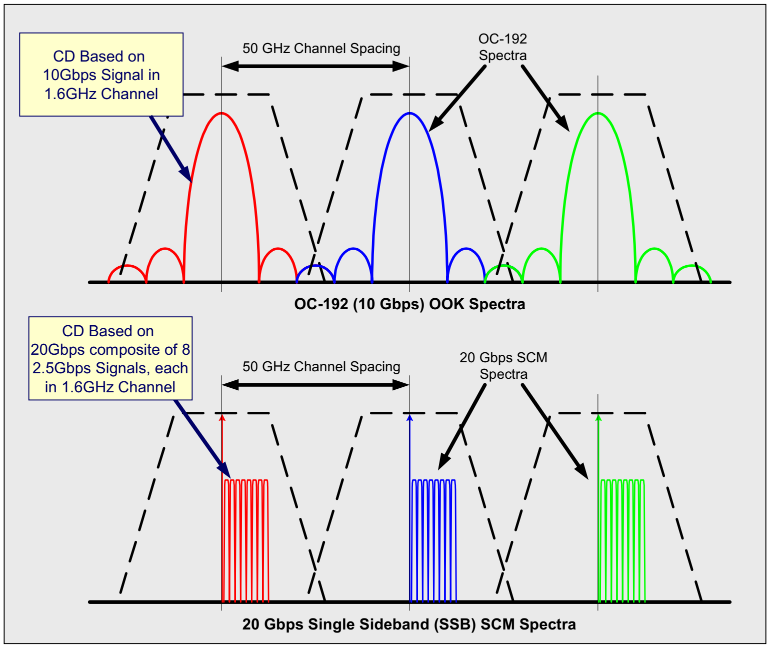
FIGURE 8

Narrower SCM Channel Bandwidths Dramatically Improve Chromatic Dispersion Tolerance



4. Conclusion

While SCM clearly provides the capability to increase optical network capacity and improve fiber bandwidth efficiency, it also provides many other potential benefits to the optical-network designer and operator. The underlying digital signal processing, RF processing, and optical modulation technologies combine to provide a wide range of advantages in the network. Flexibility in configuration and traffic mix combined with true transparency and carrier-class protection of all traffic reduces operations cost and improves provisioning. Highly robust optical links with constant optical power together with highly informative performance metrics and lower susceptibility to dispersions make SCM systems easier and less costly to design and maintain. SCM is clearly part of the future of optical networks—providing more than just capacity.

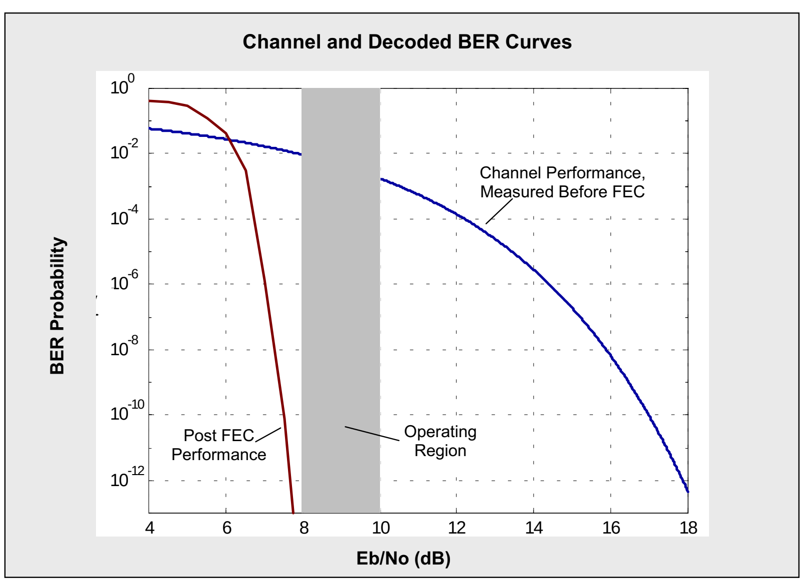
Channel BER Provides Early Detection of Channel Degradations



MPLS: Making the Most of Ethernet in the Metro

Tim Wu
Manager, Corporate Development
Riverstone Networks

Introduction

Two of the strongest trends in networking today are the migration of Ethernet from local area networks (LAN) to metro area networks (MAN) and the enhancement of Internet protocol (IP) networks with multiprotocol label switching (MPLS) technology. Most service providers are familiar with either or both of these developments. But they may not be aware of the potential stemming from the combination of the two, particularly for offering premium service-level agreements (SLA).

For service providers building out Ethernet-based networks, or thinking of doing so, the available return on investments is a central question. The kinds of SLAs that a service provider can offer are crucial to these returns. First, SLA capabilities define the scope of potential customers, as certain customers simply will not purchase services below certain standards. Second, the difference between profit and loss on individual deployments may depend on the ability to charge more for services, like transparent LANs, backed by premium guarantees of network performance. For Ethernet carriers, MPLS is the key to the connection-oriented capabilities that translate into premium service-level capabilities. MPLS will, in the long run, provide Ethernet service providers a chance to reach those customers once beyond their ken and improve overall profitability.

This study introduces MPLS and Ethernet technologies and demonstrates in concrete terms how the two can improve the economics of Ethernet-based services using the example of transparent LAN services (TLS) in a typical metro setting.

An Introduction to MPLS and Ethernet

Interestingly, MPLS and Ethernet technologies come from opposite ends of the network (see *Figure 1*). Ethernet comes, of course, from the LAN, while MPLS has its origins in the IP core. Metro networks mark their first and only point of direct interaction.

Ethernet is by far the most highly deployed network type on earth, with over 250 million devices already connected. With its domination of local-area networking secure, Ethernet has most recently taken a well-publicized leap into metro networking. Metropolitan service providers (MSP) take the same simplicity and huge bandwidth capabilities (10-gigabit products are now available; 100-gigabit products are expected within two years) and add long-distance capabilities (40-70 kilometers) and the high-performance, switch-routing equipment suited to carrier environments. The result is a potent combination of speed, scalability, and operational simplicity that has won many converts.

Leading the deployment of Ethernet metro networks are various forms of MSPs, including the Ethernet local exchange carriers (EtherLEC), building local exchange carriers (BLEC), and companies like Telseon, Intellispace, Yipes, and others. But established carriers are also looking to metro Ethernet, particularly as a data-focused supplement to existing synchronous optical network (SONET) and time division multiplexing (TDM) networks.

MPLS has its origins in the opposite end of networking—the network core—where its first deployments (by Global Crossing and UUNet) are found. MPLS has so far been deployed to address various backbone-network problems, such as integrating IP and asynchronous transfer mode (ATM) networks, reducing IP router overhead, and solving route-propagation problems. Yet, because MPLS generally adds connection-oriented, path-switching capabilities to IP networks, it is an extremely versatile technology. In the metro, its most obvious utility comes as an instrument for creating guaranteed and secure-service capabilities.

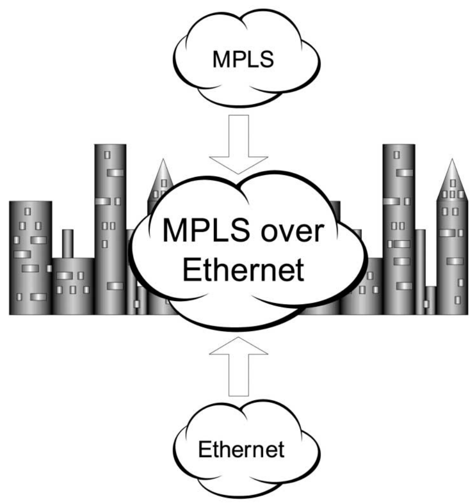
How the Two Work Together

In many ways, MPLS and Ethernet are an ideal match. Ethernet is well known for its simplicity and comfort level with IP data traffic. Ethernet is also known, however, to lack sophisticated quality of service (QoS) capabilities; this may be the key to its low cost but is also a major shortcoming.

MPLS improves on Ethernet not by changing what is good about Ethernet but by adding desired capabilities at a higher layer (what some call Layer 2). When MPLS and Ethernet are used together, Ethernet is called to focus on only what it does best—point-to-point transport. MPLS, meanwhile, adds the connection-oriented capabilities that are a tool for creating SLA-backed services.

FIGURE 1

MPLS and Ethernet Come from Opposite Ends of the Network



Creating SLA-Backed TLSs with MPLS over Ethernet

SLA Background

SLAs have come to attention with the increase of network outsourcing and the greater importance of inter-office networks. SLAs, from a customer's perspective, are crucial to optimal performance of the enterprise network and mission-critical applications. From the service-provider side, the ability to offer SLAs both sets the scope of possible customers and marks the critical point where network features actually translate into additional revenue.

The phrase "service-level agreement" refers to a contractual agreement between the service provider and customers, where the provider guarantees a certain level of service. Obviously, the guaranteed level of service can differ from customer to customer, as does the amount charged for such service levels, creating a differential pricing strategy for service providers. Traditionally, typical subjects of agreement are:

- Network availability (minimum guaranteed)
- Path/permanent virtual circuit availability
- Average round-trip network delay
- Effective throughput (network performance, burst allowance)
- Service-restoration time
- Billing methods (per usage or flat rate)

Over the last few years, SLAs have come to include more of a focus on application performance and other end-user metrics, such as the following:

- Application availability
- Application response time
- Performance in certain time windows

Many customers simply will not buy services that do not come with certain levels in a SLA. If a transparent LAN or externally hosted application is mission critical, one can expect a service offering without a certain level of SLA to be a non-starter. SLA capabilities are, therefore, a direct determinant of a service provider's potential customer base; hence the importance of premium SLA capabilities.

The Limitations of Using Ethernet to Create Transparent LAN Services

Ethernet is used in native form to offer TLS backed by an SLA, but the result is less than ideal. Most of the problems arise because Ethernet is a Layer-2 technology, ideally suited to handle point-to-point connections or LAN broadcast. Although carriers can currently offer SLAs over Ethernet networks, these SLAs have significant shortcomings, including lack of bandwidth reservation, slow recovery from network failure, and scalability limits. To illustrate, we'll use the example of TLS using 802.1Q-based virtual local area networks (VLAN) (see *Figure 2*).

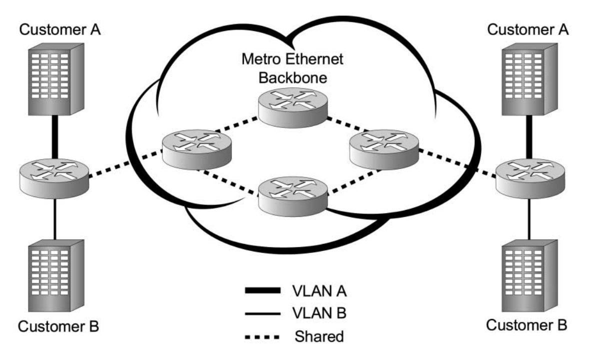
First, it is difficult for the service provider to offer a guarantee of network throughput using native Ethernet. As pictured here, the service provider has configured two VLANs for customers A and B that extend across the metro network. However, the bandwidth on the trunk (and the metro network) is shared, and it is typically oversubscribed (2:1 oversubscription is pictured here).

Nothing in native Ethernet or 802.1Q prevents customer A from acting as a bandwidth hog and ruining any potential bandwidth SLA with customer B. A service provider could implement link-level controls on customer A, or use 802.1p to create a higher priority for customer B's traffic. But neither of these approaches creates the end-to-end bandwidth reservation necessary to guarantee high levels of network throughput.

Second, native Ethernet provides less than ideal resiliency features. The gold standard in this area is SONET, with its guarantee of >50-millisecond (ms) recovery time from fiber cuts. This feature accounts for the ability of service providers to achieve five-9s reliability and sell SONET-based services at a premium.

FIGURE 2

802.1Q -Based TLS—Lack of Bandwidth Reservation Makes it Hard to Offer Network-Performance SLAs



Ethernet relies on spanning trees to provide network resiliency. Unfortunately, spanning trees are not a good solution for MANs. They can take over 30 seconds to recover from an outage (either fiber cut or switch failure). Rapid spanning-tree technology is an improvement, but it still taps out at about a full second for reconfiguration.

Finally, the VLAN approach does not scale. From a service provider's perspective, 802.1Q's limit of 4,096 VLANs per network is very significant. It creates a serious upper limit on the metro TLS business model.

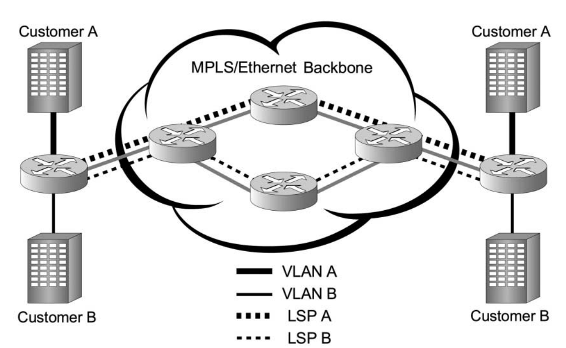
Finally, the Ethernet model comes within profound geographic limitations. The TLS service will be limited to the single network in question. A service provider, ideally, would like to offer SLAs not only within a single Ethernet network, but across WANs as well. This allows a service provider to generate revenue from customers connecting offices across the country.

Using MPLS over Ethernet to Offer SLA-Backed TLS

Using MPLS, a service provider has a powerful tool for offering premium SLAs in the metro. When MPLS capabilities are added to the TLS model, service providers can sell premium levels of service, such as bandwidth guarantees, fast recovery times, customized backup resources, or nation- or worldwide TLS (see *Figure 3*).

FIGURE 3

SLA-Backed TLS Using MPLS



In the MPLS-based TLS implementation, each customer's VLAN is mapped onto an MPLS label switched path (LSP) that extends across the metro network. Each LSP enjoys reserved bandwidth across the MPLS cloud, as well as other QoS indicia (like jitter or latency limits). The LSPs created are circuits established by the IP signaling plane that can extend across an adjacent ATM network or an MPLS WAN without much fuss. This MPLS implementation allows the service provider to provide service levels critical to offering premium SLAs.

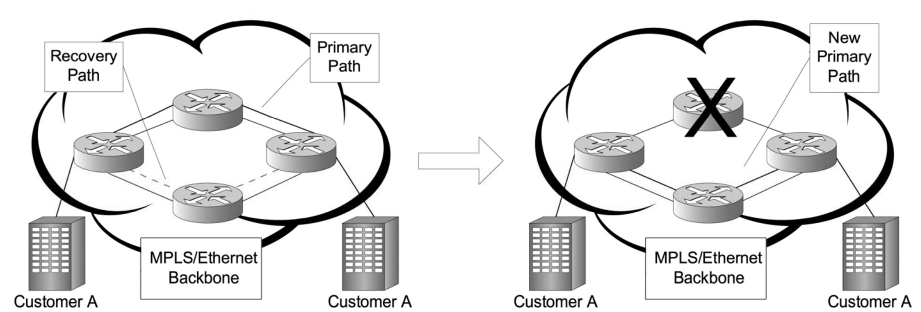
First, as just discussed, the service provider can now offer sophisticated, end-to-end network performance guarantees. The service provider can also offer a guaranteed amount of fixed bandwidth, as well as burst bandwidth contingent on availability. Note that this capability allows the service provider to oversubscribe with confidence, maximizing capital returns without jeopardizing the ability to offer bandwidth guarantees.

Second, service providers can use MPLS to offer both the speed of SONET recovery and the exact level of backup resources the customer is willing to pay for. The MPLS method for service resiliency generally depends on the establishment of an alternative, or recovery, path to complement the primary path. If the primary path is knocked out by a fiber cut or router failure, the alternative path takes over. The MPLS solution gives the service provider the ability to provision as few or as many resources for the recovery path as the customer desires. That way, providers can charge a premium rate to customers willing to pay for a backup path with as much bandwidth as the usual path. At the same time, providers can offer less expensive resiliency options for traffic that is important but not mission critical (see *Figure 4*).

Third, MPLS allows service providers to sell SLAs across a much broader range of networks. For example, in conjunction with an ATM or MPLS WAN, a service provider can offer cross-country or even international TLSs. Moreover, providers can accomplish cross-country and international services with the minimum of resource mapping. Ideally,

FIGURE 4

MPLS Service Recovery



the service provider can provide a single, reserved path for coast-to-coast service (see *Figure 5*).

Finally, for providing TLSs, MPLS does not suffer the 4,096 limitation of 802.1Q. That means a service provider can sell SLAs without worrying about running out of VLAN space.

The Path to Long-Term Profitability

Let's see how the MPLS solutions discussed here can create a long-term profit model for service providers. The important fact is that the additional services need make only modest incremental increases in revenue to drive a large increase in profits. Consider a moderately successful mid-sized service provider earning an 8 percent operating margin on revenues of $250 million with a subscriber churn of 20 percent per year (see *Figure 6*).

Adding the MPLS services described can quickly lead to substantial gains. The provider can offer premium-level TLS and other services, along with nation- and worldwide connectivity, producing 3 percent growth in new subscribers. Targeting high-churn customer segments with customized, MPLS-based services may reduce churn by 3 percent. Finally, migrating existing customers to premium SLA packages can reasonably be expected to produce a 2 percent improvement in average revenue per subscriber. Collectively, these modest improvements will deliver an 8 percent boost in revenues. If we conservatively assume that the incremental service revenues carry a 50 percent operating margin, then the overall impact of this program will be a 50 percent improvement in operating profits.

Obviously, this is a simple model, and local conditions and operating costs will affect its viability. But it shows how a

FIGURE 5

SLAs Across the WAN

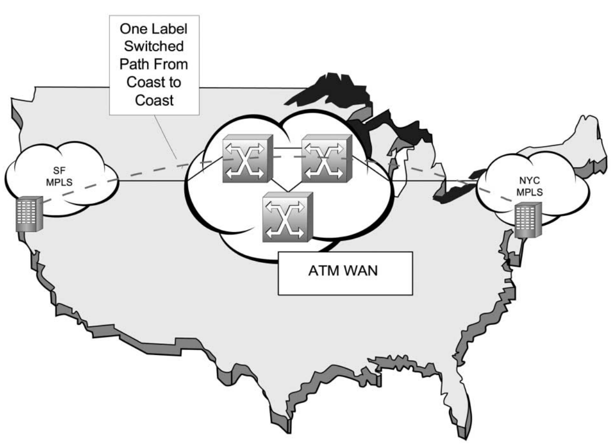


FIGURE 6

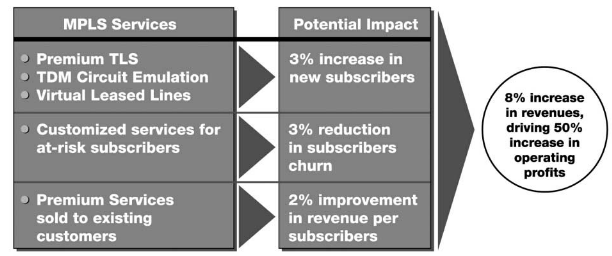
MPLS Services Driving Operating Profits



service provider can make more money on Ethernet networks than we might expect from a simple bandwidth-provisioning model.

Extensive experience with metro service providers shows that the following features loom large:

Interface Versatility
Ethernet isn't everywhere, yet, and for most metro areas, TDM connectivity remains critical to reaching a full range of customers. Packet over SONET (POS) remains important for uplink and SONET connectivity, and ATM can be useful in certain situations. The best routers support all.

Metro-optimized MPLS
As MPLS is deployed in metro areas, it is important to have MPLS implementations optimized for the features needed for MANs (essentially, an emphasis on service creation over traffic engineering).

Small-Form Factors
The simple economics of leasing and operational costs dictate routing equipment, at both the access ("basement router") and aggregation level, in a small-form factor.

Advanced Billing and Accounting Features
Eking the last penny of profit from metro networks turns out to be the key element of the profit story.

"Carrier-Class" Redundancy and Resiliency Features
Premium SLAs depend not only on the underlying capabilities of the network, but also on the resiliency of the equipment used. Look for routers with full switch-fabric and processor redundancy.

Conclusion

The "Ethernet revolution" is well underway. But it will take MPLS and similar technologies to add to the enthusiasm of a stronger profit model for service providers.

Cost-Effective Single-Fiber Broadband PON System

George BuAbbud

Vice President and Chief Scientist, Access Systems
Marconi Communications

Abstract

Recent advances in high-performance fiber-optic technologies combined with innovative optimization in the electronics have led to the evolution of a cost-effective single-fiber broadband passive optical network (PON).

This paper introduces a full-service PON system that delivers telephony, video, and high-speed data over a single fiber. A cost-effective method for the transport is presented. Simulations, analysis, and results are discussed.

Overview of PON Systems

PONs are widely used in access networks. The three major applications for PONs are fiber-to-the-cabinet (FTTCab), fiber-to-the-business (FTTB), and fiber-to-the-home (FTTH). An example of using PON in FTTH is shown in *Figure 1*. Since there are no active components between the central office (CO) and the end user, network-maintenance costs and requirements are dramatically reduced.

Because of the optical splitter, the cost for every channel at the CO will be shared by N homes. Current systems have splitting ratios between four and 32. Services delivered to the house are voice, video, and data. Video includes both cable television (CATV) and direct broadcast satellite (DBS) signals.

If a single-fiber solution is considered, voice and data operate bidirectionally on the 1310 nm wavelength, and video operates on the 1550 nm wavelength. The DBS and CATV signals could be transmitted in separate wavelengths in the erbium-doped fiber amplifier (EDFA) window. The asynchronous transfer mode (ATM) traffic carrying voice and data downstream is continuous transmission in the form of binary digital time division multiplexed (TDM) signals, while the upstream traffic is in time division multiple access (TDMA) bursts. Data rate varies between systems, but for a typical FTTH deployment, the rate is 5 megabits per second (Mbps) per home.

Overcoming Reflection and NEXT

PON systems are attractive to deploy in access networks because they are cost-effective. However, the optical signal has to accommodate high attenuation resulting from the splitting loss and the relatively long span. The splitting ratio and the distance between the optical line termination (OLT) and the optical network termination (ONT) are dictated by the sensitivity of the receiver. Reflection from the network or near-end crosstalk (NEXT) from the used devices could severely reduce the sensitivity of the receiver.

This problem is currently addressed by using a second fiber or a different wavelength to get good isolation between the transmitted and the received signals. A more cost-effective method is to shift the spectrum to higher frequency to get enough isolation to overcome the worst expected reflection, as seen in *Figure 2*, where we modulated the 25 Mbps signal on a 100 Mbps Manchester coded carrier.

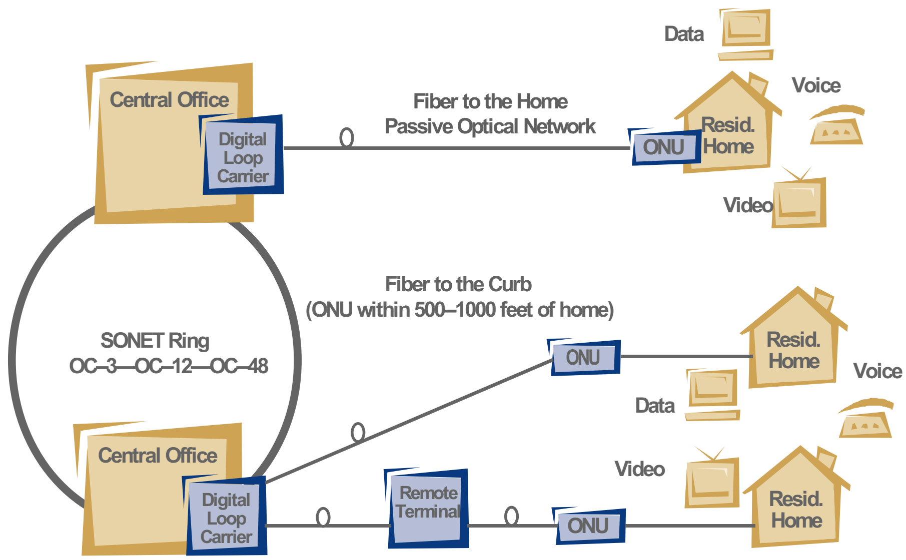
We thus achieve an isolation between the two signals of 24.5 decibels (dB). However, instead of using 100 Mbps Manchester, we can use different line code with more concentrated spectrum to get better isolation. The line code also needs to induce transitions to be able to recover the clock and data quickly and with a minimum number of preamble data.

Simulations and Results

Figures 3 and *4* show the simulation results for the spectrum of the received signals at either end, along with the reflected signal from the transmitter of each end. The worst case of –14 dB of near-end reflection was considered in this simulation. The bottom chart shows that a minimum of 35 dB of isolation was obtained by shifting the spectrum of the

FIGURE 1

PON Architecture for FTTH



upstream signal. Although the signal on either direction could be shifted, it is better to shift the signal in the upstream direction. The additional cost in the receiver to recover the higher-frequency signal is shared by N homes, where N is the splitting ratio.

A PON system with splitting ratio of eight was built, simulated, and tested. A maximum attenuation of 17 dB was introduced in the signal path. At the same time, a reflection of –14 dB from the transmitter was inserted at each receiver. At both ends, simulations show that data could be recovered accurately at both receivers.

Figure 5 shows the eye pattern for the 25 Mbps and 100 Mbps signals when there is no reflection. *Figure 6* shows the eye pattern for the 25 Mbps and 100 Mbps signals in the presence of attenuation and reflection.

RF Video Transport

A FTTH solution based on wavelength division multiplexing (WDM) allows a variety of services to be combined on a single fiber. This flexible architecture enables the cost-effective transport of video services such as broadcast CATV, DBS, as well as two-way video-based services to the end user.

The video transport originates in the system from a satellite feed or CATV head end as a radio frequency (RF) signal. These broadcast video services are optically transported to the end user by subcarrier modulation (SCM) of two 1550 nm band lasers: DBS at 950 – 2050 megahertz (MHz) and CATV at 50 – 870 MHz. The relative power ratio and respective optical depths of the modulation of the two optical carriers are optimized to deliver a CNR > 48 dB and 25 dB for the CATV and DBS signals, respectively. The SCM modulated video signals

FIGURE 2

The power spectrum density for a NRZ signal is:

$$\mathrm{NRZ}(f) := \left(\frac{\sin(\pi \cdot f \cdot T)}{\pi \cdot f \cdot T}\right)^2$$

For a 25M signal, very good isolation can be acheived if the signal in the opposite direction is shifted to 100M. The PSD for a 100M Manchester signal is:

$$\mathrm{MCH100}(f) := \left[\frac{\sin\left(\pi \cdot f \cdot \frac{T}{8}\right)^4}{\left(\pi \cdot f \cdot \frac{T}{8}\right)^2 \cdot 4}\right]$$

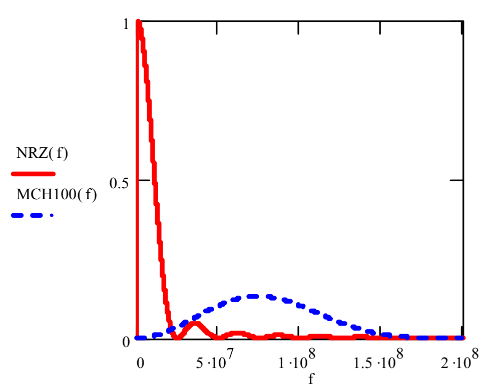


FIGURE 3

Isolation between 25 Mbps RX and 100 Mbps Reflection

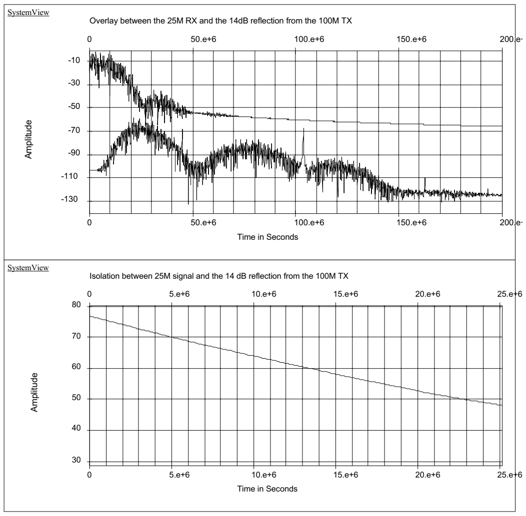

FIGURE 4

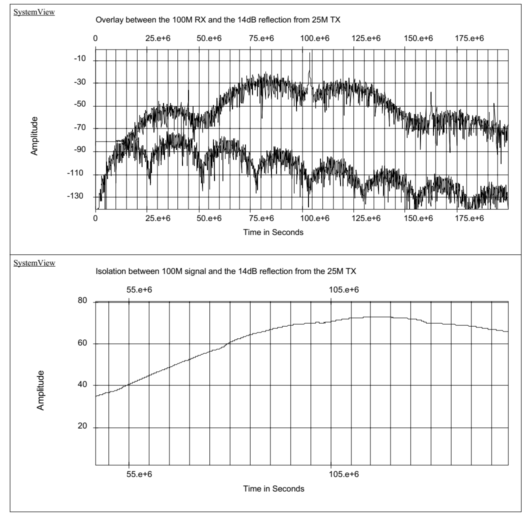
Isolation between 100 Mbps RX and 25 Mbps Reflection



are distributed using low noise figure EDFAs. These EDFAs are optimized to provide high optical power over temperature extremes, while maintaining high carrier-to-noise ratios. The amplified video signals are broadcast and optically combined, as seen in *Figure 7(a)*, with a 1310 nm baseband signal for single-fiber transport using a splitter WDM cross-connect (SWX).

At the ONT, as seen in *Figures 7(b)* and *7(c)*, the video signals are separated from the baseband signal by optical filtering. Both 1550 nm window wavelengths are carried together to the video receiver photodiode and demultiplexed in the RF domain. The 1550mnm receiver sensitivity is maximized with a simple novel circuit configuration. In the home, there are standard interface-to-75 ohm coax ports from the RF video receiver.

Optical Components

The baseband digital signals are bidirectionally transported on a single fiber by using low-cost optical duplexers. In the OLT, a two-port duplexer houses a thermally stable 1310 nm laser diode (LD) and a PIN photodiode (PD) receiver. A beam splitter is used to direct the incoming 1310 nm signal to the receiver PD, while allowing the outbound 1310 nm signal to be launched on the fiber.

After the SWX, as seen in *Figure 7(a)*, the broadcast video signal is combined with the bidirectional baseband signal and is transported to the end user via a passive optical splitter (POS). Split ratios range from two to 32 homes and are typically placed within 30 kft of the CO without using any active devices in the network. The POS is designed to operate effectively in an outside plant environment, requiring a wide thermal range of –40˚C to +85˚C. Low-cost optical coupler technologies, such as fused biconic fiber couplers, and planar waveguides are adequate for this application.

At the home, the incoming signals are separated in the ONT by a three-port optical device, or triplexer. The triplexer separates the video wavelengths from the 1310 nm baseband signal by WDM optical filtering. The filtering technology allows better than 40 dB of isolation between the video and baseband

FIGURE 5

Eye Pattern for the Recovered 25 Mbps and 100 Mbps Signals

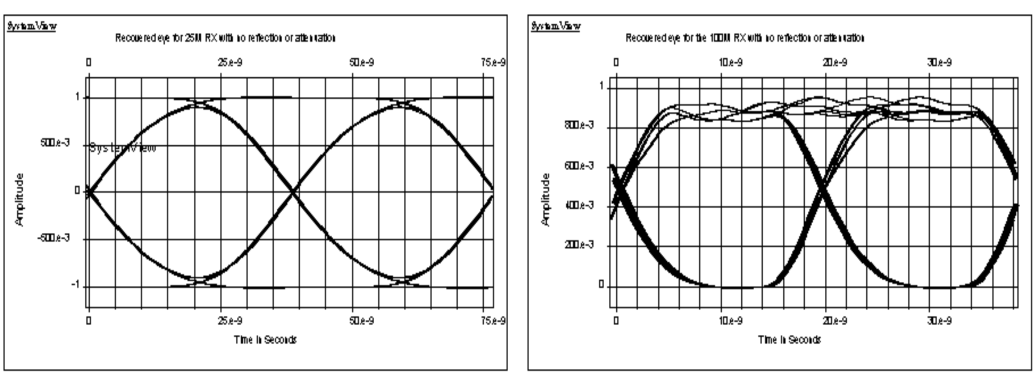


FIGURE 6

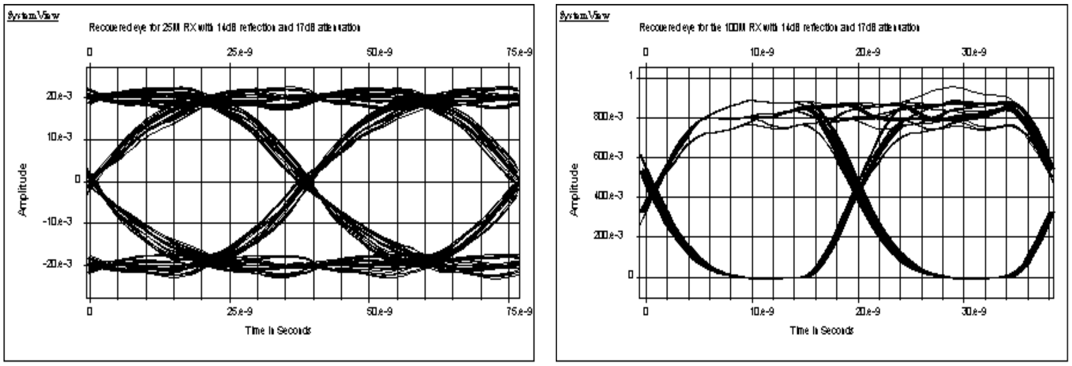
Eye Pattern for the Recovered 25 Mbps and 100 Mbps Signals in the Presence of –14 dB of Reflection and –17 dB of Attenuation



signals. The separated inbound optical signals are converted to electrical signals with a 1310 nm PD receiver and a 1550n m band PD receiver. The upstream baseband signal is launched on the fiber with a 1310 nm LD. The triplexer devices are thermally designed to operate in a residential garage or outside environment. The ONT converts the incoming signals into services required by the end user, including standard interfaces for telephony, high-speed data, and video services.

Conclusion

A cost-effective single-fiber PON system was presented. A new way of isolating upstream and downstream signals in PON systems was introduced and found to enable digital transmission on the same wavelength without limiting the sensitivity of the receivers. Spectrum shifting is more cost-effective than using a third wavelength or using a second fiber. A minimum of 35 dB of isolation was achieved. Good eye pattern for the recovered data at both receivers was obtained in the presence of worst-case reflection and worst-case attenuation. At the same time, we were able to transmit both DBS and CATV in the 1550 nm window without doing any WDM filtering at the receiver. These methods of transporting data and video enable us to provide a full-service cost-effective single-fiber PON system for FTTH application.

Trends

Voice over Internet protocol (VoIP) is a subset of next-generation network (NGN) topology, in which voice, video, and data "converge" into a single Internet protocol (IP)–based infrastructure, operating over both wired and wireless physical media. NGNs are associated with the transformation of current network architecture toward a multiservice and ubiquitous infrastructure, with unified control and management systems. Key applications include desktop voice and videoconferencing, audio and video streaming, and unified messaging—all of which are seen as potential sources of revenue for carriers and service providers. *Figure 1* depicts the exponential growth of data traffic, which is the driver behind the need for a data-oriented core networks.

There are two main reasons for this trend: 1) to eliminate the higher cost of operating and maintaining two separate networks and 2) to support new multimedia applications, which typically allow users to talk and exchange data and images in one single session. The technology has evolved into carrier-class gateways that function as the interface between IP–based networks and the public switched telephone network (PSTN), complete with signaling system 7 (SS7) support. Two key factors have contributed to the growth of VoIP. The first is the explosive growth of the Internet and other IP–based networks; the second is the trend to merge voice networks with data networks, resulting in lower operational costs.

Traditional voice links the signaling device directly to the Class-5 switch in the central office (CO), which presents it with a dial tone, collects the dialed digits, and interprets the user's request for service as a local call, long-distance call, special feature request, and so on. Under NGN architecture, the user's service request does not go directly to the Class-5 switch, but rather to the service agent, which is described as a "softswitch." The softswitch first determines the nature of the request, and then either routes it to a packet-switching network or to the conventional voice network managed by the long-established SS7. Thus, new and exciting voice features can be created without disrupting the equipment, practices, or stability of the current voice network.

The move toward the new architecture is being driven by the following:

- *Advanced solutions* enabling new ways to organize the way we work
- *Technical advances* that make it possible to implement converged solutions
- *Cost reduction* in installation, operation, maintenance, and use of the network services
- *Deregulation* allowing carriers to exploit the new developments and to offer competitive services
- *Industry standards* for open systems and integrated solutions

The stimulus for network change has traditionally been primarily cost savings. With the advent of the Internet and online access to millions of potential customers, however, supporting network-based applications that permit new ways of organizing and running the business has become the goal.

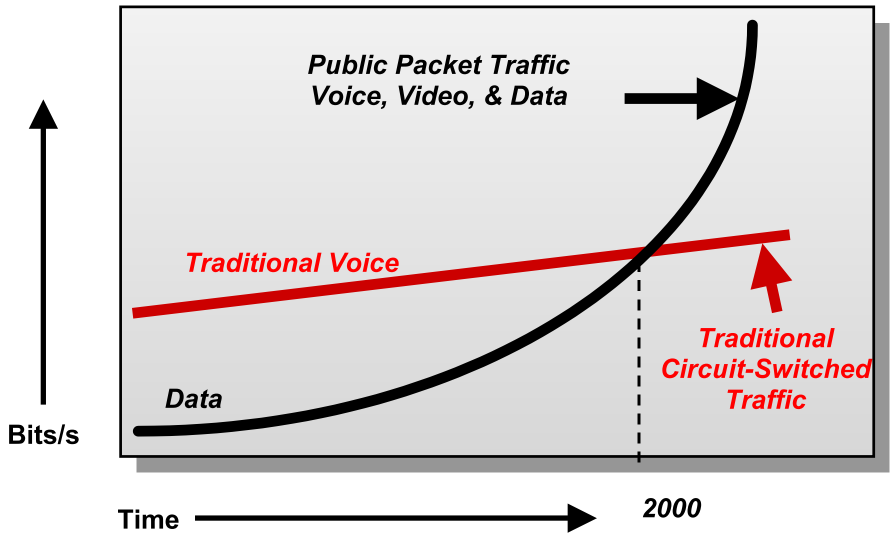
Applications

VoIP applications include the following:

- *Toll Bypass*: Routing long-distance calls through IP–based networks can reduce the cost significantly, especially for international calls.
- *Call-Center Integration*: Call centers usually use one voice link to talk to customers and one data link to retrieve information from databases. Using VoIP, these two links can be combined into a single cost-saving link. Furthermore, customers can go to the Web to find information and make calls to the call center from the Web page (click-to-talk).
- *Unified Messaging*: This application allows users to receive/retrieve various forms of messaging (voice, e-mail, fax, etc.) from a single access point.
- *IP Videoconferencing*: This application can help businesses reduce the costs of conferencing.
- *Corporate Intranets*: Many companies today have two separate networks: one for voice and one for data. These two networks can be integrated into one using IP telephony, reducing infrastructure and administration costs.

FIGURE 1

The Exponential Growth in Data Traffic Worldwide



The Evolving Standards

Data transmission and voice transmission over packet-based networks have a major difference in requirements: Data is inherently loss-sensitive and delay-tolerant, while voice is loss-tolerant and delay-sensitive. For this reason, the transport layer in the VoIP protocol stack uses the user datagram protocol (UDP) to carry voice instead of the transmission control protocol (TCP). TCP is used to carry signaling messages such as call set-up and teardown. In addition, because most VoIP applications are real-time, the real-time transport protocol (RTP) is run on top of UDP to provide end-to-end delivery services for data with real-time characteristics. These services include payload-type identification, sequence numbering, time stamping, and delivery monitoring.

One of the common VoIP standards is the International Telecommunication Union–Telecommunication Standardization Sector (ITU–T) H.323, which was designed for multimedia communications systems and is considered bulky for simpler voice applications. As a result, the session initiation protocol (SIP) was developed by the Internet Engineering Task Force (IETF) as an alternative protocol offering less complexity and more flexibility. Both H.323 and SIP are peer-to-peer protocols. These protocols have been developed with the notion of "smart terminals–dumb network," meaning the software on personal computers (PCs) and workstations handle most of the protocol features in conjunction with very few network gateways.

However, a different philosophy puts the burden on "smart networks–dumb terminals," meaning the network is responsible for handling all new VoIP features using a new class of devices. These devices are controlled by protocols such as media gateway control protocol (MGCP) and media gateway control (MEGACO)/H.248. MGCP assumes a call-control architecture, where the call-control intelligence is outside the gateways and handled by external call-control elements, and hence is a master/slave protocol. The MGCP is a combination of two earlier protocols: the simple gateway control protocol (SGCP) and the Internet protocol device control (IPDC).

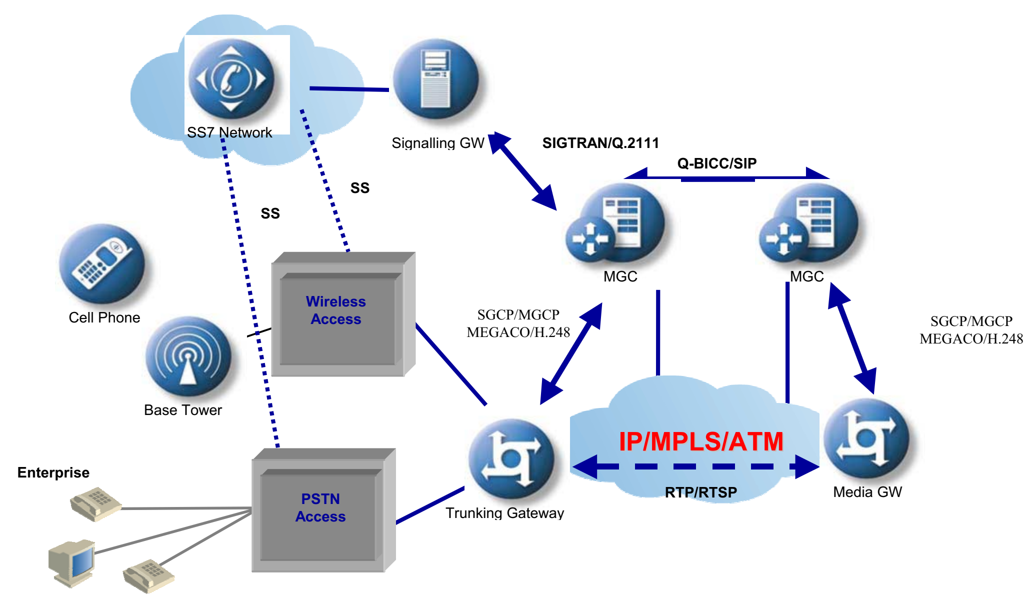
Figure 2 illustrates the generic VoIP network diagram. MEGACO/H.248 is an industry-standard protocol for interfacing between external call agents called media gateway controllers (MGCs) and media gateways (MGs). The standard is the result of a collaborative effort between the IETF and ITU standards organizations and is expected to gain wide industry acceptance as the official standard for decomposed gateway architectures sanctioned by both organizations. It was derived from the MGCP. The MEGACO/H.248 is used in Internet telephony and broadband access products, including trunking gateways, voice over asynchronous transfer mode (VoATM) gateways, IP telephony and residential gateways (such as set-top boxes and any type of digital subscriber line [xDSL] devices), and other cable–IP telephony equipment.

MEGACO/H.248 allows the separation of control-plane signaling and voice packet media transmission in the IP network, similar to the way it has been done in the PSTN and SS7 network, where the call establishment and termination are done via SS7, while the actual voice conversation is carried over the PSTN.

The next-generation decomposed architecture for IP convergence enables a network hierarchy in which a single MGC controls a cluster of MGs. This distributed architectural model presents a highly scaleable solution coupled with reliability and effective bandwidth utilization. The MG terminates voice flow to perform packet to circuit transcoding. The signaling gateway (SG) executes signaling technology adaptation. The MGC performs signaling interworking, call handling, and MGC functions.

FIGURE 2

Next-Generation Network Conceptual Architecture



Technical Challenges

The existence of several standards creates the problem of interoperability. Gateways from different vendors may not be able to communicate with each other, not only because they support different standards, but also because many vendors have proprietary solutions that may yield better performance than standardized techniques. In addition, even gateways supporting H.323, for instance, may not work with each other since H.323 itself allows for flexibility in implementation.

Another important issue in VoIP is quality of service (QoS). The best-effort service available in IP networks today is not sufficient to provide VoIP service comparable to the traditional PSTN service in regards to reliability and voice quality. Hence, certain service-level guarantees are needed. So far, IETF standards such as resource reservation protocol (RSVP) and differentiated services (DiffServ) are promising in IP QoS support, and a number of VoIP gateway vendors have implemented them in their products. However, a significant amount of work still remains to be done in this area.

When implementing VoIP solutions, there are several technical challenges that we need to consider:

The Delay Factor
Excessive end-to-end delay makes conversation inconvenient and unnatural. Each component in the transmission path—sender, network, and receiver—adds delay. ITU-TG.114 (one-way transmission time) recommends 150 ms as the maximum desired one-way latency to achieve high-quality voice.

The Jitter Factor
Quantifies the effects of network delays on packet arrivals at the receiver. Packets transmitted at equal intervals from the left gateway arrive at the right gateway at irregular intervals. Excessive jitter makes speech choppy and difficult to understand. Jitter is calculated based on the inter-arrival time of successive packets. Jitter buffers (packet buffers that hold incoming packets for a specified amount of time) are used to reduce the effects of network fluctuations and create a smooth packet flow at the receiving end.

The Packet-Loss Factor
Typically occurs either in bursts or periodically due to a consistently congested network. Periodic loss in excess of 5 percent to 10 percent of all voice packets transmitted can degrade voice quality significantly. Occasional bursts of packet loss can also make conversation difficult.

The Sequence-Errors Factor
Congestion in packet-switched networks can cause packets to take different routes to reach the same destination. Packets may arrive out of order, resulting in garbled speech. Evaluating voice quality is a major priority for companies developing voice communication systems or products. To enable accurate, consistent rating of voice quality, the mean opinion score (MOS) was developed. The MOS uses the absolute category rating (ACR) procedure to determine the general acceptability or quality of voice communications systems or products. Under ACR procedures, evaluators are required to rate the overall quality of speech samples in support of telephone communications. Listeners use a five-category rating scale (i.e., excellent, good, fair, poor, and bad) with points assigned for each level, as follows:

5 – EXCELLENT
4 – GOOD
3 – FAIR
2 – POOR
1 – BAD

Following the evaluation, a numerical MOS score for overall speech quality is calculated.

Another method for analyzing the voice quality is the perceptual speech quality measure (PSQM). It is a means for objectively assessing the quality of speech that has been degraded by a telephony network. It has a high correlation to subjective quality across a range of types of distortion and is appropriate for testing networks that are subject to different coding types and transmission errors.

Defined by ITU–T recommendation P.861, PSQM is used primarily to test networks that have speech compression, digital speech interpolation, and packetization. Networks that carry VoIP, voice over frame relay (VoFR), and VoATM have these characteristics. However, the use of PSQM is not limited to these applications and can be used effectively to test wireless systems and cable-modem systems that carry speech.

Industry-Wide Focus on Areas of Growth and Contraction

VoIP presents service providers with new difficulties as relates to telephony, transmission testing, and POTS. Even in today's Internet environments, voice telephony continues to be a component that isn't going away. As these networks migrate to IP, the integration of voice services will become even very important.

To minimize the risk of deploying and/or integrating NGN devices in new or existing networks, carriers work with vendors on extensive pre-deployment testing. The advanced communications labs, which large carriers have, conduct conformance, performance, interoperability, and emulation of various scenarios. In conformance testing, a wide range of test procedures, which assess the adherence to industry standards, is conducted. Performance testing is aimed at stressing/loading a new device or a specific network configuration to assess its behavior under extreme loads. Interoperability testing is run on specific devices from the same manufacturer (or from several manufacturers) to ensure that once they are deployed and connected on the same network, they would work flawlessly. Similarly, emulation devices are connected to the new equipment, emulating specific protocols and/or standards, to assess the communications behavior of the new device prior and post deployment.

Using these procedures, carriers are gradually implementing NGN devices into their existing architecture. The extensive testing is used to ensure the QoS is maintained according to service-level agreements (SLAs) with their customers. The new technology has been implemented by carriers worldwide. According to RHK, Inc., many contracts to purchase and implement VoIP equipment have been signed in the last year. For example, Alcatel reported signing contracts for SGs with 26 customers, which include carriers from Germany, France, China, and South America. Ericsson has also reported NGN contracts with Germany, Chile, Spain, and South America. Nortel Networks, another international player, is reporting deals in Germany, Australia (Telstra), and other countries.

In *Figure 3*, we can see a forecast from RHK pointing to growing sales of NGN technology in the upcoming years. This forecast focuses on the North American market and covers a wide range of devices that comprise the NGN architecture.

Conclusions

Carriers are realizing that using packet-networks to carry all traffic types leads to lower operational costs. New revenues can also be generated due to the much higher flexibility in introducing new services to end users. These factors, coupled with the exponential growth in Internet traffic from new users and new applications, are strong indicators that the current trend toward NGNs will continue into the foreseeable future.

The Virtual Internet Data Center

Application Service Providers Evolve their Networks with Renewed Emphasis on Multiple Layers of Security

David J. Cavuto
Lead Engineer, VPN Firewall Team
Lucent Technologies

A Look Back

I remember the first time I called a Web hosting company. The representative didn't miss a beat—she had an answer for everything.

"Absolutely, sir. We take care of everything for you. We can make any changes you need. You just put your site up, and we make sure it stays up."

Then a thought hit me: How do I "put my site up"?

So I asked her. "Just how exactly do I put my site up?"

Seemed like a fair enough question. And she had an answer.

"Well, sir, you just create your files and transfer them to our servers using FTP."

I have to admit that I was a bit surprised. This company wanted me to transfer my files *across the Internet* to this Web server using file transfer protocol (FTP).

I tried to point out my concerns about using FTP to transfer files to my Web server. "But FTP sends passwords in the clear!"

This seemed to stump her.

"How do I connect to my database server, to create tables and upload data?"

"You can just use Microsoft Access to connect to the database."

What?! She was telling me that I could directly—over the public Internet—access my database server!

Things went downhill from there.

The story does have a happy ending, though. I was able to convince the site administrators to add some router access control lists (ACLs) to block would-be attackers, as well as create additional database and file system permissions to help limit the possible scope of intrusion.

I was surprised by the lack of knowledge—and lack of concern—that my provider had regarding security issues. After all, I could have some fairly sensitive information on my site.

E-commerce sites keep track of customer billing and payment data in databases. Web-based e-mail servers hold megabytes of private e-mail for individuals. Statistics servers hold usage logs and demographics reports of usage and user preferences.

The Problem Persists

In late 2001, a quick check of several Web-hosting companies revealed the ugly truth: Providers are still not overly concerned about security.

There is a strong tendency to hide behind SSL (secure sockets layer). *"Our site is secure—see the little lock icon!"* As a matter of fact, SSL only protects the data while it is *en route* (between your desktop and the server). What about how it is stored once it arrives? What protections do those systems offer against intrusion?

There have been several high-profile incidents lately regarding information stolen off servers at large companies. In one well-publicized event, the intruder stole credit-card numbers and "held them hostage," threatening publication unless he was paid a hefty fee.

While many individuals are fully capable of running hosting services, a good number are still not sensitive to security concerns, even when presented with overwhelming evidence that their users really *do* care.

Education is absolutely the best way to arm oneself against potential vulnerabilities.

But there actually is a good, quickly deployable solution to many security concerns. And it is available now, off-the-shelf.

Enter the VPN

VPNs, or virtual private networks, provide *cryptographically verifiable* security rather than just discrete network separation.

Even if a VPN–protected conversation is eavesdropped upon, the intruder can obtain no data contained in that conversation.

Three tenets of security are as follows:

- *Confidentiality:* Make sure no one can *see it*.
- *Integrity:* Make sure no one can *alter it*.
- *Authenticity:* Make sure we know *who you are*. And, as a distant fourth:
- *Non-Repudiation:* Prove that *only you* could have done it.

VPN technologies attempt to coalesce algorithms and procedures that provide varying degrees of each of these paradigms into standards-based protocols that will interoperate among different vendors. Unfortunately, there has been a profusion of such protocols. The list is fairly long:

- *IPSec* (Internet protocol [IP] security, part of the IPv6 standard but supported in IPv4 as well)
- *PPTP* (point-to-point tunneling protocol, used by Microsoft)
- *L2F* (Layer-2 forwarding, a Cisco Systems implementation)
- *L2TP* (Layer-2 tunneling protocol, an Internet Engineering Task Force [IETF]–standard mix of the previous two)
- And even our old friend *ATM* gets thrown into the mix
- As well as a latecomer—*MPLS*

The recommendations in this article, to a large degree, are written with IPSec VPNs in mind; other technologies may provide varying degrees of protection.

Each of these protocols functions differently, but the goal is the same: to allow messages to be exchanged over a public network, ensuring the aforementioned attributes *without requiring that the applications on either end of the conversation be security-aware.*

A Practical Example

Public servers, such as Web servers, must be accessible by the general public. Firewalls can be used to limit exposure to these hosts, but they can still be overtaken by traffic directed at transmission control protocol (TCP) ports allowed through the firewalls.

One way to think about this is that putting up a firewall is just like putting up a real brick wall. Nothing can get through, including valid user traffic. You have to open a port, which is like drilling a hole through the brick wall. An attacker can still put a gun up to the hole in the wall and do damage to whatever is exposed on the other side.

For most high-performance public servers, this is about the best you can do. To the extent that the server itself, the server operating system, and the server applications are kept up to date with patches and fixes with known security exploits, you have a good line of defense. Remember that security, like skiwear, is best when applied in layers.

However, some servers do not have to have general-purpose access to non-secure networks. For example, a database server, which is the core of many e-commerce sites, absolutely should not be directly accessible from the general Internet. But, of course, it must be reachable by the site administrators, as well as the Web server itself.

One way to achieve this segregation is to build a segregated network with a combination of VPN and firewall technologies.

Network Segregation and Risk Reduction

Public servers are protected from public attack by firewalls, preferably ones with protocol validation for the publicly accessible applications. Servers that don't need public access are protected by VPN gateways. A VPN gateway will only allow traffic to pass that has been properly decrypted and validated. However, since the public servers must access the private servers, non–VPN traffic is permitted to pass through the VPN gateway as long as it comes from the public servers.

End users are then given either a VPN client or another VPN gateway so they can access their own servers. A VPN client is a software agent that is installed on any computer that needs access to the protected resources. These non-public servers are now directly accessible by the end customer, but by no one else. This design allows end customers to be able to access their own private servers (like database servers) regardless of the inherent security provided by those servers.

It is important to remember that the public servers *can* be overtaken, even when you have followed the best-known practices of securing them. When (and not *if*) this occurs, the intruder will have access to whatever data on the *private* servers that the public servers would have access to—and without any restrictions imposed by the public servers' user interfaces (application service provider [ASP], common gateway interface [CGI], etc.)

So, it is absolutely critical to severely limit access initiated by the public server toward the private servers. Make use of any application-layer protection available—use read-only logins, database table views with limited permissions, file system and operating system (OS) privileges, SYN flood, and other flood throttling—anything to limit the amount of damage that could be caused.

The mindset to have is to assume that an attacker absolutely can overtake a public server and that they can gain access to *any* information on it, including raw script code, private server passwords, database login IDs, schema information, etc. Then ask the question: "What bad things could someone do with this information?"

And follow with the *critical* question: "What harm would this cause to my business?"

Virtual Data Center Components

The main firewall is the primary line of defense for the entire data center. This firewall must be engineered to defend against a wide variety of attacks and floods. It is completely self-defeating to install a security device at the *most critical point* in the network that cannot itself survive an all-out attack. If this firewall fails, all your customers are cut off. (And you had better head for the hills.)

Because firewalls are "stateful" devices, they are subject to differing types of floods and denial-of-service (DoS) attacks. The simplest attack is a "resource starvation" attack, where the intruder simply sends many packets in an attempt to cause the firewall to consume its entire available random access memory (RAM).

SYN flood, ACK flood, and fragment flood attacks are all different special cases of flood attacks, where the goal is to make firewalls or routers fail due to lack of either available memory, or central processing unit (CPU) cycles. Many firewalls react poorly when subject to some or all of these types of attacks.

It is critical that the main externally facing firewall be able to protect itself from these attacks as well as sufficiently insulate the servers that it is protecting. For example, if your firewall doesn't protect servers against fragmentation attacks, a Jolt2 attack may be able to compromise certain server operating systems.

Additionally, since there are some protocols that are intentionally allowed through, it may be desirous to perform some application-layer protocol validation.

In other words, if the firewall allows inbound connections to TCP destination port 80 (HTTP), it might be nice to make sure that the packets going to the server actually contain valid hypertext transfer protocol (HTTP) commands—and not random garbage designed to crash the server.

This type of inspection is typically very CPU–intensive and can be time-consuming as well. As a result, it is not commonly deployed on external links due to performance considerations.

However, it is extremely important to consider this type of inspection on the *internal* VPN gateway/firewall protecting the private servers. These connections are typically much less frequent than connections to the public servers (although may still be fairly high bandwidth).

But the information on those private servers is much more business-critical than information on the public servers. And applications services on the private servers may be less robust, from a security point of view. As a result, the risk associated with compromise of the private servers can certainly outweigh the potential performance degradation caused by application-layer protocol validation.

It may also be useful to perform some *content filtering* on traffic as it is entering the data center. For example, inbound mail can be virus scanned. Posts to news servers can be inspected for offensive language. Objects posted to Web servers can be scanned for hostile mobile code (Java/ActiveX).

Finally, *intrusion detection* should play a part on the internal data-center network. In particular, three classes of intrusion should be considered:

1. Evidence that a public server is under attack (e.g., many failed root login attempts)
2. Evidence that a public server has been compromised (e.g., a successful root login from the public network)
3. Evidence that a private server is under attack (e.g., port scanning of the private server address space)

Configuring and tuning an intrusion detection system to properly signal these conditions while minimizing the number of false negatives is sometimes difficult. Testing should be performed to ensure that the intrusion detection system would at least report positives.

Mutually Hostile Customers

Private data is protected from the big bad nasty Internet. Customers must connect via VPN to access their private resources. Individuals on the public Internet can only access public servers. All is right with the world, no?

No. Not yet. At this point, the service provider's customers are protected from the public at large. However, customers are NOT protected *from each other*. For instance, Customer A could overtake its own private hosts, then attempt to use them to attack other private hosts belonging to other customers.

The Need for VLANs in a Virtual Data Center

Virtual local-area network (VLAN) technology was originally designed to allow Layer-2 switches to be segregated, making one big switch into several small switches. Then it occurred to some folks that it would be nice to hook several such switches together, preserving the segregated boundary somehow, across a single link. Thus VLAN tagging—now known as IEEE 802.1Q—was born.

In a data-center environment, there is shared infrastructure (such as access links and edge routers) as well as individual customer infrastructure (usually hosts such as Web or database servers). The trick is to allow the individual infrastructure to connect to the shared infrastructure without compromising the security of individual components.

This can be accomplished by connecting the individual components to switches that can assign VLANs based on physical port (so the hosts don't have to support VLAN tagging). These switches then must aggregate at a security device that supports VLAN tags, so intra-customer traffic is filtered upon crossing a VLAN boundary.

This allows the security device (presumably a hybrid firewall/VPN gateway) to be shared across all customers, instead of requiring one per customer in the data center. This design assumes the existence of a firewall that supports 802.1Q VLAN tagged trunks, only a few of which exist.

In fact, if your security device can support virtual firewalls, all security functionality can be collapsed into a single choke point, providing firewall, VPN, and VLAN segregation.

VPN/VLAN Integration

The final step in this architecture is to ensure that the aforementioned VPN can be strongly associated with a VLAN. Once the customer connects via VPN, they must be confined to the VLAN associated with that customer and not allowed to go poking around at other customers' servers. The customers' VPN is extended into the VLAN. A *customer* is then equivalent to a *VLAN*.

Any private equipment assigned to that VLAN could be reached by that customer (or appropriate end users at that customer, anyway). More importantly, (from a security point of view), any private equipment *not* assigned to that VLAN couldn't be reached by any individuals at that customer.

From the service provider's point of view, this design is extremely scaleable. A single data center can grow to support thousands of different hosted customers, each with their own virtual data center. The cost of operations of this center is only marginally more than the cost of a supporting a single customer.

Most hardware—except dedicated customer hardware—can be managed for the entire data center, avoiding duplication, and allowing for economies of scale. Internet protocol (IP) addresses can be conserved because the "private" servers need only be reached through the VPN, which can use RFC 1918 reserved addresses.

And the customer sees a huge benefit and an immediate improvement in operations. Either they deploy software-based IPSec (VPN) clients to each PC that needs access to the "private" network, or they install a small VPN gateway on their network premises to allow them select access into their "private" space. Either way, their traffic is completely isolated from other customers' in the data center, giving them the impression that they have their own, completely dedicated network.

Some Final Notes

Enhancements can be made to additionally secure the data center. Shared servers can be multi-noded to provide different IP addresses for management versus public service. They can be multi-homed with two physical network interface cards (NICs) to provide an out-of-band management channel to ensure that no management traffic can enter via the public interface. Full redundancy (which was omitted in this exploration for the sake of simplicity) can be added. However, these are all variations on the theme.

The point I try to stress is that service providers need to become more sensitive to their customers' security concerns. While certain security concerns may seem a bit highbrow and paranoid, individuals are becoming more security savvy every day. The two most publicized technology-related events today are viruses and security intrusions, not fancy new servers or nifty virtual-reality software.

This is an ideal time for a data-center service provider to get into the security business, because it is still considered a value-added service. In a few years, you will either be secure, or you'll be out of business.

And in case you were wondering: Yes, there are service providers deploying networks in this fashion—right now. Customer service at these companies will also address these security concerns.

Architecting the Future of IP Services

Quarry Technologies

1. Introduction

Network service providers (NSPs) are facing tough times. Lower than expected profits have forced many companies to re-examine their business plans. Offering basic connectivity and bandwidth services has become fiercely competitive, and margins on those services have suffered as a result. The ensuing price wars have taken their toll, and customer loyalty has been one of the main casualties.

Some forward-thinking providers have begun testing new, high-margin service offerings in hopes of differentiating themselves from the competition, attracting new customers, and retaining their existing clientele. The demand for advanced services, based on Internet protocol (IP) virtual private networks (VPNs) with application-level quality of service (QoS), data encryption, managed firewalls, and address translation, has not subsided, and many businesses have expressed a willingness to pay premiums for such special treatment of their important network traffic.

Unfortunately, to date, the trials of service-enabling systems have not gone as well as hoped. Though sound in concept, the first generation of IP service routers has exhibited some serious shortcomings when put to the test. These devices were designed for the era of 56 kilobits per second (kbps) dial access and over-subscribed residential digital subscriber line (DSL) connections. Most cannot handle the concurrent service mix and high-touch packet-processing throughput required by large numbers of higher-bandwidth business users who need to be sure their time-sensitive and mission-critical applications always receive appropriate precedence and security.

To solve this problem, a new architecture for the next-generation IP service edge switch is emerging. This innovative design uses high-speed application-specific integrated circuits (ASICs) in combination with programmable network processors to yield maximum packet-processing performance and feature flexibility. Interestingly, it is not focused on switching bandwidth or interface speeds, but instead on what really matters to support the business needs of service providers' customers—packet processing throughput per application flow, without any compromises.

2. No Compromises

As its name implies, the next-generation IP service edge switch is intended for use at the edge of the provider's network, where advanced services can be delivered most effectively. There, access links are aggregated and the traffic within those links is processed for optimal conduct over the backbone network. Logically then, the IP service edge switch sits behind any necessary access or aggregation devices and in front of the backbone routers. As such, it requires neither specialized access interfaces nor high-speed backbone ports, but simply the means to connect to them—technology aware, but not transport dependent.

By distinctly identifying subscriber traffic and classifying application flows at the network boundary, the IP service edge switch is able to apply QoS and encryption algorithms effectively and to aggregate flows prior to sending the traffic on to the shared IP backbone. Attempting to initiate QoS or security techniques elsewhere in the network could be futile, because the traffic would first have to cross the backbone in the clear where it might be subject to congestion and security breaches. The real challenge for the IP service edge switch is the ability to apply all required services concurrently to even the largest application flows, or class-based aggregate flows, without introducing performance-impacting latency or jitter. Additionally, because these services must be managed and ultimately billed for, detailed statistics collection is required. And, because the switch will be widely deployed in local communities, it must deliver all of these at a reasonable cost.

Such uncompromising performance is only possible if the IP service edge switch is built upon an architecture that is up to the challenge. Service providers looking to attract and retain lucrative business customers using advanced IP services will want to understand what makes these essential capabilities possible.

3. Architectural Issues

In general, an IP service edge switch receives data on its input interfaces, processes it, and, as part of this processing, determines the appropriate output interfaces, then sends it out those particular interfaces. Because the switch is designed for the edge of the network, this data-handling flow is not usually symmetrical.

On ingress to the network, many thousands of subscribers' data flows are aggregated onto a few backbone links. While the backbone links are quite large, it is still possible for them to be oversubscribed, and therefore it is important that subscriber traffic is properly aggregated according to relative priority of the type of the traffic.

In the opposite direction, data arriving from the network backbone has to be channeled into small subscriber access links. As diverse traffic flows are transmitted onto individual subscriber links that are much smaller in throughput than the core-side links, they have to be properly prioritized and controlled.

This aggregation of data flows requires a switch and packet processing architecture that can handle individual flows just as well as it handles aggregated flows and that can differentiate between different traffic types, properly manage traffic aggregation, and account for all data passing through the switch. Because the switch is deployed in a critical point of the network, it must also provide reliable operation even in the case of failures.

The basic components of an IP service edge switch are the input-output (I/O) module, the packet processing module, the traffic-management module, and the protocol-processing module. (Multiple, redundant instances of these components may be implemented to provide a high-degree of system reliability.) The protocol-processing module handles data traffic that is addressed to the system itself. Examples of this include routing protocol, system management, and tunnel-negotiation traffic. It is worth noting that data to and from the protocol-processing module requires traffic management as much as any user data going through the system to ensure smooth system operation and to prevent many different denial-of-service attack scenarios. However, because this module is not in the fast data-forwarding path, it will not be discussed here any further.

Many architectural choices must be made concerning how I/O, packet processing, and traffic manager modules are connected together. For reference, the most basic configuration would comprise one input, one packet processor, one traffic manager, and one output. A much more flexible and dependable system would have several of each of these components. But before such a system can be built, two issues must be settled.

First, the size of each component must be decided. Each I/O module obviously has to be sized in accordance with the particular media it services. Each packet-processing module has to be able, at a minimum, to handle all the processing requirements of the largest single traffic flow. Because the largest traffic flow can be as large as the largest I/O port in the switch, packet-processing bandwidth has to be sized accordingly. This means that if the largest I/O port is optical carrier (OC)–12, for example, the packet-processing module has to be able to process (terminate, decrypt, filter, translate, encrypt, and encapsulate) at this rate. Otherwise, the packet processor will back up and start dropping packets. This is unacceptable because the discard process is not intelligently managed based on QoS criteria, but rather is indiscriminately based on simple congestion.

Traffic of the same flow cannot be striped across multiple processors to increase packet-processing throughput because this could cause packets to be processed out of order, causing problems with tunnels that require sequence numbers (e.g., L2TP and IPsec) and many applications. Therefore, the packet-processing module must be sized for the task.

The second issue to be decided is how a traffic flow should be aggregated relative to all other flows. This aggregation decision must be made after packet processing has been completed. It is the foundation of the QoS treatment applied to a traffic flow. The traffic-manager module is responsible for this aggregation. Of course, it is possible to over-subscribe the switch such that more input traffic is received than the output ports can handle. But in a well-designed system, the resulting congestion would occur only at the output ports, where the traffic manager could handle it intelligently.

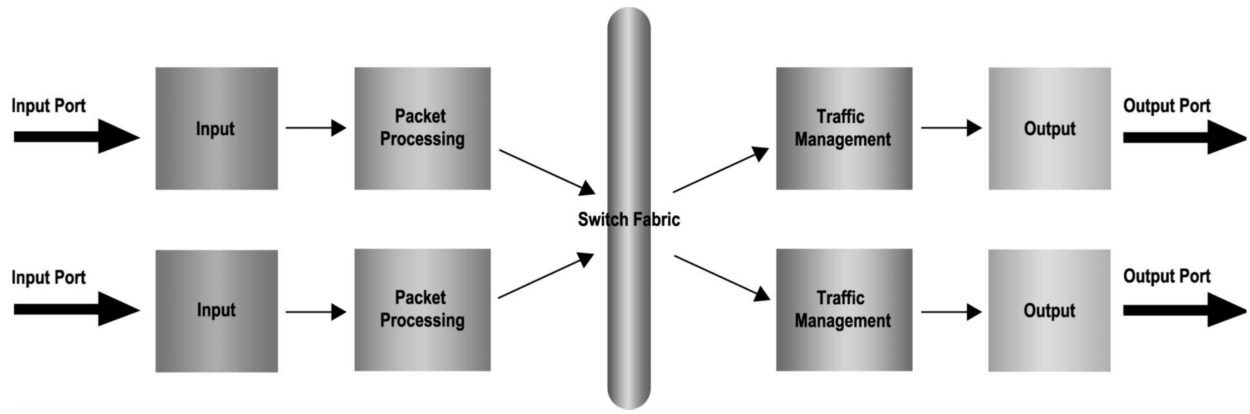
From the previous discussion, it should be clear that packet processing is an ingress function, while traffic management is an egress function. It should also be plain to see that in a perfect system all data destined to an output port would be received in the output port's traffic manager, where QoS and flow-aggregation decisions are made. The basic reference architecture therefore places the packet processor on the input side of the switch and the traffic manager on the output side (see *Figure 1*). When multiple I/O modules are connected together via an intermediate switch fabric, additional issues arise. If there are N I/O modules in the system, each with a maximum of P bandwidth, to prevent any chance of head-of-line blocking within the system, the switch fabric should provide 1xP input from each input module and NxP output to each output module's traffic manager. Thus, theoretically, the size of the switch fabric should equal NxNxP. In practice, this could be an unsustainable model due to exponential scalability requirements. However, it is intended to point out that the switch fabric must be sized to handle realistic traffic patterns between I/O modules and that an output of 1xP is clearly not enough.

Physically locating packet processing and traffic management together with the I/O module may seem like a good idea until the cost ramifications are examined (see *Figure 2*). There is a huge difference in the bandwidth requirements of I/O modules for an IP service edge switch ranging from low-speed access (e.g., T1, digital signal [DS]–3) to high-speed core-side interfaces (e.g., OC–12, Gigabit Ethernet). While one could use the same packet-processing and traffic-management hardware for all I/O modules, the cost to support lower-speed interfaces would prove to be prohibitively high. Conversely, optimizing the packet-processing and traffic-management designs for each I/O module type is not practical from the engineering resource and support aspects.

A better solution to the design of an IP service edge switch is to make packet processing and traffic management sepa-

FIGURE 1

General Data Flow in an IP Services Switch

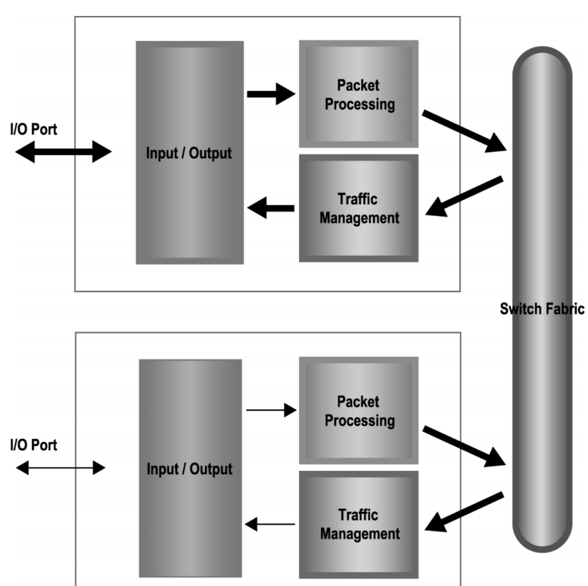


rate resources, which may be shared among multiple I/O modules (see *Figure 3*). This has the advantage of making efficient use of development and system resources, improving scalability, and facilitating system redundancy. Additionally, as seen, packet processing and traffic management are inherently separate processes (one being ingress and the other egress). As such, placing a switch fabric between them makes sense as well.

While the I/O, switch-fabric, and traffic-management modules are important components of the IP service edge switch, the real heart and brains of the system is in the packet-processing module. It is here that careful attention to design and optimization yield the greatest benefit.

FIGURE 2

System Architecture with All Resources on a Single Card



4. Packet-Processing Architecture

Processing packets is a multi-stage operation. It starts with the identification of the originator of the packets, and assigns this originator to a user group known as a subscriber. Then, databases related to this subscriber are opened according to information contained in the packet header. Tunnel termination is often required. This operation can be recursive because a tunnel may contain multiple subscribers, which may actually represent tunnels containing multiple subscribers, and so on.

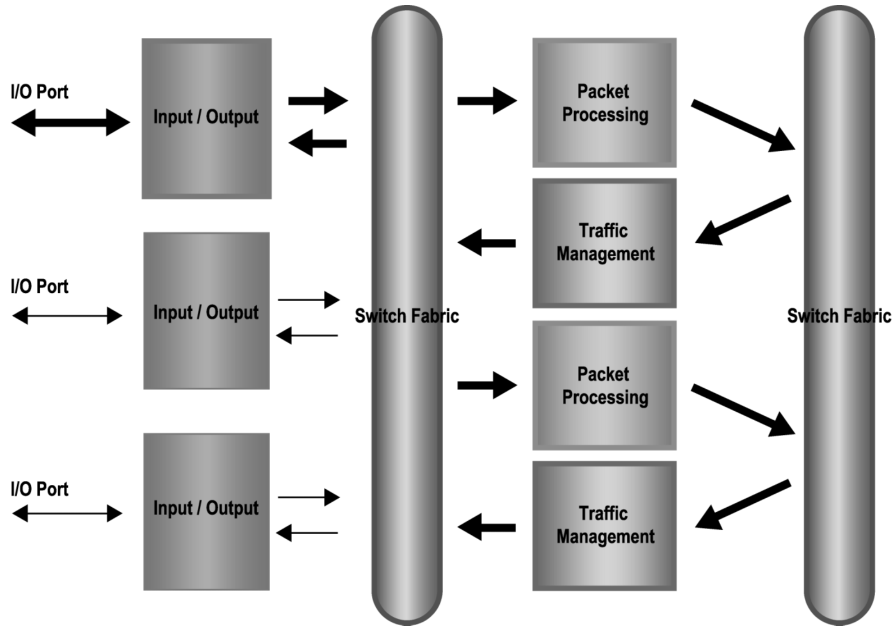
Each subscriber may have its own service-level agreement (SLA) that requires the provider to deliver services and enforce policies relating to the data flow. Of course, the service provider, being in the business of making money, had better account for the services it is providing.

In addition to subscriber identification, there are many packet-processing stages that each packet must undergo. The packet-processing module performs filtering, traffic classification, metering, marking, address translation, routing, and encapsulation. In fact, several of these steps are performed twice per packet—once according to the ingress subscriber's SLA and again according to the egress subscriber's SLA (if the egress subscriber is local to the same switch). Statistics must be gathered for every packet throughout this processing to facilitate service management and billing.

The first-generation IP services routers employed general-purpose processors to handle traffic. The bandwidth of each of these individual processors is limited to around 30 to 100 megabits per second (Mbps) of packet throughput depending on the services performed, and data flow striping cannot be used to increase the throughput per flow due to packet sequencing issues (see *Figure 4*). Therefore, the two major problems with this approach should be immediately obvious: each processor is limited to much less than the potential bandwidth of an individual traffic flow; and even this meager throughput is dependent on the types and quantities of services that need to be performed. As intro-

FIGURE 3

System Architecture with Distributed I/O and Function Cards



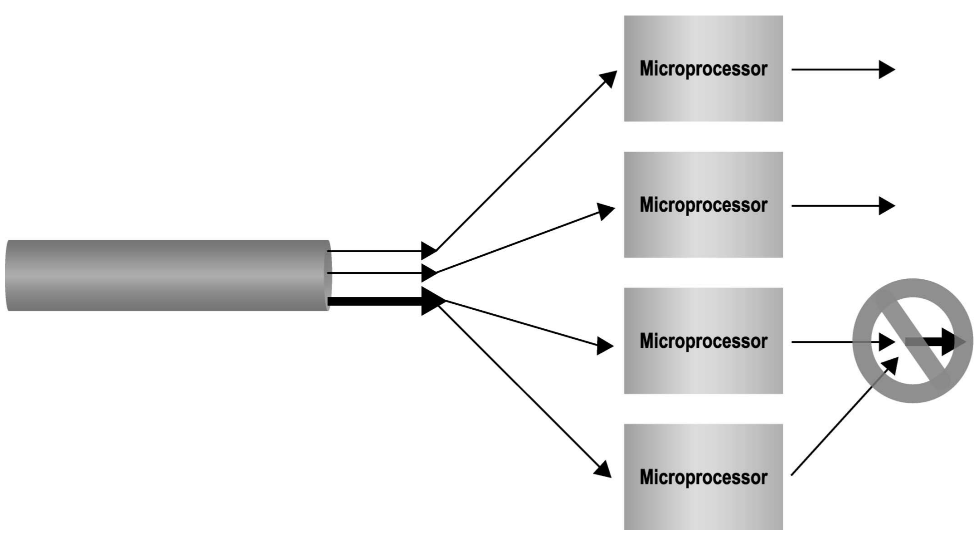
duced in the previous section, advanced IP services can be effectively applied only if neither of those restrictions is present. A packet-processing module must be able to handle the full bandwidth of the maximum size flow regardless of the processing complexity.

Pure ASIC–based solutions typically win the bandwidth race. Where they fail is in their product-execution risk factor and inflexibility. The service edge space is a fast moving, dynamic segment that continuously produces new standards and requirements. What a good IP service edge switch needs is the combination of the processors' programmability and the custom ASICs' speed.

Network processors came to the forefront in the past few years using multiple processing cores (e.g., MIPS, ARM) combined with specialized logic (e.g., CAMs) to provide a versatile approach to efficient data movement and packet processing. Network processors provide a step in the right direction but still cannot provide crucial elements of an IP service processor system, such as gigabit-speed encryption and deep, recursive traffic classification.

FIGURE 4

Data-Flow Striping and Merging Causes Packet-Sequencing Problems



The best way to build a packet-processing module is to use a pipeline of network processors and assist them in the execution of special functions using ASICs and other specialty chips. In this way, the IP service edge switch is able to provide unmatched speed and flexibility while also avoiding sequencing issues of parallel-processing systems. Multiple pipelines can then be interconnected via the switch fabric to provide redundancy, load sharing, and system scalability.

The network processors can receive and transmit the full bandwidth of the largest port in the system, then distribute this traffic to ASICs and off-the-shelf coprocessors. Thus, the network-processor pipeline effectively provides sufficient bandwidth to and from these ASICs and coprocessors far exceeding the actual data throughput (see *Figure 5*). The ASICs and coprocessors provide specialty-processing functions. They are look-up, database, search, and encryption engines, providing adjunct processing to the network processors. All packet-manipulation decisions lie with the network processors. This division of labor improves system flexibility and allows for future growth and evolution of services.

5. Conclusion

Utilizing an IP service edge switch based on this next-generation architecture with its powerful packet-processing pipeline, NSPs will improve their ability to meet customer requirements and reap the associated revenues. Trials will prove the system's capacity to run multiple advanced services concurrently without compromises. Throughput per flow will be unrestricted so that QoS and security can be delivered at full line rate on all interfaces simultaneously.

Business telephone calls are confidential in nature and corporate financial transactions are usually secret. Likewise, voice traffic requires low latency, while transactional data needs high priority. The new IP service edge switch has the extraordinary capability to assure the privacy of this traffic even as it delivers the preferential treatment these crucial flows require. At the edge of the network, the switch aggregates the traffic streams by service class for safe, swift conduct over the backbone.

With network-based IP VPNs delivering highly desirable customized services, network providers can distinguish themselves as long-term, value-added business partners that contribute to the success of their customers. Offering such premium services will increase revenues and profit margins. Moreover, this will delight existing customers and attract new ones as the word spreads.

Sustained Profitability in a Packetized Voice Environment

Julia Cotton Sommerfeldt
Director, Product Management and Strategic Business Development
ADC Corporation

Introduction

During the past several years, there has been a gradual transformation of the public switched network from one that is based on time division multiplexing (TDM) to one that uses the Internet protocol (IP). As data traffic increased and network-management costs went up, the need for a converged network—one capable of delivering both voice and data services—became more apparent. Because IP is a pervasive protocol, the adoption rate for voice over IP (VoIP) accelerated. Proprietary Class-4 and Class-5 switches are now gradually being supplemented and replaced with a more standards-based, distributed architecture, which uses gateways and softswitches.

The reasons for migrating to VoIP and for offering other IP–based applications are compelling. However, to recognize the full benefits of a VoIP network, one must consider more than just the technology platform to deploy. This paper will outline the market drivers for IP–based voice networks, some of the expenses and complexities of deploying these networks, and the critical success factors from an operations standpoint that must be met to realize and sustain profitability.

Market Drivers

VoIP, voice over asynchronous transfer mode (VoATM), and voice over digital subscriber line (VoDSL) markets will grow at a rapid rate during the next five years (see *Figures 1* and 2). The largest growth of these three, according to many industry forecasts, will occur in the VoIP sector at a global level during the next few years. Service providers and corporations are looking at VoIP as the end game, because IP networks have the advantage of providing additional multimedia applications, such as unified messaging (UM) and video services. Network endpoints, such as telephones, personal computers (PCs), and personal digital assistants (PDAs) can be IP enabled, so service providers can deploy a variety of IP services on a mass scale. While ATM currently has the advantage in quality of service (QoS), the quality issues in VoIP are being addressed and will become less of an obstacle during the next year. Private IP networks, versus the public Internet, enable the means to manage QoS on an end-to-end basis.

The drivers of VoIP markets include the following:

- International deregulation and privatization of telecommunications industry
  - Increased competition in deregulated markets
  - VoIP is not currently regulated over public, private, or virtual private data networks.
  - Toll arbitrage (avoiding tariffs) enables service providers to address price sensitive markets.
- Growth of global IP networks
- Relative to circuit-switched networks, the time to market to build a VoIP network is quicker, and the costs are lower.
- Demand for advanced applications that use voice and other media, and intelligent IP–enabled endpoints.
- Increase in IP–based intelligent endpoints (e.g., PCs, PDAs, phones)
- IP is becoming the pervasive protocol from the core to the edge and out to the endpoints.

The growth of IP networks and intelligent IP endpoints set the stage for more advanced and integrated applications such as UM, voice-enabled Web pages, voice-recognition systems, videoconferencing, collaborative computing, and IP–based call centers. Mobility is a common, or additional, requirement across the applications spectrum.

Some of the applications and their time frames driving VoIP deployment are as follows:

2000: Toll arbitrage, prepaid calling cards, wholesale services (carrier's carrier), settlement and clearinghouse (for global reach), and Internet call waiting
2001: Toll arbitrage in lesser-developed countries, UM, interactive voice response (IVR), wireless/mobility applications, and voice-enabled Web sites
2002: E-commerce, call centers, collaborative computing, videoconferencing, voice-enabled Web sites, wireless/mobility applications, and increased VoIP deployment in the enterprise market
2003: Further advancement and integration of these systems

Customers have high expectations and demands of their service providers. There is a pent up demand from both consumer

FIGURE 1

Voice-over-Packet-Network Services—North America

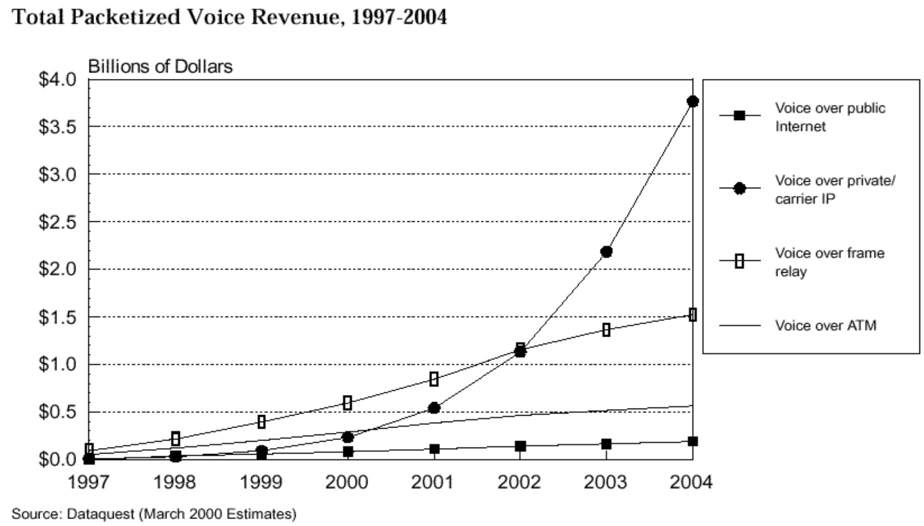

FIGURE 2

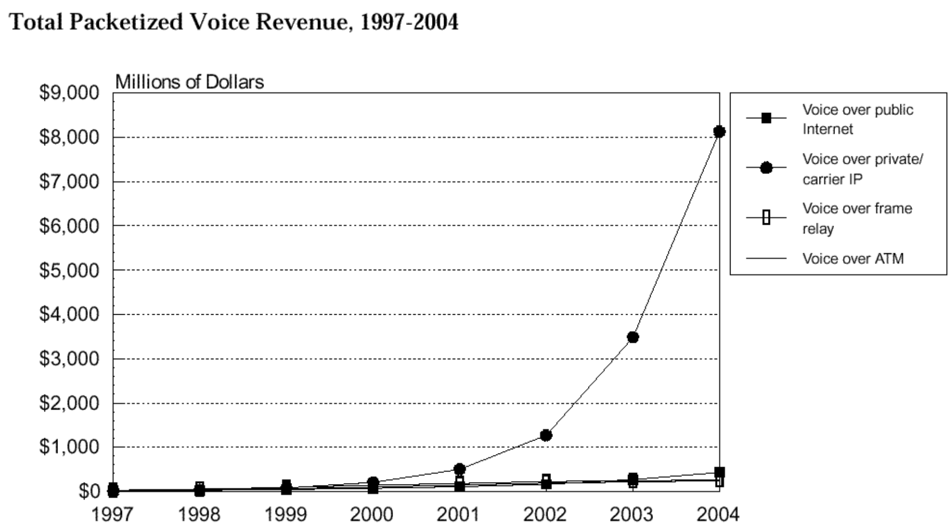
Voice-over-Packet-Network Services—Western Europe



and business markets for advanced applications and services. Customers will continue to have high expectations that their providers will offer them these services quickly and reliably. The service providers, incumbents, and new entrants need to respond to this market push.

For service providers to keep up with this demand, their networks must be stable, reliable, secure, able to scale quickly, and easy to manage. Incumbent and next-generation service providers see the value of building and managing one network to deliver multiple services—such as voice, data, and video—versus managing separate infrastructures for those applications. More and more voice service providers are migrating from circuit-based networks to packet-based networks so they can deliver advanced applications at lower costs.

Reducing Expenses and Complexities

How do we lower these costs? The idea is that if we build one network capable of transporting voice and data applications, rather than two separate and distinct networks for voice and data, we will minimize expenses. The critical factor, which is often an afterthought, is that one can maximize those cost reductions only if the converged network has the appropriate, next-generation management tools in place. As with traditional TDM–based voice networks, cost reductions in VoIP networks are specifically related to network operations, administration, management, and provisioning (OAM&P), which can amount to 80 percent of the overall expense of owning and operating a network.

There are other important short-term and long-term factors that we need to consider regarding cost reductions. How do we integrate disparate new and legacy systems into a seamless solution? In the transition period, we are adding gateway equipment and software to bridge these two networks. As the number of network elements (NEs) increases, so does network complexity. In the short term, there are more elements to manage. During this migration period, the operations support systems (OSS) used must be capable of addressing legacy and next-generation technologies, elements, and services in an integrated manner.

The long-term consideration is the need for flexibility and growth management. The capability for growth must be inclusive of the network infrastructure, the applications, and the network support systems. In the long term, the intelligent, converged network will only be as intelligent as the end-to-end OSS supporting it.

In many cases, often in a reactive mode, some service providers tend to install separate support systems for each area of functionality. Soon, there is a plethora of disparate systems that are not interconnected. This only stresses the bottom line rather than improving it. Selling more services, especially new and bundled services, will increase revenues, but to turn these services up quickly, or "on the fly," and to increase the margins, an integrated OSS must be in place. Without that, the ratio of sales to expenses is not likely to change for the better. Writing customized interfaces for these is apt to take a long time and can lower one's margins. In this highly competitive marketplace, quick time to market and lowered operational costs are vital.

Although we can deliver voice and data applications using a common protocol (IP), the requirements encompassing those two applications differ. We also need to consider that the circuit-switched network technologies and the packetized voice technologies are generations apart. There is a clear need to integrate these technologies and the system that enables effective operations. We may expect that network technicians with data backgrounds will understand voice networks and vice versa. The technicians that are highly skilled, experienced, and knowledgeable in both network generations are limited in number and increasingly demand higher salaries. At the same time, we are reducing the ratio of employees to access lines (see *Figure 3*).

This indicates that we need to handle these complexities through automation. An intelligent OSS can handle some of these complex processes in the background so that less experienced employees can operate the system. This increases the labor pool, reduces training costs, and reduces recurring operating expenses.

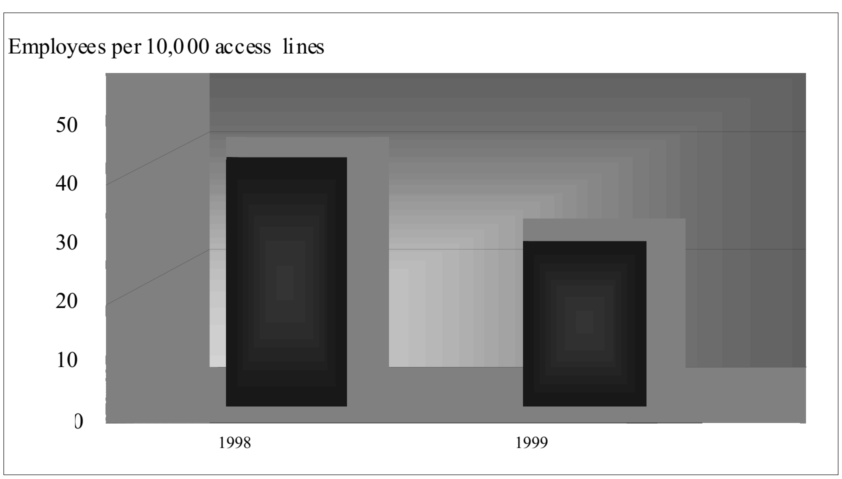
Another way to reduce costs is to reduce customer churn. Because customer satisfaction and retention are key factors in this highly competitive landscape, service providers need the ability to quickly provision a variety of services while offering service-level agreements (SLAs). Having an OSS that is part homegrown and part off the shelf, and that is not integrated, does not enable one to quickly create and deploy services. This, in turn, negatively affects revenue potential.

Some functions in the OSS process include taking a service order, designing, activating, monitoring, trouble shooting, and billing for the service with an continual, complete, and accurate understanding of the NEs. An integrated, end-to-end solution enables the tracking of all orders and requests received so we can ensure that they are moving toward completion and not getting dropped somewhere in the process. This directly correlates to efficient, timely, and accurate customer service.

How do we know what is in our network? An inventory-management system can track what is in the network and its availability. When this system ties into a product and services catalog, we can more accurately create bundles and deploy them when a customer orders them. A system tracking these orders will appropriately and automatically decrement the inventory once it is deployed.

While one can have separate systems to manage each of these processes, the most value comes through leveraging the seamless integration of the systems. Integration is the

FIGURE 3



Source: CIBC Oppenheimer

key and can meet these challenges. A model where workflow provides an end-to-end business process automation to perform the myriad of tasks in an orderly manner is a necessity (see *Figure 4*).

In the next-generation environment, the service provider's objectives to minimize risks, integrate applications, provision on the fly, accurately charge and bill for services, increase flexibility, and empower customers and customer-service representatives (CSRs) with intelligence are heightened.

There will be a transition period to this new IP–based voice network, so the OSS must work in a multivendor environment and the OSS firm must fully understand your business. Modularity and flexibility in the network equipment and in the OSS is key to accommodating network growth (see *Figure 5*).

Conclusion

A migration to VoIP networks can significantly lower costs and help service providers to sustain competitive pressures. At the same time, an IP–based network opens the doors to new revenue streams from other multimedia IP–based applications. While the hype around this is tremendous and the market forecasts are alluring, one can only maximize the gain by deploying a complete and integrated OSS that is capable of managing both generations of a network. To minimize expenses and maximize profits, the OSS must support circuit-switched voice technologies, data technologies, and the emerging VoIP technologies. With network OAM&P costs accounting for as much as 80 percent of the overall expense of owning and managing a network, the implementation of an end-to-end OSS system cannot be an afterthought.

VoiceXML: Speech and Telephony Meet the Internet

Deborah A. Dahl
Manager, Advanced Development, Natural Language Speech Solutions Group
Unisys Corporation

Abstract

VoiceXML is an emerging standard for developing telephony speech-recognition applications. Because VoiceXML uses Internet technology, VoiceXML applications can easily leverage work that has been done for graphical Web applications. This paper describes VoiceXML, reviews its history, discusses its advantages and disadvantages, and talks about where VoiceXML may go in the future.

Introduction

Using the Internet both as a source of information and to perform e-commerce transactions has become astonishingly routine during the few years that the World Wide Web (WWW) has been in existence. People go to the Internet many times a day for countless reasons, and usage is increasing exponentially. But accessing the Internet through the most typical routes can become pretty cumbersome, especially when we are away from our desktop computers and wire-based networks. What if we could access the Internet through smaller, more ubiquitous, and, frequently, wireless devices—such as the telephone? Routine information—weather, stock quotes, news, sports scores, train and airline schedules—would be available anytime and anywhere. Transactions such as making reservations, banking, stock trading, and shopping could be done at one's convenience.

Clearly, there are obstacles to this vision, and an important one is the limited graphical bandwidth of handheld devices, such as telephones and personal digital assistants (PDAs), compared to desktop and laptop computers. To be handheld, these devices must be small, but small displays and keypads limit the extent to which information can be transferred visually. Although current mobile telephones have increasingly sophisticated display capabilities, any really practical telephony-based Internet access is going to have to involve speech output at a minimum and, given the limitations of keyboards and keypads on small devices, also frequently involve speech recognition.

Speech has long been recognized as the most natural way for people to communicate with machines, but machines that can recognize, understand, and act on human speech have been much harder to create than anyone ever imagined when early speech-recognition research began in the 1950s. Although we are still many years away from computers with speech understanding capabilities approaching those of humans, simple speech-recognition applications are starting to become commonplace (a report from Jupiter Media Metrix dated September 7, 2001, states that 18 percent of consumers between 18 and 34 had used speech-recognition technology to make a purchase). Even the simplest speech-recognition applications have the potential for significant cost savings (it is claimed that automated voice systems in call centers can reduce the cost of each customer transaction to $1 to $2, compared to $40 to 60 for calls handled by a live agent [1]). Speech applications can also greatly improve user satisfaction as compared to telephone applications that rely on the limited interface provided by touchtones.

Fortunately, speech-recognition technology has come far in the last few years, and current speech-recognition technology is very usable for many applications. It is still true that interacting with current speech applications is very different from the experience of talking to a human. However, when they are well designed, these applications serve their purposes effectively—speech recognition is acceptable to most users, prompts are easy to understand, and dialogs are designed so that users can focus on their tasks, not the speech interface.

The first applications of speech recognition in telephony were based on integrating the technology with commercial interactive voice response (IVR) systems. These systems traditionally use touchtones to gather user input, using proprietary approaches. This strategy led to effective but expensive systems that required the direct participation of speech-recognition experts in the development process. A new approach was needed to make developing speech applications fast and cost-effective.

In March of 2000, a specification was released that describes a new approach to developing telephony-based speech applications using WWW technologies. The goal of this specification, VoiceXML 1.0, is to enable users to access information, particularly Internet information, using speech on small devices, especially the telephone.

History

VoiceXML is the result of the convergence of three technologies: the WWW, computer telephony, and speech recognition. In the mid-1990s, researchers at several companies began to realize the potential for synergy among these technologies, and they began developing ways for allowing telephony-based speech applications to integrate with the Internet. These early companies soon came to understand that a standardized way of supporting telephony-based speech applications would be far more potent than continuing to develop multiple competing approaches. To move toward a single standard for this technology, Lucent Technologies, AT&T, IBM, and Motorola joined together to form the VoiceXML Forum [2], which released, in March of 2000, the VoiceXML 1.0 standard. While the VoiceXML Forum was designing VoiceXML 1.0, the World Wide Web Consortium (W3C) [3] was also addressing the question of integrating speech and the WWW. The W3C chartered the Voice Browser Working Group [4] in February of 1999 to define requirements and standards relating to spoken dialogs and the Internet. The VoiceXML Forum submitted VoiceXML1.0 to the W3C in March of 2000 for consideration as the basis of a standard for defining spoken dialogs. The Voice Browser Working Group has been working on a new version of VoiceXML, VoiceXML 2.0, since then.

What Is VoiceXML?

VoiceXML (voice extensible markup language) is an XML–based [5] markup language that defines a spoken dialog just as hypertext markup language (HTML) defines a graphical Web page. VoiceXML has generated tremendous interest among the speech recognition, telephony, and Internet industries. The fact that there are currently 566 companies that are members of the VoiceXML Forum is just one measure of this interest. Let's see what some of the reasons for this excitement are.

VoiceXML lets a developer define what the computer is going to say to the user, what the computer expects the user to say in return, and what to do with the information provided by the user as well as telephony operations such as transferring a call or hanging up. Proprietary IVR platforms have these capabilities as well, so why would an enterprise that is considering deploying a speech application choose VoiceXML over proprietary IVR systems?

VoiceXML has many advantages over proprietary systems:

1. ***Open Platform:*** Proprietary platforms are just that, proprietary. Early speech applications were developed using proprietary IVR tools and run on proprietary IVR platforms. Changing platforms is extremely labor-intensive—dialogs have to be rescripted, speech grammars need to be rewritten, back-end integration needs to be redone. Application developers need specialized training for every IVR with which they work. Every platform makes use of specialized tools that are expensive to develop and time-consuming for developers to learn. VoiceXML provides an open environment with standardized dialog scripting and speech grammar formats that developers have to learn only once. Furthermore, because it is based on XML, a vast selection of generic XML editing and parsing tools is available, including both commercial and freely available open-source tools.
2. ***Leveraging Existing Web Integration:*** Most applications also require at least some level of back-end integration with databases hosted on enterprise servers. Performing this integration is a labor-intensive process with little potential for reuse of the integration software. VoiceXML allows this back-end development to be done once for any Web environment, whether spoken or graphical. In addition, back-end development is done with standard Web development techniques for both client and server-side development, such as CGI scripts, Java servlets, JSP, and ASP. This allows application developers to leverage existing Web development skills rather than learning proprietary tools.
3. ***Declarative Representation of Dialogue:*** VoiceXML attempts to make the description of the dialog *declarative*. This means that the developer describes the dialog that is to be conducted at a relatively high level. The Voice Browser platform handles the low-level details of transitioning between dialog states, activating speech recognizers, handling telephony, and playing prompts. In contrast, most current proprietary application development environments are *procedural*, in that they require the developer to handle these details manually, through programming in languages such as C++, Java, Visual Basic, and proprietary IVR scripting languages. In practice, real VoiceXML applications do require some procedural programming on the part of the developer, but VoiceXML attempts to minimize it. Of course, high-level programming environments always come at the cost of some loss of low-level control, and it is not clear that VoiceXML has achieved the right balance between these goals. However, in time, this balance will get sorted out as the industry gains experience with many speech applications and we gain a more complete understanding of how much low-level control is really necessary to good applications.
4. ***Ease of Learning:*** VoiceXML is easy to learn compared to other approaches, such as proprietary languages or full programming languages, such as C/C++ or Java.
5. ***Open Standard:*** VoiceXML is an open standard that has many advantages:
   - Because VoiceXML is an open standard, a company's investment in its VoiceXML applications is not vulnerable to the business decisions and stability of a single vendor, which might go out of business, fail to deliver promised features, or discontinue support of a proprietary product.
   - Through the W3C process, any interested company can have input into the direction of the standard by joining the W3C and participating in the Voice Browser Working Group.
   - VoiceXML is being exercised by more developers (by orders of magnitude) than any proprietary language, making it much easier to understand what features and potential features are truly important and which are peripheral. (One platform alone, VoiceGenie, claims to have 2,950 developers in 90 countries in their developers' network.)

Although in many ways VoiceXML is at this point less powerful than proprietary approaches, it exhibits all the hall-marks of a disruptive technology in the sense used by Clayton Christensen in *The Innovator's Dilemma* [6]. It is cheaper and initially less powerful than existing technology. In addition, it may be viewed with disinterest by key large customers whose chief objective is getting new features added to their current implementations and who are not interested in newer but less powerful approaches. As Christensen points out, however, the failure of a company to correctly respond to disruptive technologies invariably has severe negative consequences when the technology matures and customers start demanding it. The tremendous interest in VoiceXML will create a great deal of pressure to drive the technology to maturity very quickly. Consequently, companies that have a vested interest in proprietary systems for speech and telephony integration need to be involved in VoiceXML, or they will be left behind.

Example: Defining a Spoken Dialog in VoiceXML

One attractive feature of VoiceXML is that there is not a lot of overhead for simple applications. Simple applications are simple to define. Of course, any practical application will be far more complex than the simple example w wi'll be looking at, but this initial simplicity is very helpful in reducing the learning curve for VoiceXML. It is actually possible to get something to happen in VoiceXML with very little effort. The availability of free voice browser implementations that are appropriate for learning VoiceXML and doing simple prototyping also helps to reduce the learning curve.

We can see many of the key features of VoiceXML), which asks the user what beverage he or she would like, in *Figure 1* (from the VoiceXML 1.0 specification).

FIGURE 1

A Simple VoiceXML Example

```
<?xml version="1.0"?>
<vxml version="1.0">
  <form>
    <field name="drink">
      <prompt>Would you like coffee, tea, milk, or nothing?</prompt>
      <grammar src="drink.gram" type="application/x-jsgf"/>
    </field>
    <block>
      <submit next="http://www.drink.example/drink2.asp"/>
    </block>
  </form>
</vxml>
```

One of the most important concepts in VoiceXML is the *form*. Forms present information and gather input from the user. A form has *field* components that contain information for requesting a specific piece of information, such as a type of drink, as in this example. A *prompt*, or utterance spoken by the system to the user, is defined in the *prompt* element. In this example, the developer has decided that the prompt is to be spoken using the voice browser platform's built-in text-to-speech capability, so the only thing that needs to be specified is the actual text to be spoken. Recorded audio can also be specified using an *audio* element. In addition, if finer control over how the text is spoken is needed, text-to-speech markup elements can be included to perform such tasks as inserting pauses and emphasizing specific words.

Once the prompt is spoken by the system, the user responds with speech. The grammar defined in "drink.gram" is used by the speech recognizer to recognize the user's response. We do not see the grammar itself in this example; it is referred to by the relative universal resource locator (URL) "drink.gram," although it is also possible to include the grammar directly in the markup without an external reference. Once the speech has been recognized, the *block* is executed. In general, a block contains non-interactive executable code. In this case, the block specifies the next step to take in the dialog, i.e., moving to the "drink2.asp" document.

This example supports the trivial dialog in *Figure 2*.

Other Supporting Standards

Although this paper focuses on VoiceXML, other standards are also required in order to have fully interoperable speech applications. The W3C Voice Browser Working Group is currently involved in defining standards in the following areas:

1. ***Speech Recognition Grammars:*** The most significant gap in VoiceXML 1.0 was the lack of standardization of speech grammar formats. Speech grammars are the means by which developers specify what the system expects users to say at any point. With current speech recognizers, the system is essentially "deaf" to anything the user says outside of the grammar. Consequently, the specification of the grammar is crucial to the success of an application. The speech-recognition grammar standard defines two standardized formats for specifying grammars: an XML format that must be supported and an optional ABNF format that

FIGURE 2

A Sample Speech Dialog Supported by a VoiceXML Script

System: Would you like coffee, tea, milk, or nothing?

User: Milk.

System: (continues in document drink2.asp) is less verbose than the XML format. In addition, another specification is in progress that defines a more flexible type of speech-recognition grammar: the NGram format, which is not yet used by most current speech-recognition systems, but which will probably be available in the next one to two years.

2. ***Speech Synthesis:*** A standard for annotating text to be presented to a speech synthesizer with tags to direct how the text should be pronounced. For example, this standard describes tags for pauses, tags to indicate how loud the speech should be, and so on.
3. ***Natural Language Semantics:*** A standard for defining how to express the meaning of user's speech in a standard XML–based format, as well as other information about how it was spoken and when it was spoken.
4. ***Call Control*:** This standard will define features that support more advanced call control in Voice Browsers than the simple transfer and hang-up capabilities that are available now.
5. ***Reusable Dialogs:*** This standard will define how to develop reusable dialogs that accomplish specific tasks, such as getting a date or time from a user.
6. ***Speech Lexicon:*** This standard will define standards for how to represent the pronunciation of words. This lexicon could be used by text-to-speech systems to decide how to pronounce words as well as speech-recognition systems to decide how the words that it is listening for are pronounced.

The W3C Voice Browser Web site [4] maintains the documents that define the current state of these standards. As these standards mature, they will become incorporated into commercial VoiceXML browsers, providing significant improvements in interoperability.

Limitations and Cautions

While VoiceXML is dramatically reducing the complexity of developing speech applications, it is important not to lose sight of the fact that there are still many complexities remaining in this process. Some of these, such as the human factors of spoken dialogs, will be addressed, although not solved, by future versions of dialog markup languages, which will build in features that incorporate known principles of speech interface design. Other complexities, such as the issues that arise during the deployment and provisioning speech applications, scaling, and load balancing, are outside of the scope of VoiceXML or any future dialog markup language. They will be addressed primarily as the industry develops increasing experience with large-scale deployments.

As another caution, it should also be pointed out that while VoiceXML might appear to be simple to use, it is also very important when considering a commercial VoiceXML-based deployment to work with an established vendor that is familiar with the technology. The vendor must have the specialized knowledge and experience that it takes to develop telephony-based speech-recognition applications in general and VoiceXML applications in particular. As just one example, the human factors of dealing with voice dialogs are very complex, and it is easy to make human interface mistakes that can cause a project to fail. Without the specialized knowledge of speech-application experts, projects will flounder as the team members acquire the requisite expertise through trial and error.

Future Developments in Speech Applications

The future of VoiceXML and speech applications in general is very exciting. Advances will occur along multiple dimensions, simultaneously widening the scope of dialog applications, making them more natural and capable, and making them easier to design and deploy. Here are some new directions that we are likely to see:

1. ***Multimedia:*** Speech-only applications will be supplemented with integrated text and graphics as devices become more capable and as the technologies for integrating speech and graphics become more mature. Graphics is a better output device than speech for many types of information, such as maps and diagrams, and the only choice for information that must be conveyed in the form of images.
2. ***More Natural Dialogs:*** Current VoiceXML applications, although effective, generally tend to have a machine-driven feel, despite the fact that VoiceXML itself contains features that support mixtures of machine and user-driven dialogs. Major roadblocks to more natural dialogs include (1) current speech-recognition technology performance degrades as the number of things that the recognizer has to listen for increases, (2) difficulty to design natural dialogs with current tools, and (3) difficulty to design and debug the complex speech-recognition grammars that support natural dialogs. All of these factors will change as speech-recognition technology and dialog design tools improve. Better speech-recognition technology also will allow systems to take advantage of much more flexible and easier to design language models, such as NGram models, which will eliminate the problem of debugging speech grammars.
3. ***Better Speech Recognition and Text-to-Speech Technology:*** Speech-recognition errors will never go away entirely; even humans sometimes have trouble recognizing the speech of other humans, and there is no reason to think that machines will be able to do better than people. Sometimes there just is not enough information in the speech to tell what someone is saying. Humans have developed many strategies for effectively communicating with each other under poor conditions, and many of these strategies are beginning to be exploited by sophisticated computer dialog designers. However, there is still a great deal of room for improving the baseline accuracy of speech recognizers. Think about a conversation with a person who is hard to understand for whatever reason. For example, the person you are talking to might be speaking a foreign language that you don't know very well. Even though you can usually manage to communicate, the conversation is much easier and more pleasant when speech recognition is not an issue. Text-to-speech technology is also making tremendous improvements and sounds much better than it did only a few years ago. Nevertheless, it still sounds artificial, and serious commercial deployments use recorded natural voices as much as possible.

4. ***More Devices:*** VoiceXML browsers are primarily based on telephone platforms today, except for browsers used by a few desktop testing tools. However, a very natural next step would be to use VoiceXML browsers on PDAs and desktop computers, especially as multimedia capabilities for VoiceXML develop.
5. ***Better Tools***: Just as it is possible to design a graphical Web site with only a text editor, it is also possible to develop a full VoiceXML application. This is part of the appeal of VoiceXML. No specialized tools are needed get started. But manually managing a complex commercial VoiceXML site that not only may include VoiceXML pages, server-side code, sound files, and speech grammars, but must also interoperate with existing integration code that supports a graphical Web site, using only simple tools, is extremely difficult. Commercial design tools that reduce the complexity of the VoiceXML development process are starting to be developed. In addition to the choice of a VoiceXML platform itself, a VoiceXML development project should also give careful thought to the available tools and make a considered decision on which development tools to use based on well-understood requirements. Tools range in capability from simple XML editors, through more intelligent VoiceXML specific editors, to abstract dialog design tools that developers can use without even being aware that they are developing VoiceXML applications. Using these tools will dramatically accelerate the adoption of VoiceXML.

Conclusions

VoiceXML is an exciting technology that is not only starting to open up the Internet to telephone access, but is also dramatically reducing the development time for telephony-based speech applications. Even though the first specification was released only two years ago, VoiceXML is rapidly becoming a major factor in the speech/telephony marketplace that deserves serious consideration.

Meeting IP Service Provisioning Challenges

Anand Desai
Vice President, Marketing
DSET Corporation

IP Service Activation and Provisioning: A Journey with Great Potential, Major Challenges

When Portuguese navigator Ferdinand Magellan set sail in 1519 on a quest to find a western route to the Spice Islands, few could have known that his expedition would establish the world's first true communications network.

Magellan's ships crossed the Pacific, became the first fleet to circumnavigate the globe, and ultimately proved the roundness of the Earth.

Flash forward nearly 500 years, and today's "explorers" often take the form of telecom engineers, also on a mission—focused on delivering voice, data, and other information around the very same world as Magellan. For both journeys, provisioning was key.

"Provisioning" is a term that has long been used in the telecommunications industry to designate all of the network operations that must be completed to achieve one objective: turning on services for a telecom provider's customers. At one time, the sole focus of provisioning was to turn on POTS, or plain old telephone service. Today, however, there are numerous types of providers offering many different voice and data services, with each service holding the promise of substantial financial return in addition to presenting its own set of technical challenges.

At the start of the 21st century, Internet protocol (IP)–based services, such as virtual private networks (VPNs), are increasingly attractive to service providers and their customers alike. For providers, these services present a significant growth area in a hotly competitive marketplace. As with any telecom service, efficient provisioning can be the key to success in this market, as it can reduce costs substantially while enhancing revenues. But in the rush to surge ahead of competition, service providers must not be shackled by poorly designed provisioning solutions that limit flexibility and growth. This can only result in the failure to meet service demands, customer expectations, and revenue targets.

Multiple Services in a Multivendor Environment

Success demands flexible provisioning solutions capable of supporting multiple services in a multivendor operations environment. Such solutions must also be highly scalable, robust, and extensible to meet new market needs. Building a monolithic piece of software to address the requirements imposed by one service or a single equipment vendor severely limits a provider's ability to keep pace with the evolution of the market. However, a product whose design is based on flexibility, modular components, and service definitions will enable a provider to maximize return on investment (ROI) despite the most fluid technical and commercial conditions. A service-, device-, and vendor-neutral solution is a requirement for emerging networks.

Pitfalls of Manual Provisioning

While simple in concept, provisioning is often complex in execution, especially when it has to be done manually. Essentially, provisioning is initiated by a customer's service order to a communications provider and culminates when the customer is able to use the service purchased. During this process, the service is enabled for use on one or more devices in the network. Turning on a VPN service, for example, may entail such complexities as sending commands to several network routers.

In today's telecom environment, manual provisioning is slow and error-prone. Even provisioning a small VPN can be time-consuming. Manual provisioning also requires constant vigilance by highly skilled operations personnel attuned to myriad difficulties that can arise from changes in vendor products and industry standards. For example, the inability of digital subscriber line (DSL) to grow beyond a certain market size can be attributed to lack of cost-effective automated provisioning.

In addition, there are the problems caused by partially failed service activations. Partial failures can compromise the integrity of the service infrastructure to the point where costly manual intervention is needed. Manual rollback of a failed multisite VPN service order can be a service provider's nightmare.

A Clear Imperative

Clearly, automated IP provisioning is imperative for the success of any communications provider competing in this market segment, as well as for large enterprises seeking to manage their own networks as efficiently as possible. However, building a provisioning system that can deliver all of the capabilities critical in a multi-technology, multivendor environment is a daunting task.

To begin with, providers typically offer a variety of services supported on different types of servers, routers, firewalls, and switches. For each type of device, there may be multiple vendors. And to further complicate matters, change is always around the corner, which may be a version upgrade on a router, a new router model, a change in the way a service is deployed, or an entirely new service.

The provisioning systems currently on the market have been designed to be single-service or single-vendor solutions and lack essential flexibility and extensibility. Service providers are thus forced to buy different systems for different services and vendors. Resources cannot be shared by multiple services. Having multiple systems makes routine operations as well as maintenance far more expensive and complex than they would be if one system could be deployed to automate provisioning—regardless of the service or vendor.

Provisioning Services, Not Devices

A critical deficiency in conventional provisioning systems is that they are based on a myopic design philosophy that views the provisioning process as "device provisioning." A more elegant and effective approach is to view provisioning as enabling a service for the end user. This perspective reflects the key direction in which the market is moving. Subscribers want service-level agreement (SLA) compliance that essentially implies quality of service (QoS) guarantees. It also implies that the essence of "customer satisfaction" is developing a service model that can be rapidly deployed and that accurately represents a subscriber's expectations for that service.

A provisioning system should also be the repository for provisioned data. This is a complex requirement, since such a repository has to have comprehensive information about the service provider's own equipment, organization, and internal users as well as each subscriber's organizational structure, devices, and authorized users. Additionally, this information has to be accessible for queries from other operations support system (OSS) components that have their own fixed views of the service infrastructure and state. For example, some OSSs will issue queries based on subscribers, while others will generate queries based on devices.

Building a Better Provisioning Solution

Effectively addressing these new types of design issues requires a component-based, modular "plug-and-play" approach to building a service-provisioning system. Developing a system that is flexible and extensible also requires a clear separation of service applications from a provisioning core and device models.

A service application consists of service and policy definitions. Service definitions enable activation of the service by the provisioning core, and policy definitions include the types of policies activated for the service. This will, for example, include QoS policy definitions where policy rules relating to traffic metering/monitoring will be part of the policy definition for a VPN service.

A provisioning system should allow the dynamic introduction of new service definitions, policy definitions, and device models. This will enable the service provider to travel a very fast time-to-market path.

Another design consideration is how well a service-provisioning solution fits into the overall OSS environment, where the provisioning system will have to interact smoothly with a variety of back-end systems. For example, well-designed provisioning software must be capable of interfacing with performance-management systems so that SLA profiles can be populated with service-configuration information, such as the set of interfaces required for a VPN service. It is also desirable that the provisioning system be able to communicate with an inventory system to import information about available network devices. Similarly, a fault-management system may have to query the provisioning system to determine the service configuration for a particular device.

A Universal Provisioning Solution

A universal provisioning solution, carefully designed, can provide all of the capabilities indispensable for fast, cost-effective IP provisioning. A highly scalable, standards-based, robust, and extensible architecture is needed that enables rapid, network-wide, policy-based, and error-free flow-through provisioning of IP–based VPNs for multivendor networks (see *Figure 1*). Integration into an OSS environment by means of open interfaces into order-entry, billing, and management systems is also needed to further automate the entire management process.

Furthermore, a rich modeling of service applications, and drivers for communicating with all of the network elements that have to be provisioned and managed is needed. A platform-based approach that offers all the features of a transaction processing system, such as reliability, scalability, availability, and rollback upon failure can certainly address the service-activation needs of millions of subscribers of many blends of services.

Key Features of a Carrier-Class Service-Activation Solution

Customizability and Extensibility

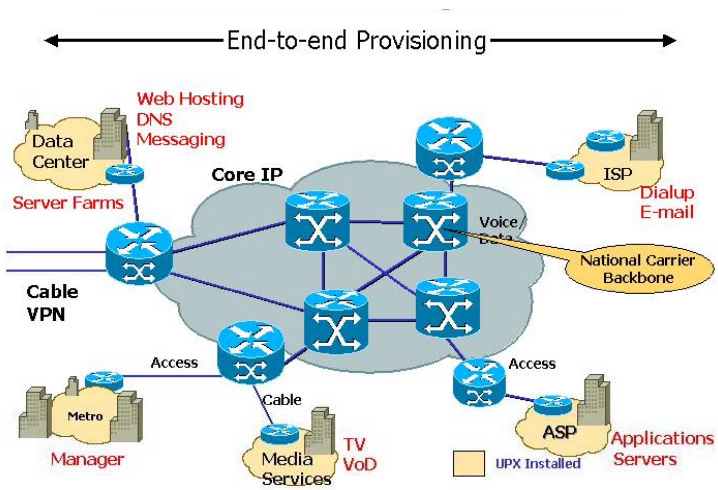
A system that allows maximum customization to support new or modified products, services, and networks without any major change is needed. Service applications based on a rich modeling of services and service models should be easily added or edited as required.

Scalability

Service providers demand scalability to address the volume of transactions as business grows. Bulk provisioning, and

FIGURE 1

IP Service Provisioning with UPX



the ability to handle millions of subscribers in real time, is the challenge that needs to be met.

Service Bundling
Bundling of existing service applications can enable the seamless introduction of new services. For example, an IPSec (IP security) VPN service may be bundled with a QoS application to significantly cut the time to market for an IPSec QoS VPN offering. These combinations can help create value-added services needed for real-time applications used in business, entertainment, and gaming.

Policy Support
Users should be able to create policy templates, such as those for security, that facilitate the creation of policy rules to be applied during provisioning. The classification of policies allows the activation manager to easily create, customize, and apply policy rules.

OSS Integration
An open architecture that supports interfaces based on extensible markup language (XML), common object request broker architecture (CORBA), and Java messaging services (JMS) to maximize interoperability with other OSSs, including order-entry, billing, inventory, and fault-management systems, can blend into an existing OSS ecosystem. Open and flexible interfaces can make the typically difficult OSS integration process a much simpler exercise.

Vendor-Neutral Provisioning
A modular and vendor-neutral design can provide support for provisioning a wide variety of devices.

Transaction Support
The network is a financial asset that needs to be utilized appropriately. Each provisioning request should be treated as an important transaction. Besides, a number of network requests may be generated from a single provisioning request. The failure of any single network request is a failure of the entire transaction. Upon a failure, therefore, automated ways to initiate rollback requests are needed to ensure that the state of all devices affected reverts to that existing before the start of the transaction.

Security
It is important that each operator is authenticated and can perform only authorized functions. In addition, security between different components should be configured to enable encryption of messages and two-way authentication through certificates. No message should be viewed in transit, and connections need to be authenticated.

Customer Self-Provisioning
A service provider's clients should be able to provision and manage their own services—a capability that can also reduce a provider's operational costs. Client self-provisioning should be securely configured so that individual clients are authorized to access and exercise control only over certain network systems and information.

Standards-Based
To help maximize utility and flexibility for service providers, the architecture should be based on industry standards such as CORBA, XML, J2EE, lightweight directory access protocol (LDAP), and simple network management protocol (SNMP). The service-application standards reflected in this architecture are IPSec, Internet key exchange (IKE), multiprotocol label switching (MPLS), differentiated services (DiffServ), and remote authentication dial-in user service (RADIUS).

Conclusion

Automated service-activation and provisioning solutions that provide carrier-grade features with the flexibility and extensibility are critical for meeting the fast-changing commercial and technical demands in the communications industry. The need has never been greater—particularly as new services and devices are continuously added to the mix.

An open architecture can further enable seamless interaction between the different components of a service provider's OSS environment. Highly scalable and robust, these solutions can minimize the money, time, and manual effort that providers need today to customize services, to bundle existing offerings to create new ones, to quickly introduce completely new services, to deploy equipment from new vendors, or to upgrade equipment supplied by current vendors.

Automated provisioning is a quest worthy of Magellan – a voyage into still uncharted seas with rich possibilities on the other side of the globe.

Cities of the Future: The Role of Smart and Sustainable Communities

John M. Eger
Van Deerlin Professor of Communications and Public Policy
President of the California Institute for Smart Communities
San Diego State University

Cyberplace and Cyberspace

According to author Charles Handy, we live in an age of paradox. The more high-tech our world, the more high-touch we are becoming. The more global, the more intensely local our focus needs to be. The more competitive our markets, the more cooperation is a critical element in developing our business strategies.

One of the more interesting paradoxes of our time is that the more we live and work in cyberspace, the more important real place becomes. While this notion runs counter to much of today's popular literature, we are already seeing the knowledge worker and the high-tech knowledge-sensitive industries migrating to highly livable communities—communities with mountains or lakes, open spaces, clean air and water, and, as in the case of Portland, Oregon and other communities where they have established urban growth boundaries, less reliance on the automobile as the primary mode of transportation.

This growing concern with urban sprawl, coupled with the nostalgic yearning that the new urbanism movement represents, are evidence of sweeping changes in public attitude toward physical space. As the Internet revolution moves into full bloom, however, there is every reason to believe it will have a dramatic impact on the architecture and landscape of communities throughout the world.

No technology in human history is having, or is likely to have, such tremendous influence on life and work and play, and, in the transforming process, on our physical space. While a "smart community"—a community that makes a conscious decision to aggressively deploy technology as a catalyst to solving its social and business needs—will undoubtedly focus on building its high-speed broadband infrastructures, the real opportunity is in rebuilding and renewing a sense of place, and in the process a sense of civic pride.

Athens, the place where civilization was born and where the city-state form of governance first began, remains a symbol of the dynamic potential of cities to create and provide the linkages among culture, commerce, and civic pride that are so important to the wealth and well-being of a community. Over the years, however, cities have been both cursed and blessed as they have been compelled to adjust to the underlying changes taking place in our movement to a global economy and society. Many cities have already died; others are in fiscal and societal decay.

The concept of cities as engines of civilization remains deeply embedded in our collective psyche. As cities of the past were built along railroads, waterways, and interstate highways, cities of the future will be built along information highways—broadband communications links to homes, schools and offices, hospitals, and cultural centers, and through the World Wide Web (WWW) to millions of other locations all over the world.

As past is prologue, surely some cities will become the ghost towns of the 21st century information age. By far, however, cities will succeed and survive in this next transition to a knowledge-based, global information economy and society. Indeed, cities of the future—the smart and sustainable communities built for the digital age—will play a central role in the rebirth of civilization in the 21st century.

The Power and Pervasive Influence of Technology

In less than a decade, the great global network of computer networks called the Internet has blossomed from an arcane tool used by academics and government researchers into a worldwide mass communications medium, now poised to become the leading carrier of all communications and financial transactions affecting life and work in the 21st century.

The growth of the Internet's World Wide Web has been even more spectacular. With 30 million-plus users worldwide, growing at 15 percent per month, it is being integrated into the marketing, information, and communications strategies of nearly every major corporation, educational institution, political and charitable organization, community, and government agency in the world. No previous advance—not the telephone, the television, cable television, the videocassette recorder (VCR), the facsimile machine, nor the cellular telephone—has penetrated public consciousness and secured such widespread public adoption this quickly.

In recent years, it has become fashionable to refer to the domain in which Internet-based communications occur as cyberspace—an abstract communication space that exists both everywhere and nowhere.

But until flesh-and-blood human beings can be digitized into electronic pulses in the same way in which computer scientists have transformed data and images, the denizens of cyberspace will have to live IRL (in real life), in some sort of real, physical space—a physical environment that will continue to dominate our existence and our future in the same way that our homes, neighborhoods, and communities do today. Nonetheless, information technology (IT) is a force that will reshape our world as never imagined.

The Rise of Smart Communities

Already, communities and nations around the globe—often without being consciously aware of it—are starting to sketch out the first drafts of the cyberplaces of the 21st century. Singapore has launched its IT–2000 initiative, also known as the Intelligent Island Plan. Japan is building an electronic future called Technopolis, or Teletopia. France, as early as 1976, initiated a plan called Telematique, an aggressive effort to place personal computers (PCs) on every desktop and in every home in the country. In the United States several years ago, the former Clinton Administration pursued a vigorous National Information Initiative, or NII, one of whose early goals was to link every school and every school-age child to the Internet by 2000.

Many communities—Stockholm, Seattle, and Sacramento, for example—have constructed large-scale public-access networks that residents can use to obtain information about government activities, community events, and critical social services such as disaster preparedness, child-abuse prevention, and literacy education. The tiny university town of Blacksburg, Virginia has transformed itself into an electronic village in which the majority of the town's businesses and residents are connected to the local data network. And counties such as San Diego, as a result of its City of the Future project, are building even more sophisticated electronic infrastructures that, one day soon, will allow a wide variety of local government, business, and institutional transactions.

Recognizing that electronic networks such as these will play an increasingly important role in a municipality's economic competitiveness, the State of California four years ago launched a statewide Smart Communities program, which has been managed since its inception by the International Center for Communications at San Diego State University. More recently, a World Foundation was established to help other communities around the world with their struggle to get on the global information highway.

The Foundation defines a smart community as a geographic area ranging in size from a neighborhood to a multi-county region whose residents, organizations, and governing institutions are using IT to transform their region in significant, even fundamental ways. A fundamental premise is that smart communities are not, at their core, exercises in the deployment and use of technology, but in the promotion of economic development, job growth, and an increased quality of life. In other words, technological propagation of smart communities is not an end in itself, but only a means to reinventing cities for a new global information economy and society with clear and compelling community benefits.

Technology, Culture, and Place

One of the main reasons that information networks can have such a profound transformative effect on people, businesses, and communities is that every other major technology advance that has shrunk space and time has also remade society in fundamental and important ways. Transportation, over the millennia for example, has done more than perhaps any other technological advance to bring the world's people closer together.

But telecommunications developments, including telephones and their more modern kin, accentuate the trends inaugurated by transportation advances in three slightly different, but very important, ways.

First, by allowing for rapid communication between distant sites, they make it possible for business and social relationships to flourish over long distances, permitting workers and investment capital to migrate to the most desirable locations and those with the highest economic return.

Second, they extend the reach of these economic, social, and other relationships far beyond national borders, creating what is truly a global economy. And third, and perhaps most significantly, they make possible for the first time the nearly instantaneous transmission of information, collapsing both space and time in a way that no other previous technological advance has done.

The Internet, the World Wide Web, and their successors are likely to produce consequences that are as great or greater than anything we have seen so far—and that are apt to be equally unexpected. If we are to maximize the positive contributions of these new technologies while minimizing their negative ones, we must begin to appreciate now how these technologies are likely to affect our people, our culture, and our perceptions of place in the years to come.

The Technical Architecture of the Smart Community

There are a few general trends worth noting. The first is the growing ubiquity of telecommunications networks. Because it is based largely on the existing telephone systems, the Internet today spans the globe, with its tentacles reaching into more than 130 countries and connecting, in one form or another, an estimated 400 million to 450 million people. This expansion shows no signs of abating. Indeed, as the Internet migrates from its almost purely copper-based telephone platform to cable, satellite, and digital cellular systems, the methods of connecting to the Internet will proliferate, access costs will decline, and the number of users will skyrocket.

The second general trend in the development of the Internet is the rapid expansion in bandwidth. In its original incarnation (which lasted for more than two decades), the Internet was primarily a low-volume text-based medium, and so required little transmission capacity.

The emergence of the World Wide Web, with its heavy use of graphics, photographs, and animation, changed this equation dramatically, and even top-of-the-line modem technologies—28.8 kilobits per second (kbps) and even the 56 kbps modems—quickly proved inadequate to the task of transporting these billions of bits of graphical information, causing many parts of the Internet to react like a two-lane freeway suddenly jammed with a hundred- or thousand-fold increase in the number of vehicles.

The third and perhaps most important trend in the development of the Internet is the proliferation of access points. Until recently, logging on to the Internet has required a fairly sophisticated computer, costing in the neighborhood of $1,000. While this is one-half of what it was just two years ago—this expense has still priced the Internet out of the range of a large share of low- and middle-income families in the United States, not to mention the vast majority of the rest of the world's population.

This high cost of access has combined with the relative inconvenience of using a computer—sitting before a computer, unlike a television, is hardly the most relaxing experience—to restrict the Internet largely to the technologically oriented, well-to-do minority. This is one of the main reasons why many communities have undertaken aggressive public access initiatives to install computers and kiosks at community centers, public libraries, and other public sites to make it possible for people who do not own a computer to use the Internet.

But this situation also is changing. Already, several companies, including Sony and Phillips, have introduced devices that allow people to log on to and browse the Internet directly from their televisions, and the number of such devices is likely to multiply during the next two years, particularly as cable-television companies become more involved in the Internet-access business. Similarly, other companies are beginning to distribute videoconferencing equipment that will allow people to make videophone calls over the Internet to and from their televisions.

As a result of developments such as these, we are quickly reaching the point where the world will be interconnected by a next-generation Internet that allows for instantaneous transmission of text, photographs, and broadcast-quality audio, video, and virtual reality, and not necessarily to expensive computers nor any other new technological device, but rather to the ordinary televisions that are now in place in hundreds of millions of living rooms worldwide.

The Changing Geopolitical Context

These technological changes are taking place at the same time that the world's geopolitical landscape is being radically redefined. No longer dependent upon national governments for policy ideas and information, and no longer content to be bound by the one-size-fits-all pronouncements of national legislators, local leaders are taking social and economic matters into their own hands, pursuing policies that will promote job creation, economic growth, and an improved quality of life within their region, regardless of the policies enacted at the national level.

This reverse flow of sovereignty, by which local governments are assuming more responsibility than ever before for their residents' well being, has come about at a time when information and markets of all types are becoming increasingly globalized. News, currency, and economic and political intelligence—not to mention products and services—can no longer be contained within national borders. Increasingly, they flow, often instantaneously, to all corners of the globe, making it difficult or even impossible for national governments to influence political situations or economic conditions over which, not long ago, they held unquestioned control. The result is a geopolitical paradox in which the nation-state, too large and distant to solve the problems of localities, has become too small to solve the borderless problems of the world.

Locally based companies that once competed with firms only in their own area code, for instance, now must battle companies throughout the world for their customers' loyalty and dollars. Local governments that once had to compete for high-value residents against only nearby municipalities and the amenities they could muster, now must struggle to attract such residents in a world where a growing number of people can live nearly anywhere they want and still have access to the same jobs, the same income, and the same products and services to which they have grown accustomed.

To meet these challenges, many far-sighted localities have begun to transform themselves from fractured, often highly contentious regions in which a thousand interests compete for larger shares of a shrinking pie into something more akin to the city states of old than to the archetypal municipalities of modern-day political-science texts.

Those that are succeeding, such as Smart Valley and San Diego in the United States; Stockholm, Hong Kong, and Infoville in Spain; or Malaysia's Multimedia Corridor possess a number of common features. One characteristic is collaboration among different functional sectors (government, business, academic, nonprofit organizations, and others) and among different jurisdictions within a given geographical region. These collaboratories are fast becoming the new model for successful urban organization in the global age and the only local political arrangement likely to make it possible for besieged municipalities to survive the increasingly intense global competition that lies ahead.

This subtle point is often lost in discussions about building smart communities and even in the implementation of many of the smart community projects themselves. But it could not be more important. Indeed, proponents argue that the more time people spend in cyberspace, the more important real place becomes, and the more civic involvement and the real values of communities—places where common dreams and visions become reality—become apparent to success and survival in this new age.

This new competitive and community spirit, however, will not come about automatically. Communities must develop a coherent and compelling vision that makes it clear how the new information networks are going to promote job growth, economic development, and improved quality of life within the community, and they must communicate that vision broadly. This is the key element that is missing from so many smart community plans today, and yet it is the most essential: for, unless a community knows precisely where it is headed and how it hopes to get there, it is unlikely to reach its destination—to its detriment and to all who are stakeholders in this new but uncertain future.

Toward a Philosophy of Permanence

Fortunately, a new breed of architects, planners, and developers is beginning to pencil in that new vision of cities in the information age. It is a bold vision that deals with the crises of growth and the current development sprawl, while returning to a cherished icon—that of a "compact, close-knit community," according to Peter Katz, author of *The New Urbanism: Toward an Architecture of Community*.

The prospect of a new century, says Katz, raises serious concerns. Former U.S. Vice President Al Gore believes we are on a collision course between our worldwide civilization and the ecological system of the earth.

Many policy wonks agree that the urgency of our dilemma has reached an acute stage. Thus, as we examine our current policies of land development and urban planning, new nonlinear solutions are imperative. The thing that we must remember, urges Katz, is that all of the strategies must be examined, tested, and tested again in relation to prevailing developmental models. Only then can we determine if a new urbanism can indeed be shown to deliver a higher, more sustainable quality of life to a majority of this nation's citizens.

One of the more interesting and exciting aspects of the new urbanism movement is that the next paradigm could well be much more than the return to the close-knit community of the small town with its village greens and mixed-use zoning. It could be a spiritual return to the kind of community enjoyed by the earliest cities.

Tessie Naranjo of the Santa Clara Pueblo in New Mexico defines community as " the human dwelling place." It is where the people meet the needs of survival and where they weave their webs of connections. Native communities are about connections because relationships form the whole. Each individual becomes part of the whole community, which includes not just the human population, but also the hills, mountains, rocks, trees, and clouds.

Until recently, advances in telecommunications and transportation have contributed to our disconnected-ness, rather than cemented us as a people—they have atomized our sense of community rather than provided us a sense of place. Yet without a cultural center, a shared history, or a commitment to neutral goals and visions, there is little to cement communities together.

Chief Sealth, for whom the city of Seattle is named, cautioned: "This we do know: the earth does not belong to man, man belongs to the earth. All things are connected like the blood that unites us all. Man did not weave the web of life; he is merely a strand in it. Whatever he does to the web, he does to himself."

As the World Wide Web becomes part of the web of life, perhaps mankind's technology will ultimately enhance and secure our connectedness to the physical world, preserving and protecting it for future generations. If successful, the smart and sustainable community will dramatically reverse an adverse trend precipitated by the invention of the cotton gin and the industrial revolution that followed, by the automobile and the fifty years of untamed growth and land development, and, worse, by the advance of a rootless culture without a sense of place and will help to lead us out of the spiritual and physical wasteland that we have created.

Conclusion

Many cities—some deliberately, others almost unconsciously—are already benefiting from the "greening" of their cities, the reinvestment in downtowns, and the high-tech information infrastructures of their urban planning.

Because nobody knows for sure what the city of the future will look like—and we are almost never writing on a clean slate, that is, launching a brand new city out of virgin territory—it makes good sense to paint our vision of the future with a broad brush but to be careful to preserve and protect our communities unique character, history, and culture.

For example, we must recognize the value of our existing investments—often downtown and in historic areas of the community wherein lies our "cities' DNA," according to Kevin Starr, historian, author, and California State Librarian. In those vital centers, we must steer both our public and private investments and encourage public/private partnerships to renew and redevelop for an information age.

Downtowns seem to be a particularly attractive haven for redevelopment and attracting the multimedia industries. Denver, with its Beaux Arts Historic Court, is halfway through a decade-long downtown investment of one billion dollars in three sports stadiums, an aquarium, and an urban shopping complex. According to a report by *New York Times* reporter James Brooks, "Denver, following retail and entertainment development downtown, is now earmarking one billion dollars in residential construction. A total of 1,334 apartments is being built or converted downtown, more than the total of the last four years."

A 1999 study by the Brookings Institution, indicated this is part of a national trend, at least in the United States. With mixed-use zoning, libraries, shops, and live/work lofts all within walking distance of one another, these communities are fast becoming the most livable communities in the age of the Internet.

Another aspect of a new agenda entails ending the "fiscalization" of land use—a new term coined to describe the extent to which tax-based concerns drive land-use decisions. Why? All too often, local officials fear that "if pushed too hard for alternatives to sprawl by requesting improvements in a development project, the developer or company involved will sue them or move on to the neighboring jurisdiction," according to Constance Beaumont of The National Trust for Historic Preservation. Beaumont explains in the publication *Smart States, Better Communities* that "given their heavy reliance on property taxes for local revenue, most municipal governments find it extremely difficult to say no to any new development, even if it means losing their identity and even their way of life."

Fortunately, the fundamental shift to a knowledge-based economy and society is fast becoming a reality. This movement, in which wealth creation hinges on our ability to create knowledge-based information products, ushers in a new era in which sophisticated electronic infrastructures allow a wide variety of government, business, and institutional transactions to take place electronically and obviates the need for travel to and from the government agencies and other places of business.

Importantly, too, such infrastructures are what are needed to attract the knowledge industries of the new information-based economy. What we are also beginning to understand is that the smart and sustainable, or livable, communities also attract the knowledge workers themselves, who are migrating to places such as Portland with its urban growth boundary and Seattle with its lakes and trees, and precious open spaces.

The agenda for retooling for the information age is enormous. Education, health care, travel and tourism, art and culture, sports, business, and government all need to be redefined in this new age, and all are vital to creating the "whole-brain" community—responsive to and reflective of the kinds of people that we are and must be to succeed in the knowledge-based global economy challenging us on every front.

Communities that want the economic and social advantages that come with being a smart community must work together to create a new vision of that future for themselves, must use the political process to engage the whole of their community in that effort, and must commit to transforming work and play, government and business for this new age. In a way, becoming a smart community is really not so much about deploying technology to reinvent the community as it is about engaging the body politic to reinvent governing in the digital age.

We have the tools of this new age—computers, telecommunications, and information appliances of all kinds. We have the software, too. Indeed, because of our First Amendment and free enterprise culture, we produce more books, movies, and software programs than any other nation in the world.

But most of all, we need people—each other—and places where culture and commerce, and civic pride are joined—where we are refreshed, energized, and challenged to achieve the best we are capable of. Cities do that; they provide the context for our lives and the fabric of our existence—our actions and our enterprises.

Information-age cities of the future, such as Athens of an earlier age, will be truly smart communities—sustainable, healthy, culturally strong, diverse, and exciting places to live and work, and play.

Heading toward Next-Generation Public Telephony

Enabling Universal Telephony through New Infrastructure Equipment and Signaling Protocols

Didier Heen
Vice President, Marketing and Partnerships
CIRPACK

Operator telephony infrastructures are moving to a new model based on open technologies. This revolution is comparable to the changes experienced by the information technology (IT) industry a decade ago, when mainframes began to be replaced by client-server equipment. At the same time, we are seeing the new broadband local loops gaining market-share. Digital subscriber line (DSL), cable, local-area network (LAN), wireless, etc., are more suitable for service providers in order to offer both high-speed Internet access and voice communications at a low cost.

However, neither telecom operators nor their customers will switch to "next-generation" protocols and infrastructures overnight, but rather over several years, if not decades. Due to massive investment done over the years in old-generation equipment, service providers are asking for technologies that enable smooth migration of both legacy infrastructures and services to the open packet-telephony model. This is how service providers will save on costs while offering more value to customers and increasing profitability.

1. From Circuit to Packet-Based Infrastructures

Over the past 30 years, telecom operators around the world have heavily invested in time division multiplexing (TDM) equipment, building hierarchical, circuit-based infrastructures. In this legacy model, the local-exchange switch provides three main functions in one box:

1. *Subscriber Connectivity:* Analog, integrated services digital network (ISDN), and V5 LE for concentration
2. *Subscriber Services:* Providing dial tone and handling class services such as call waiting, call transfer, command line interface (CLI), etc.
3. *Core Network Connectivity and Services:* E1, signaling system 7 (SS7), and transit functions

Public TDM switches were developed in the early-1970s for state-owned Post Telephone and telegraph Administrations (PTTs) so as to provide high connectivity but basic phone services. These machines are very robust and provide high-quality voice services. However, TDM technologies are now showing their age. They are based on proprietary hardware and software that are expensive to maintain and upgrade. Introducing new services is a long, difficult, and costly process. In addition, TDM is not compatible with the new broadband local loops such as DSL, cable, wireless, or LAN, which are all based on packet technologies.

Hierarchical TDM architectures are also reaching their limits. Since each switch has to handle all the complexity of a carrier's infrastructure, more subscribers lead to more central processing units (CPUs) for services and more interfaces for wires. Equipment costs do not scale down over time, but rather continue to increase when taking on new customers. This has become very critical with the increasing use of dial-up Internet access, and this is not to mention the complexity of transit network sizing and the ineffective use of bandwidth in both the local loop and the transit networks.

Next-generation networks (NGNs) have been developed to overcome these limitations. The main features and benefits of NGNs are as follows:

- Voice and data are carried over the same transport and access networks, as packets of data rather than circuits. This allows for dynamic bandwidth allocation between voice and data services and makes much better use of resources. The transmission network is easier to scale and to maintain, and services can be provisioned more quickly.
- Intelligence needed to provide voice services is centralized rather than disseminated, reducing investments for edge devices. This accelerates network deployment to reach new customers and provides greater flexibility to upgrade or introduce new services, whatever the local loop (DSL, fixed wireless, cable, LAN, etc).
- Switching tasks are distributed rather than centralized. Voice and data are carried directly to their destination

without affecting the processing power of other equipment or loading transmission networks as in the hierarchical public switched telephone network (PSTN).

- Network equipment use open technologies and standard protocols, rather than being tied to proprietary designs. Equipment interoperates with other NGN devices, making service providers independent of a given vendor or technology. They benefit from a large choice of vendors, greatly accelerating the development timeframe and making new features easier to develop and deploy.

2. New Concepts for Voice Infrastructures

NGNs have led to the creation of new concepts for voice infrastructures, where the main functions are split into different boxes (see *Figure 1*).

The Transport Layer
The main roles of the packet phones and phone concentrator (gateways) are as follows:

- To transform voice into packets
- To terminate edge signaling
- To provide additional features, such as echo cancellation and voice compression

The Control Layer
The main roles of the device called the media gateway controller (MGC), or softswitch or gatekeeper, are as follows:

- To control the call process
- To control signaling and edge devices
- To provide subscriber and transit services
- To interface various devices with each other so as to provide advanced services

The Application Layer
The main roles of the application servers are as follows:

- To provide advanced services
- To manage service activation and mediation
- To interface with the operations support system (OSS)

The softswitch controls distributed gateways via an Internet protocol (IP) command network independent of the transport network, which is using TDM, asynchronous transfer mode (ATM), or IP transport protocols (see *Figure 2*). While the softswitch handles the entire call process and delivers basic services to subscribers (dial tone, call waiting, CLI, etc.), it needs access to external servers in order to handle advanced voice services (Centrex, virtual private network [VPN], universal messaging, phone conferencing, prepaid services, etc.).

By offering a total network layer abstraction to the control layer, this architecture opens the door to universal telephony. Operators now have the competitive advantage of being able to connect any local loop, at any time, when new opportunities arise and to provide the same services to all subscribers. By using application servers, operators can easily introduce innovative services, developed in-house or via any third-party vendor complying with industry standards.

3. Signaling as the Key to Interoperability

Signaling is the key to making universal telephony a reality. For service providers to connect any type of local loops together with any type of core network, softswitches and gateways must implement, understand, convert, or relay multiple TDMs and packet-based protocols. Building an NGN, while preserving old-generation equipment and services and maintaining interoperability with the networks of other operators, is giving rise to three different signaling challenges:

1. Transparently carrying ISUP/SS7 and ISDN protocols over IP to maintain existing services
2. Managing pure end-to-end IP telephony signaling in order to introduce innovative services and devices
3. Enabling calling between circuit (TDM) and packet (NGN) telephony devices

TDM Signaling Transparency over a Packet Network
SIGTRAN
Signaling transport (SIGTRAN) has been developed by the Internet Engineering Task Force (IETF), the international

FIGURE 1

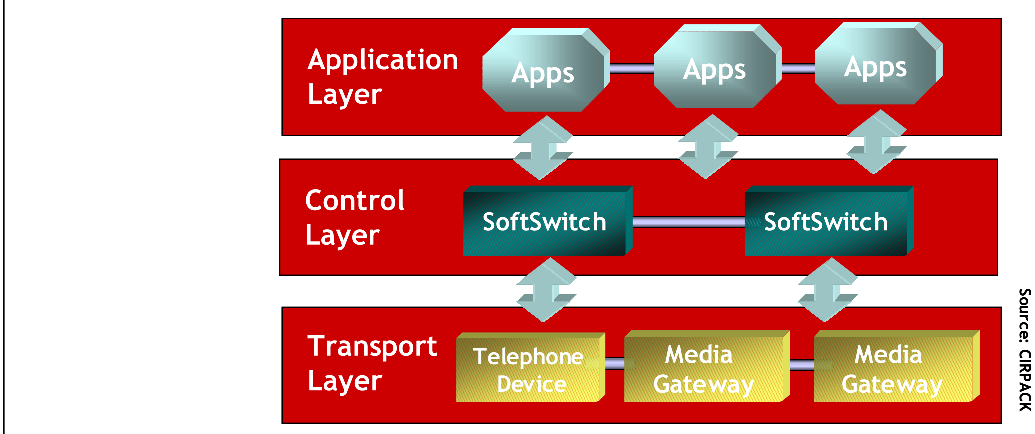

FIGURE 2

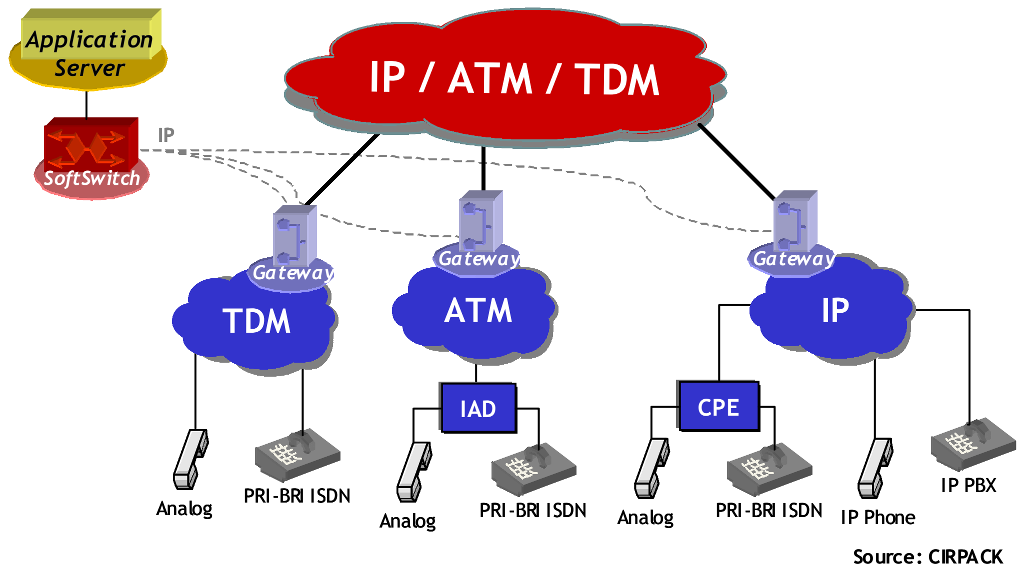


body responsible for the IP. SIGTRAN defines a suite of protocols (see *Figure 3*) enabling IP networks to transport PSTN signaling, such as ISDN (Q.931) or SS7 messages (IDSN user part [ISUP], signaling connection control part [SCCP], etc.), between IP nodes such as gateways, softswitches, IP–based databases, etc. It is a critical protocol to allowing the NGNs to support and interoperate with legacy services and equipment. The three main components of SIGTRAN are simple control transport protocol (SCTP), M2UA, and M3UA.

SCTP is a new transport protocol designed as an alternative to transmission control protocol (TCP) and user datagram protocol (UDP), aiming to carry signaling messages reliably over IP networks. M2UA and M3UA are two of SIGTRAN's adaptation sub-layers, supporting specific primitives required by a particular signaling application protocol. Other adaptation sub-layer protocols defined by the IETF include M2PA, SUA, and IUA.

H.248
In Geneva, on August 4, 2000, International Telecommunications Union–Telecommunication Standardization Sector (ITU–T) Study Group 16, which is responsible for multimedia services and systems, and the media gateway control (MEGACO) Working Group of the (IETF) agreed on a single standard for the control of IP/PSTN gateway devices: H.248.

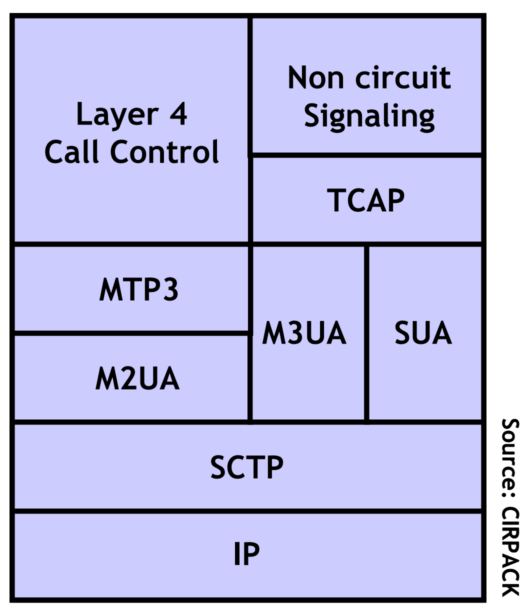
The new standard supports gateway devices passing voice, video, fax, and data traffic between conventional telephone and packet-based data networks, such as commercial IP networks or the Internet.

The unified support of H.248, from the IETF and ITU–T, facilitates scalable and seamless implementation of services and applications over circuit-switched and IP–based networks. As a result, H.248 now dominates gateway control protocols.

ISDN Transport over Packet
The association of H.248 and SIGTRAN enables ISDN signaling to be transported to the softswitch over packet networks (see *Figure 4*).

SS7 Transport over Packet
The association of H.248 and SIGTRAN enables SS7 signaling to be transported to the softswitch over packet networks (see *Figure 5*).

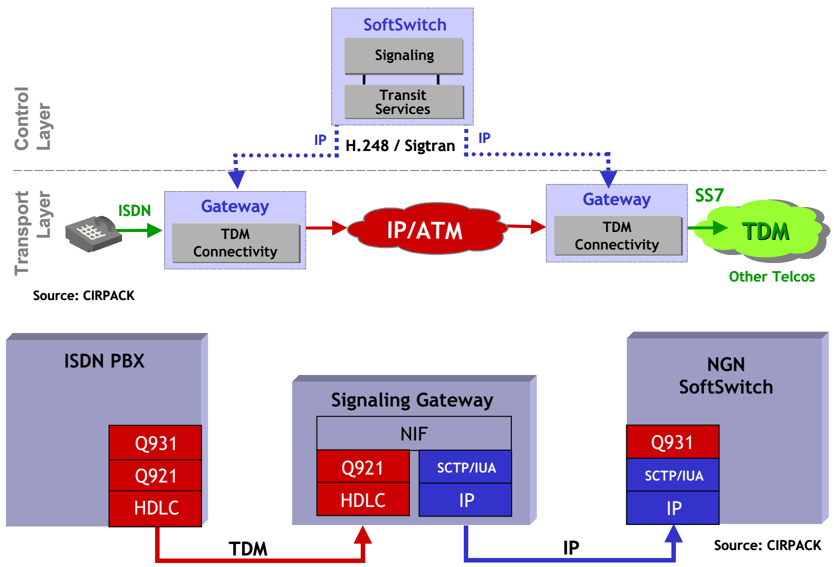
FIGURE 3



SIGTRAN Protocol Stack

FIGURE 4

SIGTRAN allows transparent transport of ISDN signaling over IP, and H.248 is the protocol controlling the gateway.



Signaling between Softswitches

The inter softswitch signaling must also support transparent transmission of SS7. SIP for telephone (SIP–T) enables ISUP messages transmission between softswitches.

SIP–T provides ISUP message transmission transparency across PSTN/IP connections. Traditional telecommunications services such as call waiting and 800 numbers are supported via SIP–T ISUP message translation.

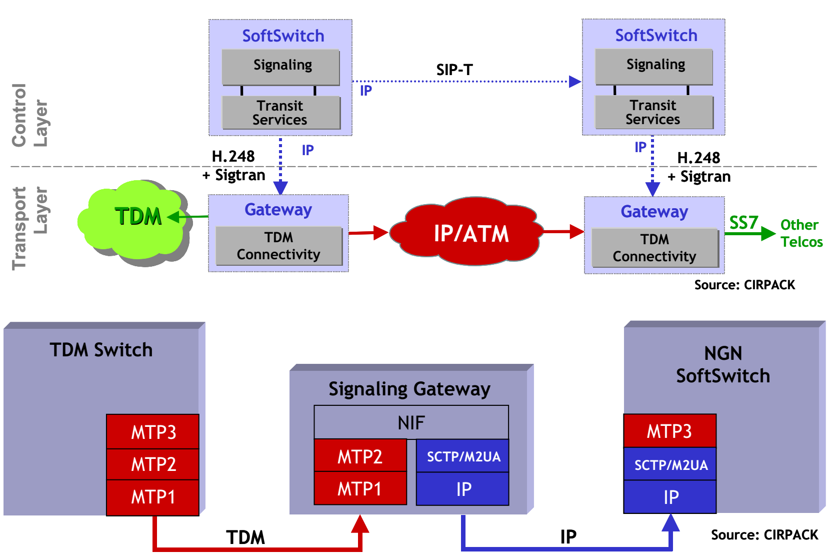
Handling Pure End-to-End IP Telephony Signaling

Session Initiation Protocol

Session initiation protocol (SIP) was developed by the IETF and is a text-based control protocol for creating, modifying, and terminating multimedia sessions on an IP network, such as multiparty Internet conferencing and Internet telephony sessions. It supports real-time communications from simple audio calls to complex multimedia sessions. SIP supports unicast and multicast capabilities, is independent

FIGURE 5

SIGTRAN allows transparent transport of SS7 signaling over IP, and H.248 is the protocol controlling the gateway.



of the lower-layer transport protocol, and can be readily extended with additional capabilities.

In an IP telephony call, SIP can locate the called party and determine its capabilities. SIP supports mobility by creating proxies and redirecting requests to the location of the user. This allows the implementation of intelligent network (IN) features, such as name mapping, call forwarding, and call redirection. SIP address messages are formatted as human-readable text, which is compatible with the Internet address message format—also human-readable text.

With its scalability, flexibility, and performance characteristics, SIP is a leading contender for carrier-quality public IP–based telephone networks.

Media Gateway Control Protocol
Media gateway control protocol (MGCP) is a device control protocol that provides the means to interconnect a large number of IP telephony gateways, allowing them to work together as one (see *Figure 6*). MGCP is not an industry standard, and, due to a number of factors including its limited voice over IP (VoIP) networking functionality, is not expected to become one. However, MGCP eliminates the need for complex, processor-intensive IP telephony devices, simplifying them and lowering their cost.

MGCP and SIP are used by the softswitch to perform call control to IP telephony devices. Using MGCP, SIP, and H.248 to transmit analog phone traffic over a packet network, softswitch can also control the customer-premises equipment (CPE) or gateway.

Universal Telephony Signaling
By implementing a mixture of SIP, SIP–T, H.248, and SIGTRAN (plus MGCP in some cases), telecom operators can support all circuit and packet-telephony applications for perfect interoperability of their infrastructures with old and new services and networks of other providers (see *Table 1*).

4. Convergence Ahead

NGNs are gaining momentum in the telecommunications field. Not only do NGNs allow universal telephony, but

FIGURE 6

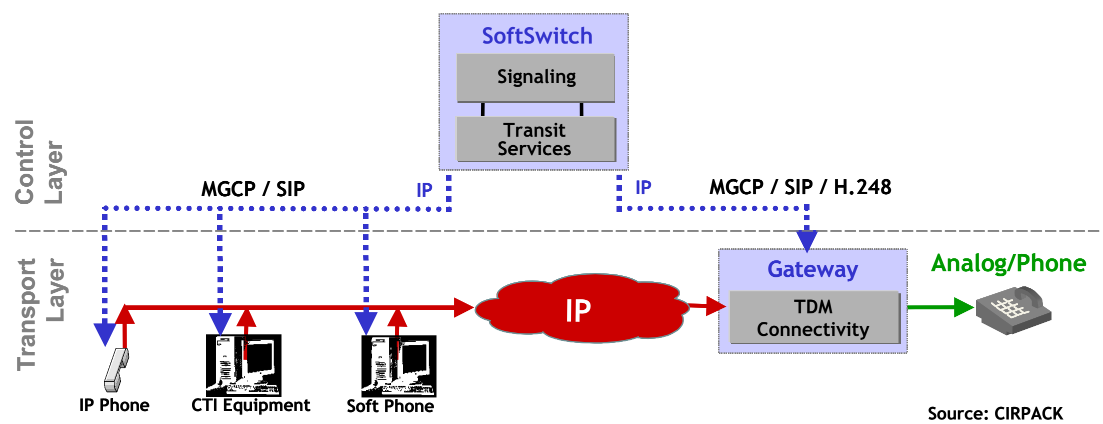


TABLE 1

Signaling for Use between Edge Device and Softswitch	SIP	MGCP	H.248	H.248 + SIGTRAN
IP phones	Best Fit	Best Fit	Feasible

they are also essential for service providers in order to leverage their data networks and to increase profitability by offering innovative converging services. Powerful protocols are now available to ensure perfect interoperability between legacy circuit-switched public networks and NGN packet-based infrastructures and to maintain service continuity between users connected to various local loops and operators.

Operators that have massively deployed TDM technologies can move to NGNs while preserving investments and the customer base. New entrants, such as Internet service providers (ISPs) owning packet infrastructures, can now easily offer a full range of voice services at a fraction of the cost by deploying signaling gateways and Class-5 softswitches. The race to NGN is now open, as it allows the introduction of new breeds of services to catch the minds of subscribers—and their money. The current success of broadband Internet access, and the inevitable rise of local-loop unbundling, will accelerate deployment of NGNs.

The Future of IP Services

Greg Howard

Principal Analyst and Founder

The HTRC Group, LLC

1. Executive Summary

Internet protocol (IP) services represent an increasingly large opportunity for service providers, information technology (IT) companies, and enterprises. Yet the expense and inflexibility of current network solutions continue to constrain the market for IP services.

Network service providers (NSPs) continue to witness an explosion in data traffic. Yet generating high-margin revenue and creating unique customer value from selling pure access and bandwidth remains a challenge. NSPs are examining how to break out of traditional access service models and into high-margin IP services.

Application service providers (ASPs) have been offering IT outsourcing to enterprise customers for some years. However, this form of outsourcing often requires expensive private or leased network arrangements to meet network quality needs. Although the Internet provides a cheaper delivery alternative, performance and security are uncertain.

Enterprise customers desiring advanced IP services typically make expensive capital and networking investments, limiting the penetration of IP services across the industry. Competitive companies continue to focus on their core and strategic competencies while outsourcing IT applications and services. Several factors, however, constrain the outsourcing trend, including service flexibility, concerns over service quality and security, and expensive network access arrangements.

All consumers and suppliers of IP services will benefit from a service-delivery architecture that addresses fundamental business requirements. Network connectivity between ASPs and consumers needs to be as reliable and secure as private leased-line networks with the affordability of the Internet. In addition, enterprise customers want the flexibility to purchase and consume advanced IP services when required, without expensive IT and networking infrastructure.

A new architecture for advanced IP services will consist of partnerships between three suppliers: the service portal, the ASP, and the NSP. The architecture reflects the well-established business relationships between retailer, wholesaler, distributor, and end-customer.

Service portals are easy-to-navigate, point-and-click, Web-based interfaces that let customers order any number of advanced IP services—such as unified messaging (UM), software rental, or videoconferencing. The service portal is the retail storefront for advanced IP services.

ASPs sell wholesale advanced IP services to the service portal, which then retails the service to the business customer. ASPs focus on their core IT outsourcing competence and not on network services nor on marketing. With broadband service deployments solving bandwidth bottlenecks, ASPs will offer a broad range of attractive applications that will take the form of advanced IP services, such as voice over IP (VoIP) and videoconferencing over IP.

NSPs own the service networks that connect business customers to the service portals and ASPs. This distribution infrastructure allows consumers to obtain services that they have purchased from the service portal and that originate from the ASP. NSPs will deploy quality and security mechanisms in the IP network to offer secure applications across an affordable Internet infrastructure.

Through the examples of video and data conferencing, this document will show how all three players in the service-delivery architecture can profitably address the demand of enterprise customers for future IP services.

The result of the next revolution in IP services will be the delivery of outsourced applications to the enterprise market. NSPs, ASPs, and service [ortals will capitalize on the multi-billion dollar high-margin IP services revenue opportunity. The new architecture introduced in this paper provides a structure for delivering the next generation of IP services.

2. IP Services

Undeniably, business applications and services have gravitated to a common application and networking protocol—the Internet protocol. This section describes the current characteristics of business consumers and suppliers in this evolving IP services market, with the intent of articulating the key requirements of a future architecture to address the existing shortcomings.

2.1. Examples of IP Services

IP services are going beyond today's Web-site and e-commerce applications to provide advanced services of ever-increasing value to business around the world. Advanced IP services include the following:

- Integrated voice and data applications
- Videoconferencing
- Document storage and back-up
- Outsourcing of mission-critical applications
- Software rental
- UM
- Computer telephony integration (CTI)
- Network-based training services

Many of these applications and services are available in various forms today. However, their implementations are typically capital intensive and lack flexibility, resulting in limited deployment to a few early adopters. In addition, an inherent lack of end-to-end performance inhibits wide-scale deployments of these applications across the Internet.

2.2. Enterprise Customers

In the 1970s and 80s, a few large companies were able to achieve strategic advantage through enterprise-wide applications, but the implementation of IT strategies required costly investments in networking and data-processing technologies. While these infrastructures provided process automation across the enterprise, they were expensive to maintain and inflexible to changing business conditions.

Even as the costs of basic networking and applications continue to decrease, the costs of skilled IT staff to keep systems operating and properly maintained are increasing. Additionally, most chief information officers (CIOs) want to focus on the competitive advantage brought by information strategy and not the "bits and bytes" of information technology.

These trends have motivated many CIOs to focus capital and resources on core and strategic competencies and to outsource non-strategic IT applications and services. Companies no longer have to operate large and expensive data centers and private voice and data networks in-house.

This move toward outsourcing points to an even greater latent need: the unmet demand for guaranteed, secure, flexible, and affordable IP–based applications and services.

2.3. Service Providers

2.3.1. Application Service Providers

First-generation ASPs have been offering IT application outsourcing for some years. Many ASPs provide scale economy benefits to their customers by sharing the costs of expensive data-center mainframes, databases, and infrastructure across many customers. Hence, customers can save money through outsourced data-center arrangements, compared to operating dedicated data centers in-house. However, these initial offerings have been limited in their flexibility, as most arrangements required multi-year commitments. In addition, expensive dedicated networking arrangements have typically been required to meet service-level guarantees to each customer site. As a result, the expense and commitment associated with traditional outsourcing has essentially limited the market to mid-sized and large enterprises.

Web hosting ranks as one of the more common IP application services offered today. The explosion of Web-based content and services has permanently transformed the way businesses interact with their customers and partners. A notable advancement in Web hosting has been the re-architecting of large, mission-critical applications into so-called "thin-client" IP applications. Thin client applications minimize bandwidth usage through communications between client workstations and centralized application and data servers. Companies such as Arepa.com and Interliant AppsOnline have adopted thin-client technology and are already offering applications for rent over an IP network.

While ASPs are achieving success in offering services over expensive private networks or via existing best-effort Internet networks, the IP services industry will explode when quality guarantees can be offered across the Internet. The market will take off when a broad range of enterprise-class IP services is within the reach of small to mid-sized companies. Offering end-to-end guarantees for service quality is necessary to support advanced IP services. For ASPs to increase their revenues and market-share, future IP services will need to be "bundled" offerings of both network and application components. The offerings must be easy to purchase, with flexible billing and configuration arrangements. Business customers will subscribe to applications that are tightly coupled with reliable, secure delivery. Ordering and using the service will be as easy as placing a phone call.

2.3.2. Network Service Providers

NSPs continue to witness an explosion in IP data traffic. To address these demands, today's providers offer a plethora of data-network access and bandwidth options.

NSPs are starting to offer affordable virtual private network (VPN) services based on IP technologies. Most businesses understand a data VPN's fundamental benefits: facilitating communication with customers, suppliers, and partners, and reducing wide-area network (WAN) costs by using public networks rather than expensive leased-line networks. Businesses can use VPNs to connect employees, work sites, and external organizations (including outsourced data centers). VPNs based on IP technologies have significant cost benefits relative to dedicated ATM or frame-relay offerings. However, IP technologies are currently limited in their ability to support bandwidth guarantees.

While IP traffic continues to grow exponentially, generating high-margin revenue and creating unique customer value from selling pure bandwidth remains a challenge. Competitive pressures and technological advances have long since chiseled away the high margins on data access and bandwidth. Although NSPs are filling their networks with bandwidth due to ongoing improvements in broadband access technologies, the revenue produced from that bandwidth is relatively small compared to voice services and the margins are being eroded.

NSPs need to shift their focus to selling high-margin data-application services, analogous to the multitude of enhanced voice services (e.g., call waiting, messaging, voice-mail, voice conferencing, 1-800 numbers, etc.) that are offered to business customers along with basic voice transport.

To capture their share of future IP service revenues and margins, NSPs will need to overcome customers' concerns regarding IP bandwidth guarantees and security. NSPs will also need to offer on-demand configuration of IP VPN connectivity for network-based IP services to address the rapid, unpredictable pace of business today.

3. Requirements for Future IP Service Delivery

Business consumers and service suppliers will benefit from an infrastructure that supports the following common requirements: guaranteed quality of service (QoS), security, and on-demand subscription.

3.1. Guaranteed Quality of Service

In this paper, guaranteed QoS refers to the IP network's ability to deliver deterministic performance from end to end, measured by a number of specific parameters including bandwidth, delay, and jitter.

Standard IP QoS mechanisms (e.g., DiffServ) do not apply to specific applications or users, limiting the utility of these standard measures for granular control of mission-critical applications or for high-profile users. In contrast, guaranteed QoS will be delivered and measured by user and by application.

Another important distinction is that guaranteed QoS must be offered across the complete network connection—from the ASP to the business customer's local-area network (LAN). While ASPs typically offer service-level agreements (SLAs) within their areas of control (i.e., the data center) and NSPs typically offer SLAs between the edges of their core networks, what business consumers require is guaranteed QoS from the ASP data center to the business location.

3.2. Security

Security over IP networks has received a great deal of attention across the industry. Unlike frame relay, ATM, or private-line services, IP networks do not assign a "dedicated" physical or logical circuit between applications or users. Fortunately, the industry is making progress on security mechanisms across IP networks. Using tunneling technologies (IPSec), encryption algorithms (DES, triple–DES, Blowfish), key-exchange algorithms (Diffie-Hellman), and authentication mechanisms, security is being addressed. Business consumers can feel increasingly confident that sensitive business information can be securely transmitted across an IP network.

3.3. On-Demand Subscription

Another common requirement is the on-demand subscription, provisioning, and activation of future IP services. This capability allows the enterprise to respond quickly, with minimal cost, to new and unforeseen business needs. All the components of the architecture must facilitate this objective, including the dynamic provisioning of the appropriate guaranteed QoS and security starting from the ASP, across the NSP's network, to the enterprise consumer.

On-demand subscriptions must also be supported by usage-based billing mechanisms—much like pay-per-view movie services offered by cable television (CATV) operators. The cable network is similar to the IP network in that both are transparent to the subscriber. Customers will subscribe to advanced IP services and not to the transport and application infrastructure. Instead of purchasing bandwidth (e.g., 56K, T1, T3) users will be able to subscribe to a collection of services ranging from renting applications to scheduling videoconferences as needed.

4. A New Architecture for IP Services

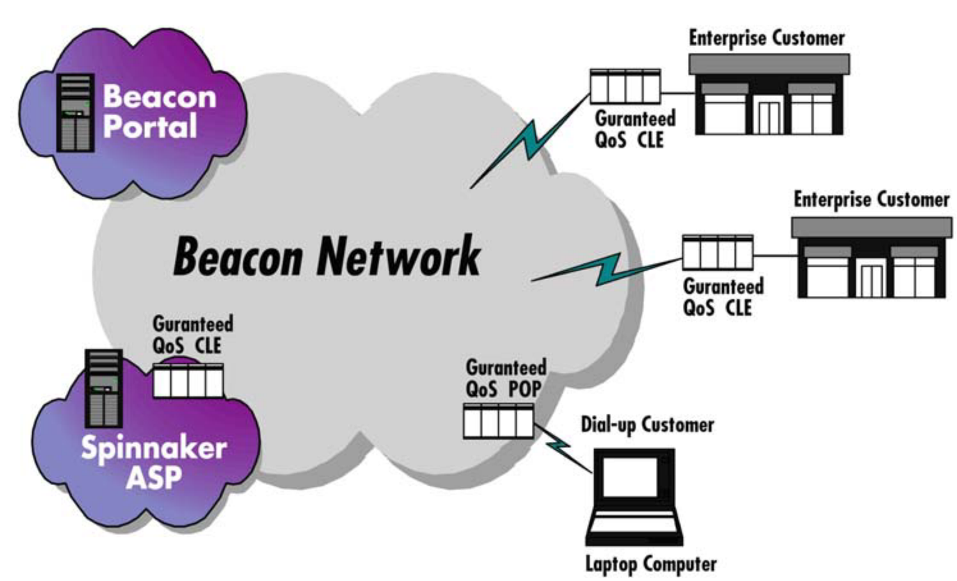
The objective of this section is to provide a guide for service providers on implementing a new architecture to support the on-demand subscription of advanced IP services.

4.1. The Three Partners in the New Architecture

Three partners have unique roles in supplying advanced IP services to enterprise customers in the proposed architec-

FIGURE 1

New Architechture for Delivering IP Services



ture: service portals, ASPs, and NSPs. *Figure 1* shows the three partners working together. The architecture reflects the well-established business relationships between retailer, wholesaler, distributor, and business consumer. To illustrate the relationships, fictitious names have been assigned to the different elements. Beacon Network Services, Inc. is an NSP that operates both the service portal (Beacon Portal) and the service network (Beacon Network). Spinnaker, Inc. is an ASP.

4.1.1. Service Portals

As has been said, service portals are the retail storefront for advanced IP services. They are easy-to-navigate, point-and-click, Web-based interfaces that let business consumers order from a number of advanced IP services, such as UM, software rental, or videoconferencing. Service portals deliver advanced IP services based on the bundling of required resources from both application and NSPs. In addition, service portals provide the first line of technical support and customer service for advanced IP services.

4.1.2. Application Service Providers

ASPs provide advanced IP services to service-portal customers and act as wholesalers to the service portals. With broadband service deployments resolving bandwidth bottlenecks, ASPs focus their core IT competence on providing a growing range of applications, including VoIP and videoconferencing.

4.1.3. Network Service Providers

NSPs are the distribution component of the IP services architecture and own the QoS–enabled network infrastructure that connects business consumers to the service portals and ASPs.

To guarantee QoS for each application, a service demarcation point at the customer's location is recommended. The LAN/WAN boundary is a queuing point, making it the best place to perform policy management and to guarantee performance and security. Secure, guaranteed QoS will work best with a new class of customer-located equipment (CLE) at each business location. By managing and operating CLE for broadband services and point of presence (POP) equipment for dial-up services, the NSP can control security and guaranteed QoS features for a myriad of advanced IP services.

4.2. Service Portals

4.2.1. Business Strategy

Beacon Portal—the service portal—generates revenues by offering advanced IP services to enterprise customers. Beacon Portal's core competency is marketing IP services to customers. Beacon Portal's key challenge is attracting and retaining customers to new services.

Advanced IP services will consist of the bundling of two wholesale service components. ASPs, such as Spinnaker, will provide the application services while NSPs, such as Beacon Network, will offer the network-connectivity services. In essence, Beacon Portal takes advantage of an arbitrage opportunity between wholesale and retail pricing while adding value in exceptional service bundling, customer care, and billing/settlement capabilities.

To combat competition and minimize churn, Beacon Portal will differentiate itself through the creation of "sticky services"—advanced IP services with a strong potential for retaining existing business customers as well as attracting new ones. For example, a sticky service is an integrated voice and data application. A Web site can be enabled with IP telephony so that a customer browsing the site can talk "online" with a live service representative. The Web site would have a guaranteed QoS connection to service representatives in order for users browsing the Web site to communicate effectively. Beacon Portal may also focus on vertical markets, such as financial, medical, or manufacturing sectors.

4.2.2. Service-Portal Operations

Implementing a service portal requires the development of close business and technology relationships with business consumers, ASPs, and NSPs. Beacon Portal will need to integrate its service-order systems with its wholesale providers. Service portal operational systems will use open, standards-based technologies to best integrate with NSPs and ASPs. The objective is to support on-demand subscription to the application and network resources required for the service.

In this example, business consumers order conferencing services on-demand through Beacon Portal's interactive, Web-based service portal. The service portal automatically contacts the NSP and the ASP to ensure service-resource availability. Once resource and service availability have been confirmed, Beacon Portal provides its customer with a service confirmation message and a password to allow access to the service. When the service has been activated, the conference participants can log on to the ASP for the videoconferencing call over guaranteed QoS network connections provided by the NSP. *Figure 2* shows Spinnaker providing services to enterprise customers.

4.2.3. Billing and Settlement Mechanisms

Service portal operations will also require integrated billing and settlement mechanisms with its wholesale service providers. Beacon Portal collects usage information from the network and bills the customer, retaining its fee and sending settlement notices to Beacon Network for the network resource used and to Spinnaker for provisioning the videoconference service. Providing a unified bill is a competitive advantage, solidifying the customer relationship. In the service architecture, Beacon Portal provides the unified bill.

Figure 3 shows revenue flow from the enterprise customer to Beacon Portal, which then pays settlement fees to Spinnaker and Beacon Network.

4.2.4. Managing the Customer

Beacon Portal is responsible for managing first-level customer-support operations. When a problem occurs, the business consumer first contacts Beacon Portal, which attempts to diagnose the problem through the integrated network-monitoring and trouble-management systems it maintains with its partners. If Beacon Portal's first-level support team cannot resolve the problem, they escalate the issue with the appropriate partner to take action and restore service.

4.2.5. Financial Example

Beacon Portal provides the retail storefront for advanced IP services. Beacon Portal offers Spinnaker's on-demand video- and data-conferencing services over Beacon Network's guaranteed QoS network services.

FIGURE 2

Conferencing Subscription

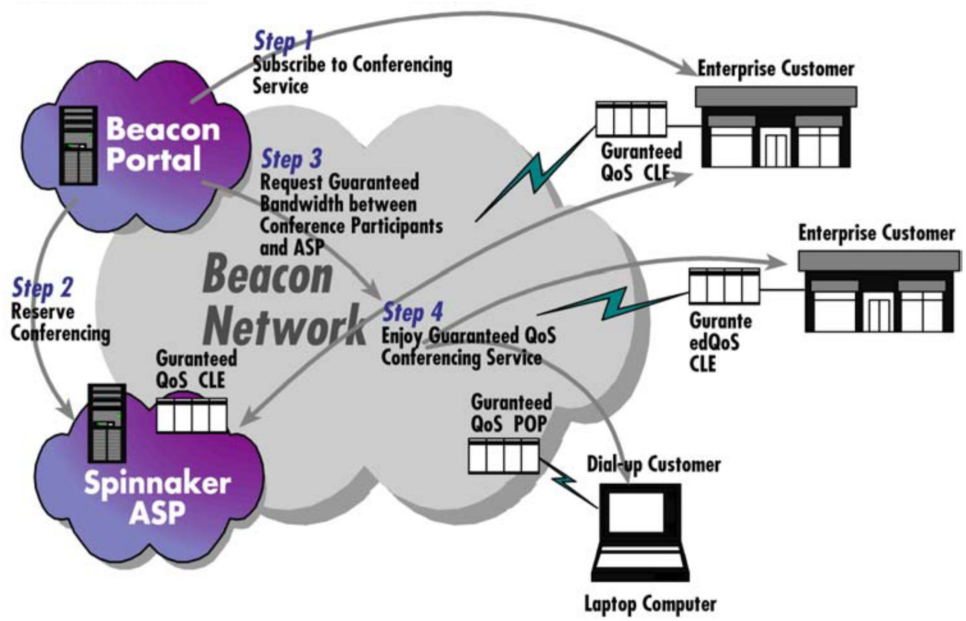


FIGURE 3

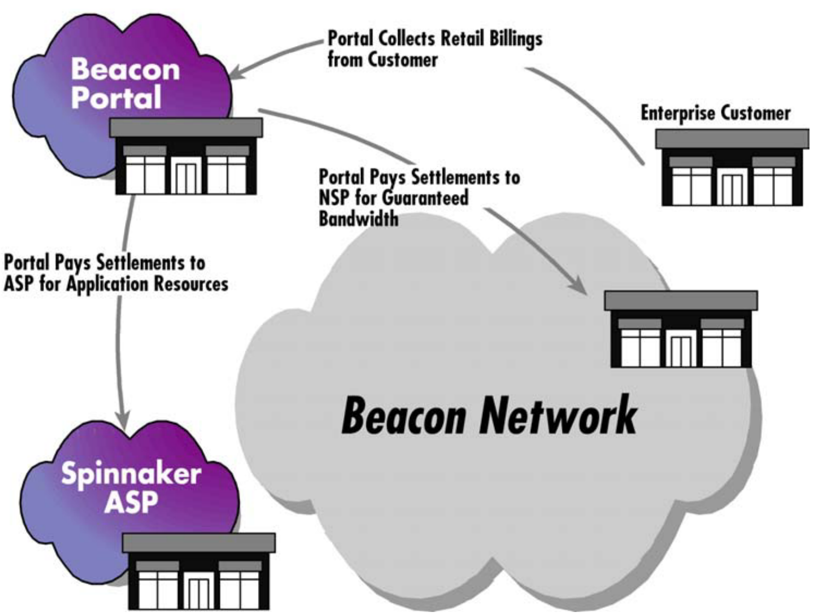
Billing and Settlements



All of the financial examples presented in this document identify revenue, cost of sales, and gross profit over a three-year period. The assumptions used in the creation of all examples were based on feedback from service providers and portal companies, and on extrapolations from industry trends. The examples are intended to be used as a guideline only. Actual costs, revenues, and return on investment (ROI) may vary.

Common conferencing-service assumptions across all examples include an 8% adoption rate of existing customers being serviced by a large NSP. Customers use the conferencing service an average of 30 minutes per day.

Beacon Portal assumptions include the following:

- Retail revenue is based on charges of $0.35 metered rate per minute.
- Cost of sales includes settlement charges to Beacon Network and Spinnaker, support costs, and amortization of capital investments ($650,000 for Web Server,

customer care, on-demand service ordering, and billing and settlement systems).

4.2.6. The Bottom Line

As the retail storefront of the delivery architecture, Beacon Portal's revenues are substantial. Remembering that this financial example represents only one of what will be many services, the opportunity exists to generate significant revenues and cash flow.

The largest costs are the settlements paid to the ASP for the conferencing service and to the NSP for guaranteed QoS connectivity. After settlements, the largest operational cost is support, as Beacon Portal provides first-line support for its subscribers. The net margins, after sales, general, and administrative (SG&A) expenses following the first year, are around 8%.

Beacon Portal quickly recovers its initial capital investment of $650,000 for a billing and settlement system, customer-management software, and portal Web servers.

The cost of sales is high and the margins are relatively low compared to those of ASPs and NSPs, because Beacon Portal's business is an arbitrage opportunity between business customers and wholesale suppliers (ASPs and NSPs).

Like any retailer with wholesale suppliers, the service portal's business model is based on cash flow and volume. Beacon Portal has the largest revenue of the three partners because it is charging retail prices to end customers.

4.3. Application Service Providers

4.3.1. Business Strategy

ASPs specialize in providing network-based applications and services. In the example, Spinnaker partners with Beacon Portal to gain access to retail customers. Spinnaker generates wholesale revenue by delivering advanced IP services to the service portal's customers. Spinnaker relies on Beacon Portal to bundle and provision the guaranteed network connectivity for Spinnaker's advanced conferencing services. Spinnaker, a wholesaler of advanced IP services, can partner with many service portals to maximize its customer base.

Spinnaker's core competency is server-farm and application management. Spinnaker faces the challenge of building partnerships with application developers, portals, and NSPs. Application developers provide content and services for ASPs to host.

Historically, the relatively high cost and commitment associated with traditional outsourcing has limited the market to mid-sized and large enterprises. By lowering these barriers, the new architecture opens ASPs to a wide range of customers, from small businesses to large corporations.

PictureTel provides a real-life example of a developing ASP business in the context of the proposed architecture. PictureTel's IP–based videoconferencing application is being used by Enron Communications to deliver conferencing services to users. Enron is both the NSP and the service portal. PictureTel plans to offer its suite of conference applications through Enron to enterprise and service-provider customers.

4.3.2. Service Requirements

Applications may require that certain service characteristics, such as bandwidth and latency, be in place to fulfill the business customer's expectations. Spinnaker defines the service and specifies the required IP security and guaranteed QoS parameters required to support the service across the network. This is a one-time activity performed and negotiated with the service portal. Once the service definition is established, the service portal can support thousands of subscriptions to a single definition.

ASPs can offer a range of service-quality guarantees. For example, an ASP could specify three levels of service quality and security:

1. Real-time priority would be required for latency-sensitive applications such as voice over packet or videoconferencing. This quality level requires a low level of latency (e.g., less than 60 ms).
2. Mission-critical priority could be for applications less sensitive to latency but requiring strict security and encryption requirements. ASPs can assign a mission-critical quality level to enterprise resource planning (ERP) applications. Distinguishing ERP traffic from best-effort traffic guarantees that large data back-ups and file transfers do not interfere with ERP processing at critical times.
3. Best-effort priority could be assigned to applications such as data back-ups or e-mail. This level of service would be the most economical for non-latency dependent applications.

Spinnaker also specifies the parameters required to provision the service (e.g., IP addresses), how to bill for the service (e.g., $/minute of use), and what guaranteed bandwidth is required across the network (e.g., 356 Kbps per conference attendee).

TABLE 1

Beacon Portal Buisness Model

($000s)	Year 1	Year 2	Year 3
Revenues	$11,464	$63,086	$146,421
Cost of Sales	$8,987	$48,482	$112,240
Gross Profit	$2,477	$14,604	$34,181
Percentage of Revenues	22%	23%	23%

Once the service definition is agreed upon with the service portal, the integrated on-demand order processing software will reference this definition. This software system will forward the parameters for quality and service requirements, along with user-defined variables (e.g., IP addresses) to the ASP for application resources and to the NSP for IP network connectivity.

4.3.3. ASP Operations

ASPs host applications and make them available to business users. ASPs may develop their own applications and application content, or they may partner with application developers. Most of the ASPs provide IT hosting and outsourcing. Some ASPs also venture into software development, converting existing applications, such as ERP, to function as networked interactive applications. IT outsourcing companies see an opportunity in adapting to an on-demand provisioning business paradigm. And application developers view the ASP business as a new way to distribute applications to users, targeting new market segments facilitated by developing network technologies.

In the example, Spinnaker has established integrated provisioning, trouble-management, and settlement systems with Beacon Portal. Beacon Portal's relationships with the Beacon Network provides Spinnaker with the infrastructure that enables services to be delivered with true end-to-end QoS and security guarantees, extending service-quality commitments beyond Spinnaker's data centers.

4.3.4. Managing the Applications

Service problems that arise are initially identified and resolved by the service portal. When required, complex application problems are escalated and subsequently resolved by Spinnaker. To identify, track, and facilitate the resolution of problems, Beacon Portal integrates network-management systems and trouble-ticketing applications into the ASP infrastructure.

Customer-billing information is sent from Spinnaker to Beacon Portal, allowing the service portal to track usage and billing information.

4.3.5. Financial Example

Spinnaker, Inc. assumptions are as follows:

- Wholesale settlements are based on a $0.15 metered rate per customer minute from Beacon Portal.
- Cost of sales includes support and amortization of capital investments (conferencing servers, CRM software, billing and settlement systems, integration, and data-center facilities).

4.3.6. The Bottom Line

The wholesale revenues for Spinnaker's video- and data-conferencing services are significant. Remembering that this financial example represents only one of what could be many services, the opportunity exists to operate a profitable ASP.

Costs are dominated by the amortization of capital investment. In the example, Spinnaker makes a $3,750,000 investment for server-farm facilities, servers, conferencing software, billing and settlement systems, and integration. This initial investment accounts for the lower gross margin in the first year. Ongoing SG&A costs will likely be low because of the partnership with Beacon Portal, being that the service portal will bear most of the marketing and customer-acquisition costs, and will sell services directly to customers. Additional ASP costs will include developing new or enhanced application service offerings and building partnerships with application developers, portals, and NSPs. In the financial example, the net margins are 33% in the second year and 36% in the third year.

The financial model indicates that ASPs can expect significant margins on their revenues.

4.4. Network Service Providers

4.4.1. Business Strategy

NSPs provide on-demand IP network-connectivity services between business consumers and ASPs based on the security and guaranteed QoS parameters specified by the ASP for their particular service. Beacon Network provides access and bandwidth services. However, the commoditization of transport services means that the NSP must seek to support advanced IP services across its networks to benefit from the higher margins that these services can command.

The new architecture for delivering IP services enables Beacon Network to partner with third-party service portals and ASPs to deliver advanced IP services. NSPs can offer network-based services, such as voice over packet and VPNs, as well as network services packaged with application services offered by ASPs, such as software rental or data back-up services. Advanced IP services further drive bandwidth and application usage, increasing guaranteed QoS bandwidth consumption and thereby increasing Beacon Network's revenues.

Beacon Network's core competencies are operating a large network and maintaining guaranteed QoS connectivity to a

TABLE 2

Spinmaker, Inc. Business Model

($000s)	Year 1	Year 2	Year 3
Revenues	$4,913	$27,037	$62,752
Cost of Sales	$3,687	$13,818	$30,200
Gross Profit	$1,226	$13,219	$32,552
Percentage of Revenues	25%	49%	52%

significant number of customers. Beacon Network's key challenge is partnering with as many service portals and ASPs as possible to maximize its share of connectivity revenues for future IP services.

An actual example of an NSP operating in the new architecture is Enron Communications. Enron is an NSP that delivers high-bandwidth products and services to its customers. Enron has overbuilt its network to provide performance and has integrated intelligence into the network to deliver advanced IP services. Enron can define security and QoS on a per-application basis and it has partnered with companies such as PictureTel to offer advanced IP services designed to attract new customers and retain existing ones. Enron Communications' advanced IP service offerings include delivering live television content, videoconferencing, streaming video, distance learning, network-hosted applications, and new forms of entertainment. Enron Communications offers these advanced IP services to both broadband enterprise and service- provider customers.

4.4.2. NSP Operations

When business consumers order advanced, on-demand IP services through Beacon Portal, the service portal forwards the necessary service-provisioning information to Beacon Network. For pure network-based services (e.g., on-demand IP VPN connectivity), Beacon Network will provision guaranteed QoS connectivity between the requested locations. For ASP–based services (e.g., conferencing), Beacon Network will provision guaranteed QoS connectivity between the ASP's data center and the consumer location.

The NSP will require an on-demand provisioning system that can automatically configure the QoS requirements into the CLE based on subscription requests from Beacon Portal.

The integrated systems among Beacon Portal, Beacon Network, and Spinnaker provide the foundation to deliver guaranteed end-to-end QoS and security.

4.4.3. Technology Alternatives for an NSP

To offer advanced IP services, security and QoS must extend to the customer's location and must assign network resources by user or by application. Providers are just starting to implement QoS technologies, such as multiprotocol label switching (MPLS) and DiffServ, on their backbones today.

The network for delivering advanced IP services will be transparent to the business consumer and may include a variety of technologies and protocols such as asynchronous transfer mode (ATM) and IP routing utilizing copper, fiber, and wireless communications services. Both IP routed networks and ATM networks have advantages and disadvantages. Operating on Layer 3 of the open systems interconnection (OSI) model, IP routing is more common and relatively easy to maintain. The IP routing QoS mechanisms, however, are not yet deterministic. Operating at Layer 2 of the OSI model, ATM QoS mechanisms are more evolved and deterministic. ATM, however, is more complex to operate and maintain.

Most NSP networks will likely include a combination of both ATM and IP routing topologies, which together must be equipped to provide end-to-end service guarantees for advanced IP services.

4.4.4. Managing the Service Network

The service portal will identify and resolve service problems that arise. When required, Beacon Portal will escalate complex network problems to Beacon Network. To identify, track, and facilitate the resolution of problems, Beacon Network integrates the service portal's network-management systems and trouble-ticketing applications into the NSP infrastructure.

Customer billing information is sent from Beacon Network to the service portal so that Beacon Portal can track all usage and billing information. Hence, integrated settlement systems will be required.

Because the NSP owns and manages the infrastructure that supplies IP services to end users, it can provide service-level reporting to business consumers, service portals, and ASPs.

4.4.5. Financial Examples

Beacon Network generates revenue in two basic areas: basic access to the guaranteed QoS network and fees for the transport of usage-based advanced IP services. For simplicity, guaranteed QoS and advanced IP services opportunities are examined separately in this model.

1. The first financial example examines Beacon Network's investment and return for the basic access service to the guaranteed QoS network, including CLE.
2. The second financial example examines the business case for delivering an advanced IP service over the guaranteed QoS network.

TABLE 3

Beacon Network Guaranteed QoS Access Buisness Model

($000s)	Year 1	Year 2	Year 3
Revenues	$5,525	$29,660	$68,142
Cost of Sales	$6,016	$19,843	$42,006
Gross Profit	$491	$9,817	$26,136
Percentage of Revenues	–9%	33%	38%

4.4.5.1. Financial Example—Guaranteed QoS Access
Beacon Network assumptions are as follows

- Beacon Network has an existing QoS–enabled network backbone.
- Revenue from basic access services to the guaranteed QoS network assumes 2,000 customer connections added over a three-year period.
- Revenue sources include recurring access charges to the guaranteed QoS network and CLE installation fees.
- The cost of sales includes guaranteed QoS–enabled CLE, on-demand service activation operations support services (OSS), monthly local-loop circuit and leased equipment, installation, and OSS provisioning integration.

4.4.5.2. The Bottom Line—Guaranteed QoS Access
The financial example is typical of a broadband IP access service. Although revenues are significant and growing, margins will continue to be squeezed. Continuing to offer only basic access and bandwidth services does not present the most compelling business case.

The cost of sales includes capitalization of CLE and local-loop equipment, and expenses for CLE installation and support. Costs also include the capitalization of first-year investments, including $5 million for initial billing, on-demand service-activation OSSs, and systems integration. The first-year loss is largely due to the cost of integrating critical operations and provisioning systems. In the model, the net margins after the first year will increase from 7% in the second year to 18% in the third year.

The key value of the service network is the foundation that is created for high-margin revenues from the transport of advanced IP services.

4.4.5.3. Financial Example—Connectivity for Advanced IP Services
Beacon Network assumptions include the following:

- Wholesale settlements based on an $0.08 metered rate per videoconferencing customer minute and a $0.03 metered rate per secured data-conferencing customer minute from Beacon Portal.
- The cost of sales includes guaranteed QoS bandwidth between ASP conferencing servers and customers connected to the service network, as well as support and network operations.

4.4.5.4. The Bottom Line—Advanced IP Services
Although wholesale revenues from guaranteed QoS transport are expected to be less than the wholesale revenues generated by the ASP, the revenues and margins for Beacon Network are still significant. It is important to remember that this financial example represents only one of what will be many advanced IP services transported across the network. In addition, the revenues created by the delivery of advanced IP services are incremental—over and above existing access and bandwidth income generated by typical MNSPs today.

The incremental costs of additional bandwidth provisioned across an installed network infrastructure are quite low. Support costs are low because Beacon Portal is handling level-one support. Ongoing SG&A costs will likely be low

TABLE 4

Beacon Network Business Model

($000s)	Year 1	Year 2	Year 3
Revenues	$2,138	$11,766	$27,309
Cost of Sales	$1,163	$4,602	$10,152
Gross Profit	$975	$7,164	$17,157
Percentage of Revenues	46%	61%	63%

TABLE 5

	Core Competency	Revenue Magnitude	Gross Profit
Spinnaker ASP	Information Technology	Medium	Medium (52%)
Beacon Portal (Service Portal)	Marketing	Large	Low (23%)
Beacon Network (NSP)	Networking	Medium for Access Large for IP Services	Medium (38%) High (63%)

because of the partnership with Beacon Portal. In the model, the average net margin is about 36% over the first three years. This net margin is much higher than the margin for pure access.

5. The Result

Table 5 summarizes the key findings for the service portal, ASP, and NSP in the proposed architecture and illustrates the tremendous gain for all players in terms of core competency, revenue magnitude, and gross profit.

Enterprise customers will leverage the latest networked applications in an on-demand, pay-as-you-go format, with little incremental investment. Advanced IP services offer a viable and attractive outsourcing alternative to internal IT initiatives that are capital and resource intensive. Small and medium-sized enterprises, which previously could afford neither extensive internal IT departments nor high-end outsourcing, now gain access to a range of valuable IP services.

The three architecture partners will capture an increasing share of corporate IT spending by addressing the common requirements of guaranteed bandwidth, security, and on-demand service activation. The combination of services created by partnerships generates customer loyalty and reduces churn.

The architecture allows each player to focus on its core competency in turning the vision of advanced IP services into a reality.

IP Intelligence in the Access Platform

Jean Huppé

Director, Network Technology Development
Bell Canada

For the purposes of this paper, Internet protocol (IP) intelligence shall refer to IP services, particularly IP Layer-3 routing functions. Access vendors are incorporating more IP Layer-3 functions into their platforms. Typically, these new intelligence services are centralized in routers or boxes and implemented in the network core. However, IP Layer-3 routing functions are being pushed toward the network edges as an increase in demand for them emerges. This paper examines whether IP Layer-3 routing functions should be kept at the network edge or integrated into access platforms. Furthermore, it will address alternative approaches for delivering IP intelligence in the access platform.

Functionalities

Access vendors have worked hard to develop basic asymmetric digital subscriber line (ADSL) functionality and good digital subscriber line access multiplexer (DSLAM) capability. They now seek to add value to those products by incorporating more IP Layer-3 functions into their platforms, such as broadband–remote access servers (B–RAS), multicast functionalities, and voice softswitch gateways. The reality is that access vendors consistently introduce new ideas to service providers. *Figure 1* indicates the core, edge, and access layers of IP intelligence.

The core layer refers to the area of main concentration, and the edge refers to peripheral central offices (CO). The access layer serves as a link to customers. More mature functionalities, such as B–RASs, have been used for a couple of years and can be deployed in the DSLAM or at least very near to it. Multicast functionalities are also mature but are not traditionally integrated into the DSLAM further than the B–RAS location because point-to-point protocol over Ethernet (PPPoE) already connects to the B–RAS. Other Layer-3 service functionalities are being developed, such as multiprotocol label switching (MPLS) and IP virtual private networks (VPN) for business customers. Those functionalities are still being implemented in the network core but are being pushed to the edge. Eventually other functionalities will include a voice gateway softswitch and a voice over IP (VoIP) softswitch. More mature technologies are easier to interoperate between vendors and platforms, and standards for these technologies are also more mature. *Figure 2* illustrates the maturity level of various technologies.

However, many leading-edge technologies are less mature and proprietary in nature. It is often difficult to interconnect these less mature technologies to multiple vendors, as interoperability is often sacrificed for the sake of differentiation and speed to market.

Multiple Access Platforms

Incumbent local-exchange carriers (ILEC) have already deployed a series of different platforms in their networks and will continue diversification to deliver IP services to residential and business customers (see *Figure 3*).

Multiple generations or vendors of the same technology type may also be deployed. However, problems do arise when multiple access platforms are used to deliver IP services to the customer. For example, there is a need for many different types of platforms, such as DSLAM, very-high–data rate digital subscriber line (VDSL) in a multiple-dwelling unit (MDU), residential fiber-to-the-home (FTTH), business passive optical network (PON), and direct fiber. Multiple access platforms are likely to have several access vendors per platform for relationship diversity—it is possible that platforms such as ADSL will have two or three vendors in the next 5 to 10 years. In such situations, vendors may work well with one type of platform but not with others, which will obviously affect performance. Over the long term, the same vendor may also end up with different generations of products in the field. Bleeding-edge technologies have limited features and have a potential of a few years. Leading edge technologies may never have all the necessary features but have a potential of three to five years in the field, and mature technologies have a potential of 5 to 10 years in the field. For example, service providers might already have two generations of DSLAM in the field, such as standard-density and high-density DSLAM. Some advanced IP functionalities will be supported on the high-density generation but not on the standard-density generation. Therefore, multiple generations of products could exist even within the same platform and with the same vendor.

Distributed Intelligence

The advantages to distributed intelligence include rapid treatment of quality of service (QoS) and functionalities that are closer to customers. However, the disadvantages of distributed intelligence include the necessity for interoperability between multiple vendors. For example, if Layer-3 IP intelligence is distributed into each of those platforms, the same basic functionalities must be provided for different

FIGURE 1

Introduction

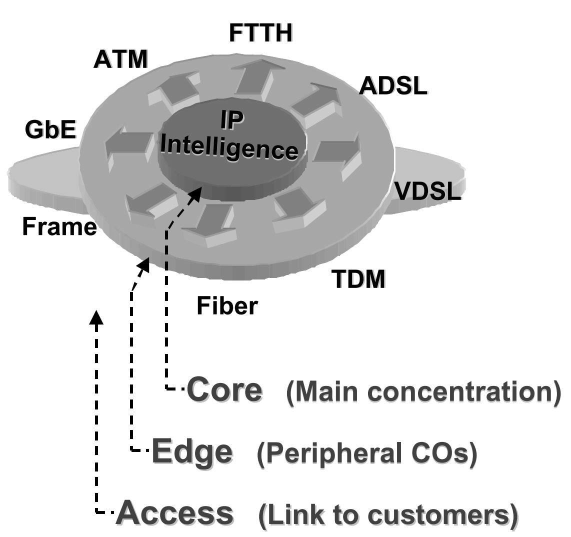


FIGURE 2

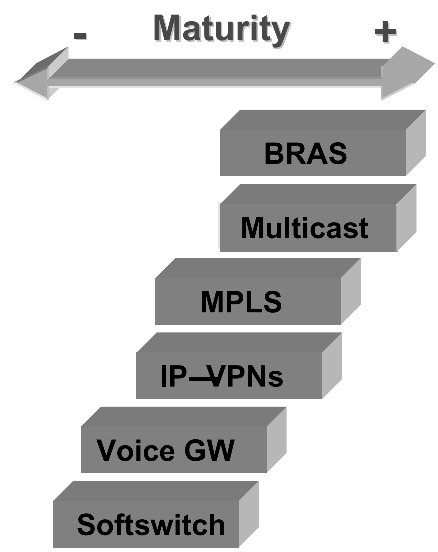
Prevalent IP Functions



platforms, vendors, and generations of products. In addition, if an IP VPN service over MPLS is to be provided, it is essential to the customer that it looks and acts the same from any platform. *Figure 4* illustrates this point.

The disadvantage of distributed intelligence is that the availability of functions will not be the same. Each of those platforms indicated in *Figure 4* must be able to connect to different backbones in the network. For example, service providers with multiple backbones might have asynchronous transfer mode (ATM) for DSL, a multiprotocol label-switching (MPLS) backbone, and gigabit Ethernet (GbE) resilient packet rings (RPR). There are different access and different backbone platforms, which makes it difficult to fit those functionalities inside each of those platforms, an obvious disadvantage. In the end, distributed intelligence leads

FIGURE 3

Multiple Access Platforms

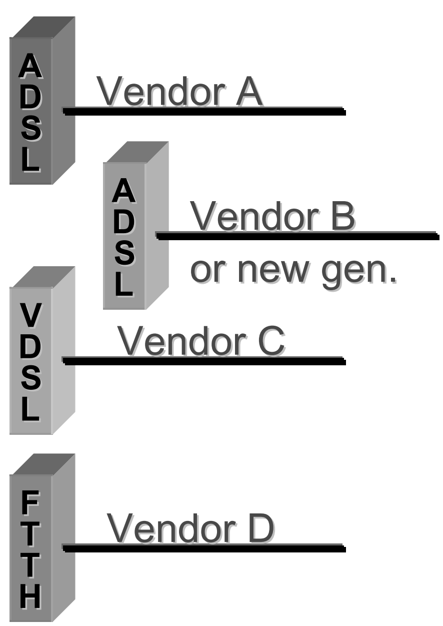


FIGURE 4

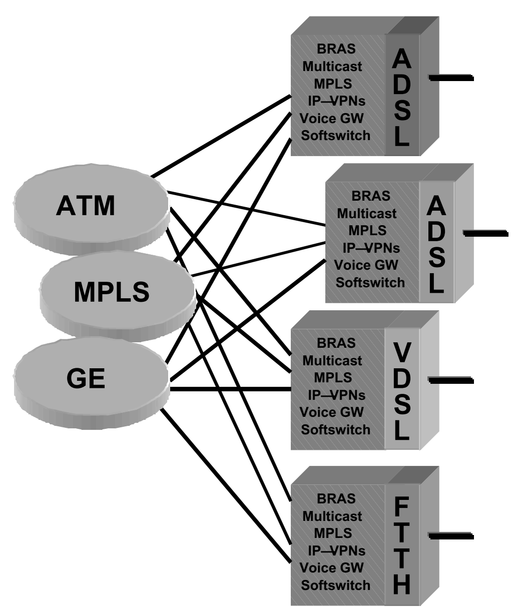
Distributed Intelligence



to more complex operations and more complex information services (IS) and information technology (IT).

Centralized Edge Intelligence
Another option would be to centralize those functionalities, placing them at the edge of the network and thus keeping them separate from the access platforms. This keeps those access technologies fairly independent of the Layer-3 functionality. The advantages of centralized edge intelligence include simplified management and uniformity of IP functions. It is easier to select a best of breed vendor of a particular IP function without being biased by the connectivity layer. Edge intelligence is independent of new access platforms, as it is not necessary to have functionalities connected to access platforms. Connectivity to the backbone network is thereby simplified (see *Figure 5*).

The main disadvantages to centralized edge intelligence include the addition of another box in the network and the potential for bandwidth bottleneck.

Super-Box Concept
Another solution would be to have a single box that could deliver everything from ADSL and VDSL to fiber to the home. It could also connect to all types of backbone infrastructures. This concept can be applied more easily in a competitive local-exchange carrier (CLEC) and data local-exchange carrier (DLEC) environment where the market is focused and people start from scratch. It is more difficult in an incumbent local-exchange carrier (ILEC) environment where there are a number of legacy access platforms delivering IP connectivity. *Figure 6* illustrates the super-box concept.

This super box does not function well in networks with multiple platforms, product generations, or vendors. Ultimately, even CLECs might have problems maintaining this super box in the network.

Conclusion

Good Layer-2 technology might be what is truly needed in the access platform. With limited bandwidth, it is necessary to have good QoS and class-of-service management capabilities. Mature functionalities, such as B–RAS or multicast, could be included in the access platform and not just beside it if they provide efficiency. In the access platform, it is advisable to avoid bleeding- and leading-edge Layer-3 functions that would incorporate proprietary developments by specific vendors unless it is the only access platform. An approach that is too decentralized will increase costs and should be avoided in the access platform.

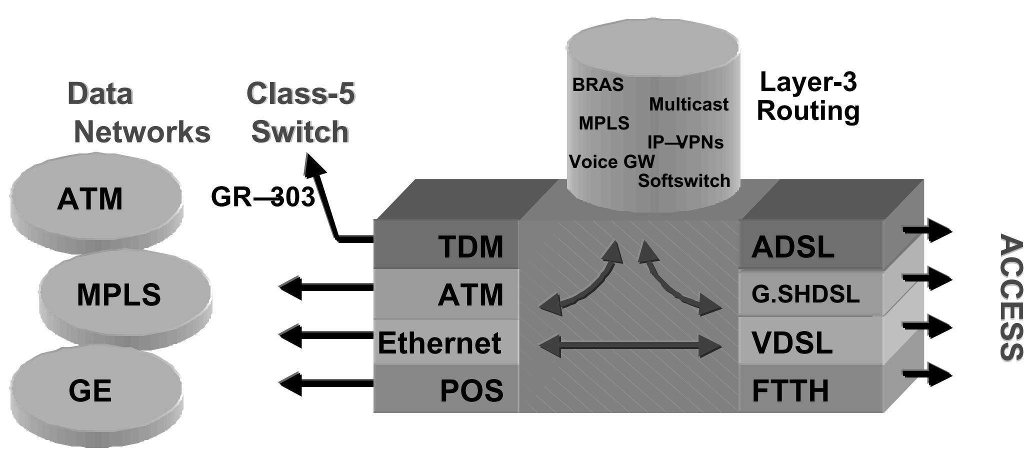
Super-Box Concept



IP Telephony Interoperability: What It Takes to Be Carrier-Ready

Michael K. Kaczocha

Senior Engineer, Voice Evaluation and Research Team

AG Communication Systems

Introduction

Internet protocol (IP) telephony systems commonly claim interoperability with one another but don't go into much detail regarding what interoperability means. One of the main topics of conversation within the vendor community during the last few months has been the lack of progress with carriers and other customers in moving beyond non-revenue trials. These two are related. To have an offer that is ready for full deployment, it must perform as well as traditional equipment.

To verify that customer-premises equipment (CPE) devices provide the feature set, stability, administrative capability, and conversation capability required to become a recommended product for customer use on the iMerge Centrex feature gateway (CFG), the device must undergo a series of tests and real-life applications prior to being qualified. The tests and live-use applications performed on these products are broken into three phases: 1) iMerge CFG to CPE interoperability, 2) voice quality, and 3) internal employee trial.

The first two phases of testing are performed in a controlled laboratory setting where all aspects of the testing are under the control of the test person. The third phase of testing, the internal employee trial, involves subjecting the CPE device to real customers (company employees) by providing them the device for use in their normal day-to-day telephone activities. Using these three testing and equipment application environments when testing each of the qualified devices assures those customers who purchase the iMerge CFG and utilize the qualified CPE devices that the iMerge CPE solution will provide a level of service that satisfies all needs and expectations.

The CPE devices that undergo qualification testing are divided into five categories: 1) analog IP phones, 2) integrated services digital network (ISDN) IP phones, 3) analog access gateways, 4) ISDN access gateways, and 5) softphones. Each category of devices has its own set of test suites that are executed for that device type.

Prior to CPE vendors' submitting their device for qualification testing, documentation is provided that defines the expected operation of the CPE device when connected to an iMerge CFG. This document provides specific signaling/message-handling guidelines for the multitude of voice path set-up, configuration, and maintenance messages that can be presented to the CPE device over the packet network. In addition to the signaling characteristics document, the CPE manufacturers are provided a functional specification document that defines the expected operation of the device. These documents are used as the foundation for generating the test suites used during qualification testing.

Interoperability Testing

The first phase of testing undertaken is interoperability testing. Interoperability testing is designed to prove that the device can be configured and administered by a system administrator, that the device is capable of performing a predefined feature set, that it is stable, that it provides reliable operation, and that it can be maintained in a live customer environment. To prove these factors, the tests include the following:

- Registration capabilities
- Signaling capabilities (in-band, out-of-band)
- Q. 931 compliance
- Subjective conversation capability
  Place real calls from the device being tested to various network terminations (e.g., device being tested to a plain old telephone service [POTS] analog telephone)
- Verification that product aspects that influence voice quality and general operation have been addressed. In cases where traditional telephony standards exist, they are used.
  - Echo cancellation
  - Dial-tone delay
  - Ringing delay
  - Ring-back tone delay
  - Flash/on-hook delay
  - Differentiates services (DiffServ) tagging
  - Comfort noise
  - Packet loss
  - Packetization rates
- Verification of conversation capability at supported compression rates

- Basic telephony capabilities (e.g., flash, voice-mail message-waiting indicator, hold, three-way calling, distinctive ringing, speed dial, redial, etc.)
- Administrative capabilities
- Provisioning capabilities
- Security
- Test load simulation (for gateway type devices)

Using an automated call generator, it is determined how well the devices perform under repeated call originations and terminations. The performance of the device is measured according to its lost-call rate (For every 10,000 calls provided to the device, how many calls were completed?). IP endpoints are tested with an eye toward the same standards of performance as traditional endpoints.

Voice-Quality Testing

The second phase of testing involves evaluating the voice quality of a device. How humans perceive sound and, in turn, judge voice quality is not straightforward enough to allow voice quality to be easily or accurately measured solely with objective test methods. The voice-quality evaluation approach includes both subjective and objective testing, but overall emphasis is placed on subjective testing, since voice quality is subjectively perceived.

For subjective voice-quality testing, experienced/expert listeners, who are trained to listen for and identify impairments in voice quality, are used. This method has advantages in that it provides judgment as to general voice quality as well as providing additional information as to the actual impairments heard and surrounding circumstances. This also allows further investigation and problem resolution and provides the information needed to test updates to the product to validate impairment resolution.

Objective methods are used to measure an attribute or combination of attributes related to voice quality by using test equipment. Objective tests are good for pointing out potential problems and are excellent tools for analyzing impairments and their root causes.

The iMerge testing approach incorporates several individual objective measures, such as delay and loss, but does not rely solely on the objective predictors because of their known shortcomings and lack of informative results.

To ensure a user's perception of voice quality is addressed, voice-quality evaluation is separated into three testable components. These components are voice clarity, echo, and delay.

Because subjective conversational testing is the most straightforward and expedient way to obtain initial voice-quality measurements, in most cases the evaluation starts with this type testing. Also, there are some impairments that may only show up in conversation testing.

Examples of some of the voice-clarity problems identified in this phase of testing are as follows:

- Distorted speech
- Speech too loud
- Speech not loud enough
- Clipping of speech or noise (in double-talk situations)
- Clipping of speech or noise (without double-talk)
- Echo
- Awkward conversation interaction—delay
- Lack of noise, feels like connection dropped
- Extra annoying noise(s)
- Fluctuating speech or noise levels

An additional conversational test method used for evaluating voice quality and for reproducing impairments is the recorded conversational method (RCM). For RCM testing, digitally recorded two-way conversations between various types of voices (e.g., male-to-male, male-to-female, female-to-female) are played through the system, and the resultant listening path is digitally recorded. The digital recording of the listening path is then played back and analyzed for perceptible quality degradations.

The initial testing for determining whether echo is a problem is accomplished through the conversation tests mentioned in the voice-clarity section. Another method used is the composite source signal (CSS) echo loss test. This test is performed by playing a digital recording into the device under test, recording the return listening path and analyzing the recording for instances of echo. A G.168 echo loss test is also used for echo detection. This echo loss test varies slightly from the CSS test in that it tries to match the echo loss test mentioned in G.168 documentation.

To measure the delay component of voice clarity, periodic measurements are taken, and then an average is calculated. Test equipment that utilizes a recorded signal rather than a pulse to measure delay is the primary method used. For this, test a signal that contains many different properties of speech is delivered in a single recording. The recorded .wav file analysis method is also used for measuring delay. This test is performed by simultaneously playing a digital recording (pulse followed by speech) into the path, recording the listening path on both ends of the connection and analyzing the recordings using a software program.

Other factors that can influence voice quality and which are considered during voice-quality evaluation are as follows:

- Packetization rates
- Jitter buffer
- Codecs
- Voice packet loss
- Voice packet jitter

Internal Employee Use

The third phase of testing CPE devices involves subjecting the device to a real-life environment where real users (company employees) utilize the CPE device for everyday phone use.

In the case of analog IP phones and ISDN IP phones, the users normal desk phone is replaced by one of these devices, which is then used as their normal telephone. The IP phone is connected to an iMerge CFG and then to the Centrex switch, which provides their telephone services. For analog and ISDN access gateways, the normal desk phone will be routed to the gateway and then to the iMerge CFG, which is connected to the building Centrex switching system. For both the IP phone and the access gateway application, the user will continue to use the same telephone features that he or she has used up to the point of converting to the new connection.

Internal field trials for softphones are handled in a very similar manner. Employees are provided the software and hardware, where applicable, and they utilize the device in a direct local-area network (LAN) hook-up or in a remote dial-up environment. For remote dial-up applications, the user/employee is provided a connection to a building modem pool, which provides access to the iMerge CFG and the company Centrex switching system, thereby providing he or she with the same telephone services that he or she would have while working in the office. The Centrex switch used in the employee trial is a live switch that has all of the characteristics of a switching system that would be utilized in a live customer environment.

During the trial period, the end users are solicited to provide information regarding performance and satisfaction level. In addition to obtaining valuable feedback from real users, very important information regarding application guidelines (e.g., how to configure the device in a non-lab network) is obtained. The internal trial is a very important part of the testing. It provides the confidence that each CPE device and the features associated with that device can operate in a real-world environment.

Conclusion

By subjecting a CPE device to the comprehensive battery of testing discussed, a robust solution can be demonstrated to a carrier whose customers have high expectations of the reliability and quality of their communication systems. Many IP telephony systems have not met those expectations; they have been plagued by poor reliability, limited functionality, and disappointing sound quality. Carriers are looking beyond the hype attached to voice over IP (VoIP) and are measuring the performance of these products to the same standards as traditional systems. A testing regimen such as that described provides assurance that the “table stakes” attributes of reliability and quality of service (QoS) are available.

Many vendors will further evaluate equipment on human factors and other traits, which are also critical in the carrier arena. These do not fall under the realm of interoperability and are not addressed in this paper, but a vendor would do well to look beyond the scope of this paper if they expect to achieve broad deployment by a carrier.

The Dilemma of Digital Transition

H. Steven Klein

Vice President, Business Development

Tut Systems

1. Introduction

1.1. Problem Statement

As the Post Telephone and Telegraph Administration (PTT), regional Bell operating companies (RBOCs), and telecommunications operators begin offering digital video services, they are faced with some key economic and technical obstacles in trying to create a competitive model against embedded cable television (CATV) service providers. With two-way digital cable systems, the fixed capital cost to pass each home is very high in relation to customer-premises equipment (CPE) and in-home installation costs. On average, infrastructure capital costs are about two-thirds of the cable operator's installed cost percentage, and the combined CPE and in-home installation costs are about one-third. This is due to the cable operator's need to pass every home, whether or not service is taken.

The phone-company service provider looking to enter the video arena and compete with cable operators using digital subscriber line (DSL) technology face the opposite problem than that of the cable operator. The nature of DSL access systems allows system capacity to be engineered to a planned take rate rather than pass every home. Therefore, the telco service provider has low fixed capital costs to build the DSL network to support video.

However, all video and data services in the home are digital, unlike a two-way cable system that has both analog and digital channels. Therefore, a set-top box (STB) is required at each television. According to recent surveys, the average U.S. home has 2.3 television sets. This implies that in order to offer a complete video service, telco operators need to provide three STBs to a majority of homes. And the various distribution schemes in the home to distribute services digitally to appliances often require extensive in-home wiring. The end result is the telco operators sees one-third of its capital costs in fixed infrastructure and two-thirds in the variable CPE and in-home wiring costs on an installed-cost basis.

Because the cable operator has such high fixed capital costs for infrastructure, take rates and churn become critical factors to profitability. Cable operators focus a great deal of time and effort on capturing and keeping as many customers as possible. In the past, the typical 15 percent annual churn experienced by cable operators has had a direct and negative impact on profitability.

On the other side of the coin, telco operators must enter a market already served by cable operators and offer competing services with hopes of taking customers away from the incumbent. The low infrastructure capital costs favor them in that regard. But once the customer is won, they must absorb a higher cost to place STBs in the home and perform installation.

This paper looks at the issues and problems related to CPE in the home and at the in-home wiring options for the telco operator offering a bundled video and data service using DSL. It examines the issues, as well as the alternatives and solutions, as they relate to making a successful business case. It attempts to identify the most economic ways to deliver a whole home solution with DSL.

1.2. CATV Background

Until recently, CATV systems were analog only, and therefore did not require an STB at every television in the home. An STB was used only if the subscriber purchased premium channel packages that required descrambling, and cable operators could charge a fee for the services as well as for the rental of the STB.

Today, cable operators are upgrading their systems to two-way digital and now require a STB to access digital broadcast. But, because the hybrid fiber/coax (HFC) cable system remains both analog and digital, the subscriber can have digital on selected television sets (with an STB) and remain on analog for secondary televisions with no STB. Likewise, subscribers can choose to purchase more expensive digital broadcast service packages, or not. Therefore, only those customers upgrading from analog to digital need an STB. In the United States, about 15 percent of the entire cable subscription base uses an STB today.

1.3. The Dilemma for Telcos

Telcos offering video over DSL must provide a set-top box to all subscribers and all televisions. They do not have the option of offering analog to a specific subscriber or certain televisions within the living unit as cable operators do. So the initial capital investment in CPE devices supporting digital video services over DSL is considerably higher than that faced by cable operators.

Over time, cable operators will increase their digital footprint and service penetration and will also have to provide an increasing number of CPE devices. In the United States, numerous cable industry surveys assert that the average number of televisions per household is in the 2.3 to 2.4 range. Already, AT&T Broadband offers two digital STBs in its Platinum Service Digital Package, in recognition that more than one television exists per home. Forecasts for digital STBs in the CATV industry indicate that two-way digital penetration will reach 54 percent (50 million households) across all U.S. households by the end of 2005. This will create a more even parity in competitive service offerings with telcos, as well as closer parity in CPE costs per subscriber.

1.4. Implications to Telco Video Providers

Early DSL business models (harkening back to Video Dialtone in the early 1990s) assumed a value-added service overlay to existing CATV services. In this model, DSL would be used to deliver digital video to a STB located on one television (the main television), with a service offering including video on demand (VOD), specialty channels, and interactivity/games. Rather than competing with cable, the telco would offer its own unique and differentiated services. Over time, this model has proven ineffectual. Current thinking is geared to offering "full service" video directly competing with cable plus enhanced services as part of the bundled full service offering.

Telcos that must compete with the cable operator, which implies taking the customer away from the incumbent cable provider, must also provide service to more than one television in the home where this situation exists. There is no business case rationale for a subscriber to keep his analog cable service and also purchase digital service for a selected television from another provider. Competitively, it becomes an "all or nothing" proposition.

It should be noted that the models differ around the world based upon governmental policy, etc. Therefore, a series of business models exist imposing design and development challenges to equipment manufacturers trying to come up with solutions for video over DSL. The notion of "one box fits all" simply does not play out.

Several different approaches are under consideration to address serving televisions in the home. The biggest driver, outside of the applications and service requirements, is economics. A combination of lowest feasible electronics (CPE) costs, and practical matters such as ease of installation, all come into play.

2. Pros and Cons of Various CPE Models

2.1. Analog and Digital RF Combining at the STB

In a number of European countries, the government requires service providers to offer "free to air" channels as basic broadcast. There is little interest by telcos to absorb the cost to encode and support free to air channels for which they get no revenues. At the same time, a telco cannot offer its pay-TV services because doing so would require it to disconnect the subscriber from access to free to air content.

A solution to this issue would be radio frequency (RF) combining of analog and digital over the in-home coax, with the STB providing both a digital decoder and analog RF output. This type of solution would resolve the issue posed in the analog + digital CATV model, where a need exists to provide both types of content (channels). And it allows the telco operator to offer its premium pay-TV digital services to a main television in the living unit. There is an added cost for the RF in combining technology at the STB, but it is probably much more acceptable than other alternatives. However, this solution is probably not practical in the United States, where even analog cable service is a pay service. The telco operator would not want to provide both analog and digital services nor would the subscriber purchase two services from different providers.

2.2. Distributed Set-Top Box

The FS-VDSL Committee is a group of more than 70 international companies that share a common vision for an end-to-end multiservice, video-centric network platform based on very-high–data rate DSL (VDSL) technology. Many members of the group, and others around the world, favor an open DSL interface at the home, with Ethernet or HPNA 2.0 (a de facto industry standard endorsed by the Home Phoneline Networking Alliance, or HomePNA) used for in-home distribution to discrete STBs at each television to be served. The principle behind this is to segregate access from CPE and eventually open the path for set-top devices to be purchased by consumers through retail distribution. It may also be a "mandatory" requirement to have a service separation point for regulatory reasons as well as to allow an operator to support both wholesale and retail services from multiple service providers.

The opposing viewpoint is a single residential gateway device with multistream Moving Pictures Experts Group (MPEG)-2 outputs, requiring a single piece of CPE in the home for video and data service connectivity. The distributed model requires a modem device with routing capability to distribute bandwidth to each discrete device in the home, as well as an STB on each television served. In today's environment, the economics are significantly higher in the distributed model.

A major argument, in favor of the distributed model, is the hardware costs associated with offering high-end interactive television services versus basic broadcast service. First, the digital service suite continues to expand, including VOD, games, and other interactive applications, as well as personal video recorder (PVR) functionality. There is a cost associated with such applications in the form of hardware and client software. In a distributed model, a feature-rich STB could be placed at the television, where these services are required (and additional fees are paid for), while other televisions could be served with low-cost basic STBs. In a residential gateway model, the cost for all of the additional hardware and software is paid for in the box for all televisions, even if the subscriber is only willing to pay for the enhanced features for one television.

Second, the distributed model allows operators the ability to charge for services on a per-TV basis. In the current residential gateway business model, the customer pays the same for digital service as cable charges but gets the capabilities enabled to every television (something cable does not do without extra fees).

Third, and importantly, the distributed model allows CPE to migrate to retail distribution. This gets the operator out from under the capital cost burden of providing the CPE to enable service. This type of model is already established in the direct broadcast satellite (DBS) and TiVo/Ultimate TV markets.

2.3. *Residential Gateway Model*

The concept of a single CPE ("mega STB") residing at the main television and providing multiple MPEG-2 video stream and data connectivity has enjoyed commercial deployment for a couple of years. This solution leverages common electronic components on a single board to provide what is in effect the functionality of three STBs and a modem in a single unit. Compared to CATV digital STBs (such as the Motorola DCT2000) or DSL single STBs, the cost of the residential gateway is significantly less. Assuming that the average of 2.3 televisions per household is accurate, a three-stream residential gateway can solve the "digital dilemma" in a large percentage of U.S. homes.

While the economics appear to favor a residential gateway model over the distributed CPE model, there are some significant issues and downsides to be considered, such as the following:

- Currently, the only commercially offered residential gateways are proprietary to a specific vendor's access system, not allowing their use with other access systems or technologies.
- In households with only one television (much more common in Europe and the Far East than in the United States), a residential gateway is actually more costly. Having multiple televisions to serve in every home is needed to justify the residential-gateway business model.
- There are additional "peripheral requirements" to enable a residential gateway to work, such as antennas for receiving remote control signals from television locations away from the main television where the residential gateway resides. *(Wiring issues are discussed later.)*
- Unless the residential gateway becomes a "generic" interface and non-proprietary, it can never migrate to a retail distribution model.
- Whenever hardware and software enhancements are added (such as a PVR hard drive, high bit-rate graphics for gaming, etc.), the price of the residential gateway increases, even if the features are only needed at one television. The box cannot be feature-scaled to the service needed at each television based on its integrated design.

2.4. *"Combo Box" Model*

Bell Canada's ExpressVu is promoting a combo box model, where digital video is input via dual DBS receivers, and asymmetric DSL (ADSL) technology is used to deliver VOD, data, and interactive services. It assumes DBS is more cost-effective than VDSL in a residential single-family home serving area, and the longer rate and reach that ADSL affords allows a data and interactive overlay to broadcast from the satellite.

The counter arguments to a combo box approach include the costs for the satellite dish and installation, the cost of the box itself, and the limited use of DSB in high-rise multidwelling unit (MDU) buildings. It will have to be seen if this approach is commercially successful (or the product actually works as specified).

2.5. *Conclusions*

The biggest issue today is not that of product quality but of volume. DSL–based set-top and residential-gateway boxes are high volume in a relative sense because there has yet to be any mass-scale deployment of video services over copper by telcos. Whether it is Pace, Thompson, Motorola, or NextLevel Communications, it is hard to leverage reduced component costs and manufacturing efficiencies when annual volumes are sub-100,000 worldwide for set-top devices. Cable, on the other hand, can leverage manufacturing volumes into the millions for STBs. It will take a worldwide demand of one million or more to begin seeing volume reflected in pricing. Also, it will take that kind of volume to engage large consumer electronics manufacturers and retail outlets to enter the game.

Secondly, through the efforts of worldwide consortiums, such as FS-VDSL, the industry must be driven to some common ground regarding CPE reference designs and open interfaces. One of several things will need to happen to allow leveraging of volume across a large telco market segment worldwide:

- Either the proprietary interface to the residential gateway must change to an open one to allow common product support across various access systems (assuming the worldwide consortium agrees that such a residential gateway concept is the best solution overall); or
- The consortium defines a common interface and signaling methodology that allows a residential-gateway design to be licensed and manufactured by consumer electronics companies for the worldwide market (including retail); or
- The worldwide consortium defines and agrees on a distributed architecture and basic set-top requirement that presents a universal means of connecting CPE to the access network and enables volume production of STBs ranging from basic to full-featured; or
- A combination of all three, based on defining interfaces, signaling, and control is ideal. This then allows different telcos and countries to choose set-tops or residential gateways and operate their service network from a common back-office platform. Each access vendor would be free to insert its own added-value features and capabilities, supported uniquely from its access platform, as a means of product differentiation, rather than having the CPE device determine differentiation between system solutions.

3. *Considering In-Home Distribution Related to CPE Alternatives*

The "Achilles heel" thus far in the limited commercial deployment of video over copper has been in-home installation. In the early stages, in-home installation took an average of seven hours per home. It has been refined through better procedures, training, and some technology enhancements to now average less than 3.5 hours, allowing an installer to do two service orders per day.

In-home distribution must serve each television and assume one or more personal computers (PCs) as well. The media available in the home consists primarily of existing coax for

CATV distribution and twisted pair Cat. 3 copper for telephone and modem connection. With VDSL terminated at the network interface device (NID) (where lifeline plain old telephone service [POTS] is split off the drop) or at a modem device (in the distributed model), bandwidth and service must be distributed by using the existing distribution media, or else new media must be installed.

In the current residential-gateway model, VDSL is placed on the existing coax, and a coax in-home "network" is used to provide service to each television. Cat. 5 copper is installed from the gateway to the PC, which is usually not located in the same room as the main television, where the gateway resides. This becomes the most problematic installation piece.

The current distributed model assumes in-home distribution uses Ethernet over Cat. 5 copper to both televisions and PCs. This is no less an installation problem, as the majority of homes is not pre-wired with Cat. 5 and have RJ-45 jacks in each room.

Ideally, broadband wireless technology would be developed to allow VDSL over the air with no in-home wiring required. While this is being studied and may become a future possibility, the solution does not exist today. And there will always be an issue with wireless interference (frequency separation) when the application is in a large residential high-rise apartment or condominium complex.

A third alternative is using HPNA 2.0 for both video and data distribution. HPNA 2.0 can work on either coax or Cat. 3 copper and provide up to 30 megabits per second (Mbps) of bandwidth—more than enough for video and data services.

The good news is the availability of several technology and physical media options to deliver video and data services in the home. Before looking more closely at the pros and cons of each solution, it should be remembered that the objectives for deciding the best topology are as follows:

- The solution that best optimizes the amount of time spent installing in the home
- The solution that is best capable of delivering bandwidth and performance for current as well as future services and applications
- The solution that represents the lowest-cost approach to service installation, including electronics and/or peripheral devices

3.1. VDSL over Coax (TV) and Cat. 5 Ethernet to PC

Reuse of coax in the home to serve multiple televisions, as done with a residential gateway, is a fairly effective approach. With the aid of a balun, VDSL terminated at the NID can be bridged directly onto the coax at the side of the home for distribution. This has several limitations, however:

- It assumes the CATV entry and telephone entry are on the same side of the house or within proximity of one another.
- It assumes that the home is pre-wired with coax. This is true for a majority of homes in the United States and Canada, but much less so in Europe and other parts of the world. It may require new coax distribution be installed in a number of international markets.
- It still requires some changes to coax splitters in the home to maintain a quality video stream.

Second, and more costly, is the need to run Cat. 5 from the gateway, where the main television is to the location of the PC for data service. As an option, HPNA 2.0 may be used. The problem still remains that, in many homes, there is no phone jack located where the main television is, so wiring and installation may still be required.

In-home installation intervals (excluding actual VDSL drop provisioning) ranges from two hours for a single-family home with existing coax to three hours with PC connectivity. Condominium and apartment complexes require less time, in the range of 1.5 to 2 hours. If the home does not have coax distribution placed, or new coax needs to be run to a television, installation increases to 4+ hours per home.

3.2. VDSL Termination, Ethernet Distribution

With most STB manufacturers offering a 10BaseT (or 10/100BaseT) interface, video deployment over DSL (mostly ADSL DSL access multiplexer (DSLAM) architectures) uses Ethernet for in-home distribution. DSL is terminated at an intelligent modem and then distributed to STBs around the home using Cat. 5 copper carrying Ethernet. If multiple televisions and/or PCs are connected, a multiport Ethernet bridge is used.

10BaseT Ethernet provides acceptable bandwidth for delivering video to a set-top device. It is limited, however, in providing sufficient bandwidth to a multistream gateway that may also support data service. And it does not support bandwidth required to offer high-definition television (HDTV) service as a future consideration.

The main issue is in-home wiring cost. Except for the newest homes, the vast majority of homes are not pre-wired with Cat. 5, nor are RJ-45 outlet jacks installed in the home. Therefore, complete new in-home wiring must be performed. This, coupled with the modem costs, may make this solution too costly for any commercial mass deployment. A home with more than one television and a PC could take well in excess of four hours for in-home installation, and it is unlikely that this topology could ever migrate to self-install.

3.3. HPNA 2.0 Home Distribution

HPNA 2.0 offers some interesting enhancements over traditional Ethernet. The distinctions are greater bandwidth and the ability to deliver high bandwidth over existing in home telephony pairs (Cat. 3).

Based on the current Broadcom chip package with HPNA 2.0, both 10/100BaseT and HPNA outputs are provided. HPNA 2.0 in its present form can deliver somewhere between 15 and 18 Mbps of bandwidth for home distribution. While this sounds acceptable for multiple video streams as well as data, the reality is that Ethernet-based packets are not ideally suited for constant bit-rate (CBR) video, and mixing bursty data traffic presents a potential problem. If HPNA 2.0 is to be used for the delivery of both video and data inside the home, it probably requires a much larger "pipe" to compensate for the bursty traffic, probably in the range of 30+ Mbps. Technical developments are pushing HPNA 2.0 to a much higher rate, and it could be feasible to deliver a whole home video and data solution over existing telephone wire.

HPNA 2.0 offers the option to deliver service via telephone pairs or coax. Thus, it is flexible in its in-home implementation to best reduce installation time. Putting HPNA 2.0 onto coax requires only an inexpensive balun.

Once the bandwidth is increased to support mixed traffic, HPNA 2.0 will be ideal for delivering both video and data to multiple devices in the home. The trade-off between asynchronous transfer mode (ATM) and Internet protocol (IP), when it comes to mixed broadband transport, is related to the lack of dedicated PVRs for service mixing inherent in ATM. So the only practical solution, as mentioned, is to increase the size of the pipe.

Current-generation chips supporting HPNA 2.0 appear to deliver around 15 Mbps of bandwidth. This may be acceptable for two broadcast streams and data but likely not for three broadcast streams. The next iteration of chips, due in 2002, should deliver 30 Mbps, which would be a large enough bandwidth pipe for three video streams and data. Prototype lab chips indicate the capability to increase bandwidth to more than 100 Mbps. This is a compelling argument for HPNA 2.0, since there appears to be a definitive migration path for higher bandwidth.

One approach would be to start with both a 10/100BaseT and HPNA 2.0 interface. The 10/100BaseT could be used for video, since most DSL STBs today only support a 10BaseT interface. This would require installation of Cat. 5 copper to the STB and does not, again, simplify the in-home installation issue more than the other choices. HPNA 2.0 could be used to deliver data to PCs using existing Cat. 3 telephone lines in the home. It also offers the ability to connect other IP devices, such as security systems, smart appliances, etc., over telephone lines within the home and in a variety of locations (such as the kitchen). The converse can also be deployed, especially in homes where only one to two televisions are connected. In this case, HPNA 2.0 with a balun could be used to serve televisions over coax (or directly over telephone lines if the STB had a HPNA 2.0 interface) and the 10/100 port used for PC connectivity for data.

A major benefit to HPNA 2.0 is that it uses a medium that is familiar to the telephone company and has the flexibility of running over telephone lines or copper. This makes HPNA 2.0 flexible in both the U.S. and international markets, where the availability of coax varies greatly. It also has a bandwidth migration path that forecasts much shorter in-home installation times. Another advantage would be locating the smart modem at the most accessible telephone jack to access home distribution, rather than trying to network access from the main television, where a gateway is located.

4. Final Remarks

This paper has talked about the capital costs for the cable operator being heavily weighted on the fixed infrastructure side, with the CPE and in-home costs being the reverse for the telcos. To put this in perspective, on an equal take-rate basis, the installed costs for two-way digital CATV with two digital STBs per home (the standard service offering of most U.S. cable operators) is more then double the costs for the telco using DSL and digital STBs. The telco problem is more business-case–related, as take rate is a higher risk and the return on investment (ROI) acceptable to a cable operator is significantly lower in the mind of the telcos.

There are a number of DSL access systems that offer scalability and performance for video and offer a means to deploy infrastructure at an acceptable cost. Recent advancements have reduced the costs to build a digital video head end, and lower encoding rates have made bandwidth utilization more efficient. The problem, therefore, comes down to CPE and in-home installation.

In a real sense, set-top manufacturers and other consumer electronics producers that could build low-cost STBs have been reluctant to develop products due to the lack of market. Until the worldwide telcos demonstrate a serious plan to deploy video services, the manufacturers best able to drive CPE costs down will be hesitant to enter the market, as volume drives price in most consumer electronics.

There is encouraging news, though. In the past few months, a growing number of set-top and CPE manufacturers have announced plans to develop either "home gateway" devices or low-cost "distributed" decoder set tops. Of particular interest is the concept of a full- featured STB in the home serving the primary television, with subtending inexpensive, small "decoder" boxes at the other televisions. If the preliminary prices are accurate, this distributed approach can match the cost of a non-distributed, multistream residential-gateway device. This may satisfy the needs of both U.S. RBOCs and worldwide PTTs.

As presented, a number of in-home wiring options are available. Unless a high-bandwidth, high-performance, and low-cost wireless broadband solution is developed for video distribution in the home, there will always be a labor cost associated with home wiring. The near-term goal, through the technology options available, is to simplify and minimize the installation, not eliminate it. Whereas several years ago, a single-family home installation to three televisions and a PC took as long as seven hours, today this number is more like 3 to 3.5 hours with technology improvements. With some of the suggested approaches, such as HPNA 2.0, this can hopefully be reduced to 2 to 2.5 hours. In comparing in-home installation to the cable competitor, there is parity at this level, as they spend an average of 2 to 2.5 hours per home to install two-way digital services to two televisions.

MPLS versus PNNI Control-Plane Architectures in 21st Century Service-Provider Networks

Andrew G. Malis
Chief Technologist
Vivace Networks, Inc.
Chair, Technical Committee, and Vice President, Technology
MPLS Forum

1. Introduction

The purpose of this paper is to provide overviews of the private network-to-network (PNNI) and multiprotocol label switching (MPLS) control-plane architectures, compare their salient features, and demonstrate MPLS' superior applicability to meeting today's and tomorrow's public service-provider control-plane architecture requirements, especially in converged multiservice networks.

2. PNNI

2.1. What is PNNI?

PNNI [1] was created for asynchronous transfer mode (ATM) networking and offers extensive capabilities for connection control among the nodes of ATM networks. ATM was originally created in the late 1980s to be the heart of the envisioned broadband integrated services digital network (B–ISDN), which was at that time intended to completely replace time division multiplexed (TDM) voice and data with hardware-based packet switching. At that time, the only type of packets that could be switched in hardware had to be fixed length, and, in addition, these fixed-length packets (called cells) were felt to provide better quality of service (QoS) capabilities than variable-length packets, which was necessary to replace TDM's ability to carry voice traffic. The use of a fixed cell size has led to a number of consequences, including complicated adaptation functions to carry variable-length Internet protocol (IP) and other packets over ATM, and extremely complex QoS service classes and cell-scheduling algorithms.

Because ATM was intended to replace TDM, it has many characteristics in common, including a requirement that all user cells (carrying both voice and data) be carried over connections that were explicitly established before any cells could be sent. Part of the connection establishment process was to determine the connection's routing through the network, which was then fixed by the connection-establishment process.

PNNI was created by the ATM Forum to provide a standards-based method of routing and signaling connections in ATM networks. Its capabilities include the following:

- *Addressing:* PNNI uses 20-byte network service access point (NSAP) addresses, which were originally invented for International Organization for Standardization (ISO) connectionless network protocol (CLNP).
- *Link-State Routing:* PNNI includes all of the functionality of a link-state routing protocol, such as open shortest path first (OSPF), including a hello exchange, topology generation, and flooding routing updates (known as topology state packets) on the state of all of the network's switches and links to every ATM switch in the network. This routing information allows each ATM switch to determine the optimal route through the network to set up a new connection. That route is then explicitly carried in the connection set-up signaling.
- *Signaling:* PNNI uses the signaling ATM adaptation layer (SAAL) to encapsulate signaling messages that carry the connection set-up requests from switch to switch along the path chosen by the routing function. The signaling messages themselves are an enhanced superset of the International Telecommunication Union–Telecommunication Standardization Sector (ITU–T) Q.2931 connection signaling protocol, which was created for use in the B–ISDN. A specific virtual path identifier (VPI) and virtual circuit identifier (VCI) are used for carrying PNNI signaling information.
- *Multiservice Capabilities:* PNNI is an ATM–only control protocol. To carry other connection-oriented protocols

on PNNI–based networks, additional interworking protocols are required. For example, frame-relay carriage requires the use of the Frame Relay Forum's FRF.5 specification on frame-relay/ATM network interworking, which adds complexity to the network. In addition, carrying frame relay and other packet-oriented networks on a PNNI network requires a one-to-one mapping between frame-relay and ATM connections. (Note that FRF.5 does include an optional many-to-one mapping, which has never been operationally deployed.)

PNNI can be thought of a single monolithic whole encompassing all of the aforementioned functionalities. Its architecture can be visualized in *Figure 1*.

The interfaces on each side are to other switches in a PNNI–based network or across private ATM network boundaries

2.2. PNNI Control-Plane Issues

PNNI has a number of issues that affect its suitability for use as the signaling control plane in a multiservice network. These include the following:

- PNNI was designed for, and is highly optimized for, use on ATM–only networks. It does not natively support signaling or carriage of other protocols—this must be supported by using additional functionality, such as provided by FRF.5 for frame relay.
- Although PNNI was originally intended for use between different vendors' ATM switches, because of its complexity, multivendor interoperability was never really achieved and practically all PNNI networks are single-vendor deployments. In addition, many service providers with ATM networks have opted to use their vendor's proprietary control-plane protocols, such as Lucent/Cascade's Virtual Network Navigator and Marconi/Fore's ForeThought, due to their added functionally and vendor differentiation when compared to PNNI.
- It should be noted that PNNI does not, of itself, provide any particular QoS services for user traffic. Rather, PNNI has the capability of including, in its connection signaling messages, the ATM service class that is requested by the user. It is the job of the ATM switch, where the connection originates, to find a path through the network that can carry the service class and the job of each ATM switch on the path to provide that QoS to the ATM cells on the connection.
- PNNI's use of NSAP–format addresses is problematic, since although this address format was invented for ISO CLNP, these addresses (like CLNP) have never been operationally deployed. It also means that IP deployments on PNNI–based networks need a network translation function.
- PNNI signaling also has a number of scalability concerns. As previously mentioned, carrying frame relay and other packet-oriented networks on a PNNI network requires a one-to-one mapping between frame relay and ATM connections, which will create a large number of ATM connections to be managed and signaled. In addition, because every ATM switch in the path of the connection must actively participate in the PNNI signaling, this means that interior switches in the middle of the network need the signaling and switching resources to support very large numbers of ATM connections, which has a direct effect on the scaling abilities of such networks.

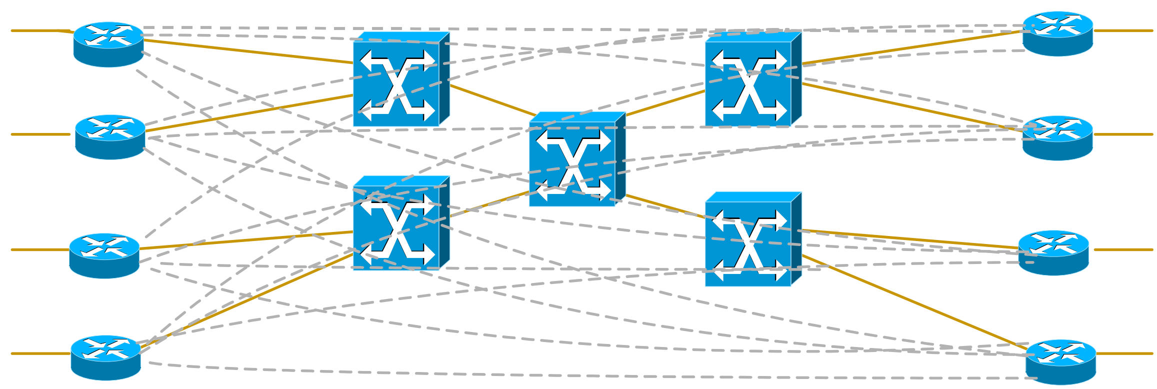
IP over ATM Network



3. MPLS

3.1. What is MPLS?

MPLS [2] is a set of IP–based signaling protocols that were designed by the Internet Engineering Task Force (IETF) to allow the use of connection-oriented traffic engineering in IP networks and to enhance the operation of IP over existing ATM networks. It has lately been enhanced with additional functionality, which will be subsequently discussed further.

Prior to MPLS, router-based IP networks used hop-by-hop routing of IP packets, which tended to send IP packets over a small number of possible paths though the network, causing congestion on some paths and underutilization on others. During the relatively short period when ATM switches tended to be faster then IP routers, IP backbones were built around a core of ATM switches. The ATM switches allowed the use of ATM connections to perform traffic engineering in order to evenly spread the load of IP packets on the network's links, but with a number of costs. The process of adapting variable-length IP packets to ATM's fixed-length cell produced a large amount of overhead, known as the *cell tax*, which could be up to 30 percent of a link's bandwidth. Typically, network operators used a full mesh of ATM connections to interconnect the IP routers, which used a large number of connections and other resources in the ATM network. In addition, an Internet service provider (ISP) was required to procure and operate two sets of network infrastructure equipment—both ATM switches and IP routers. This is illustrated in *Figure 2*.

In *Figure 2*, the solid lines are physical connections and the dashed lines represent a full mesh of ATM VCs that are being used to interconnect the routers around the core of ATM switches.

Once routers began to use hardware switching in application-specific integrated circuits (ASICs) to match and even surpass ATM's switching speeds, the only use for ATM switches in ISP backbones was to provide traffic engineering. To reproduce this functionality in routers, the concept of label switching for IP packets was invented in late 1996. This simply prepends variable-length IP packets with a fixed-length 20-bit label to quickly switch the packets through the routers along a path that was independent of its destination IP address, thus allowing traffic engineering in routers without the use of ATM switches. As a result of its genesis in the IP routing community, MPLS is much more "open" than PNNI, and it has reaped the benefits of more than 30 years of packet switching technology experience.

3.2. MPLS Advantages

The various aforementioned aspects of PNNI can be compared to their MPLS counterparts:

- *Addressing:* MPLS uses the same 32-bit addresses as IP. In the future, MPLS can be extended to IPv6, just as IP itself is being extended.
- *Link-State Routing:* MPLS uses the existing IP link-state routing protocols, OSPF and intermediate system–to–intermediate system (IS–IS), with a small set of extensions to provide additional information for traffic-engineering purposes. A service provider has the flexibility to choose one or the other routing protocol; neither is mandated by MPLS.
- *Signaling:* MPLS has defined three signaling protocols, again with the network provider making the choice as to which to use in their network. The three signaling protocols are RVSP–TE (traffic-engineering extensions to the existing resource reservation protocol [RSVP]), LDP (label distribution protocol, used for running MPLS in a basic mode of operation), and CR–LDP (constrained routing extensions to LDP, also used for traffic engineering). All MPLS implementations contain LDP and either one or both of RSVP–TE and CR–LDP.
- *Multiservice Capabilities and Scalability:* The MPLS architecture includes the capability to set up multiservice connections to carry ATM, frame relay, Ethernet, TDM, and other Layer-1 and Layer-2 services. When MPLS–based networks are used to carry these multiservice connections, such as ATM or frame relay, many multiservice connections are hierarchically carried in a single MPLS LSP. In addition, the ATM and frame-relay connections are only visible to the endpoint switches where they terminate; the switches in the interior of the network do not participate in the signaling. This hugely increases the scalability of

MPLS networks for multiservice traffic when compared to PNNI.

- *QoS:* MPLS provides the ability to allocate bandwidth to LSPs and to associate LSPs with QoS service classes to ensure that user applications will receive the required end-top-end QoS from the network. In addition to MPLS' standardized QoS capabilities, Vivace Networks has incorporated the lessons learned from ATM switch design to provide its customers with the best of both worlds: MPLS' signaling scalability and packet-based forwarding combined with the capabilities to provide rigid QoS guarantees for its customers.

3.3. MPLS Flexibility and Future Direction

In comparison to PNNI's monolithic design of one protocol handing topology distribution, routing, and connection setup, MPLS was designed in a modular manner. MPLS has been built upon already existing and proven protocols in use in packet-based networks, such as OSPF and IS–IS, for topology distribution and routing. In addition, MPLS allows service providers the specific choice of which routing and signaling protocols they wish to use to best suit their requirements, while PNNI attempts to cover all possible operational situations, with no service-provider flexibility allowed. All of this makes MPLS the perfect control-plane architecture for use in packet-based multiservice backbone networks.

In comparison to MPLS, PNNI represents a technological dead end. The ATM Forum, where PNNI was standardized, has vastly shrunk in size and interest, and it is extremely doubtful that there will ever be another revision to PNNI. In direct contrast, the IETF and the Optical Internetworking Forum (OIF) are cooperatively working on extending MPLS' capabilities to become, as generalized MPLS (GMPLS), the control plane of choice for service-provider core optical networks. In addition, the MPLS Forum is complementing the IETF's MPLS standardization work by actively extending MPLS' application space and standardizing MPLS' protocol conformance and functional testing.

4. Summary

Table 1 summarizes the salient points of PNNI and MPLS.

TABLE 1

PNNI and MPLS Summary

Functionality	PNNI	MPLS	Comments
Data units	Fixed-length cells	Variable-length packets	MPLS is much better suited to today's IP–based protocols.
Standardization background	ITU–T and ATM Forum, based on B–ISDN	IETF, based on IP routing and signaling	PNNI is one monolithic whole and difficult to adapt to changing times, while MPLS is modular in design, and each aspect can be updated on its own.
Typical data rates	T1/E1 to 2.5 Gbps	9.6 kbps to 10 Gbps, 40 Gbps in development	
Addressing	20-byte NSAP addresses	32-bit IPv4 or 128-bit IPv6 addresses	ATM's different addressing structure requires the use of a mapping function when using IP over ATM.
Signaling	Superset of ITU–T Q.2931	LDP, CR–LDP, RVSP–TE	
Routing	Included as a part of the protocol	OSPF or IS–IS	MPLS makes use of routing protocols that were designed specifically for IP.
Network scalability	Two-level hierarchy (VCI and VPI)	Infinite-level label stack	ATM VCI and VPI fields are limited in size and make network scaling difficult.
QoS	Not provided by PNNI per se, but by the underlying ATM switches	Included in the MPLS architecture	In addition, Vivace Networks has innovated to provide QoS capabilities over and above those in the base MPLS architecture.

TABLE 1

PNNI and MPLS Summary (cont'd)

Protection and resilience	PNNI can take multiple seconds to re-establish connections that break due to a switch or link failure	MPLS has 50 ms LSP restoration capabilities	PNNI relies on underlying SONET/APS to provide 50 ms restoration; MPLS has it built in.
Connection set-up resilience	PNNI includes crankback to try alternate routes if a problem occurs during connection set-up	MPLS includes crankback to try alternate routes if a problem occurs during connection set-up	PNNI and MPLS are identical in this regard.
Overhead	ATM cell tax (up to 30 percent for packet-based services)	Label stack in front of packets (32 bits per label)	MPLS is much more efficient for packet-based services.
Privacy and security	ATM uses VC separation to prevent mis-delivery of user data	MPLS uses LSP separation to prevent mis-delivery of user data	
Network backbone convergence	As discussed, PNNI and ATM have serious scaling and efficiency issues when used as the basis for multiservice converged backbone networks.	MPLS is able to efficiently and scalably concentrate the traffic from Layer-1, -2, and -3 services at the edge and move them transparently across the core.	
Operational Cost	IP over ATM requires two separate control-plane architectures.	Single converged backbone	Converged MPLS core simplifies operation and maintenance and reduces the troubleshooting time under network outages.
Multivendor interoperability	Very few multivendor deployments	Proven in real network deployments	
Migration to new optical core technology	PNNI is incompatible with the forthcoming OIF optical interfaces.	The OIF UNI and NNI interfaces are based on GMPLS, a superset of MPLS.	MPLS eases the migration to the forthcoming GMPLS–based optical core and enables the direction cooperation of service provider data and optical switching equipment.

Data-Centric Design and Its Impact on Storage and Network Architecture

LightSand Communications, Inc.

Abstract

When computers were making a major impact on enterprise productivity in the 1980s, the world was starved for processing power. The most important feature in a computer system was how fast the central processing unit (CPU) ran. We were, in effect, CPU bound. As the world moved into the decade of the 1990s, CPU power became more and more plentiful. However, the world soon perceived an ever-increasing need to network computers together in a globally scalable fashion. We shifted our attention to our new weak spot: networking. Now that processing power and connectivity abound in the first decade of the new millennium, we have shifted our attention to storage. Since our attention is now on data and how to make sure that it is safe and available in the location in which it is required, several new requirements are being levied on the world's infrastructure. These are predictable quality of service (QoS) as well as a security infrastructure to guarantee that data is protected and authentic. These new requirements will propel the design of high-bandwidth, low-latency infrastructure for the world with end-to-end protection of the data.

Introduction

The decade of the 1980s truly belonged to the CPU. Since Moore's observation[1] that the number of transistors per square inch on integrated circuits has doubled every year, the pace has settled down and continued to double every 18 months. The decade of the 1990s has seen an even faster rate of growth in the network bandwidth capacity that doubled every 9 months. With the advent of the Internet and faster global communications networking, storage requirements are exploding at an even more rapid rate. E-mail, e-commerce data, and continued conversion of documents, pictures, and video to digital storage are just examples contributing the exponential growth rate that is doubling storage every six months. In addition, business focus is shifting to 24x7x365 data availability. Down time has been estimated by the Gartner Group[2] as costing anywhere from $300,000 per hour for industries such as health care and media to $3 million per hour for highly automated businesses, such as the financial and telecommunications industries. More recently, the World Trade Center disaster has highlighted the importance of business continuance using back up, mirroring, and other reliable disaster recovery mechanisms. The first decade of the 21st century may well belong to storage infrastructure innovation.

Historically, storage has stayed very close to the computer, where data reads and writes originate. This has allowed the storage industry to develop very high throughput and low-latency infrastructure to optimize the storage access. However, as bandwidth started to explode, the economics has shifted to networked storage. Networked storage allows the sharing of storage resources across the enterprise and reduces operation and management costs. Network-attached storage, Fibre Channel storage-area networks (SANs), iSCSI, and InfiniBand technologies are examples of such networked storage solutions.

As networked storage becomes ubiquitous, two new issues need attention. First is the latency introduced by increasing the distance between the server and storage through the network, and second is the security that must be addressed as mission-critical data starts to share networking infrastructure in both enterprise and public networks. Storage transactions pay a premium for accuracy of the data and require acknowledgement when a write is accomplished before the transactions are committed. As the networks increase the distance between the server and the storage device, management of both latency and security becomes critical. In this paper, we examine the impact of latency and security on storage networking and identify key requirements that must be satisfied by the networking infrastructure. Storage caching among distributed data centers will become an important way to not only utilize the efficiencies provided by high-bandwidth pipes at ever decreasing costs, but also to mitigate the limitations imposed by latency over distances. As storage comes out of the traditional data-center closet and becomes globally networked, many of the security risks will be addressed with similar technologies that have provided solutions for the traditional Internet protocol (IP) networks.

Emergence of Storage Networks

First-generation storage devices were directly attached to their servers. Large computer systems from IBM used the enterprise system connection (ESCON) interface, while small systems use the small system computer interface (SCSI). The SCSI protocol was developed in 1981 to interconnect disk drives and other peripherals to small computers. It was submitted to the American National standards Institute (ANSI) standard committee and was formally adopted as a standard in 1986. The initial version of the SCSI interface allowed up to seven devices to be attached to the computer. Since SCSI was intended to interconnect devices within the computer itself, the interface was left as parallel and large ribbon cables were used to connect peripherals. Various extensions to SCSI increased the speed of the interface as well as the number of users that could simultaneously use the bus. The latest version of SCSI allows up to 15 devices to be attached to the server and supports data rates up to 320 megabits per second (Mbps).

As more complex storage arrays were assembled, two attributes of SCSI drove the storage industry to develop Fibre Channel SANs. These were the distance limitation of SCSI (25 meters) and the lack of addressable devices (15). To mitigate these limitations, Fibre Channel networks were adopted using the Fibre Channel protocol to provide a switched fabric for the interconnection of multiple SCSI devices. Fibre Channel provides a switched 100 Mbps interconnect between devices. New standards have doubled this data rate to 200 Mbps equipment, with this equipment available now. Not only did Fibre Channel allow for hundreds or even thousands of devices to be interconnected, but it also increased the maximum distance from 25 meters to 10 kilometers.

The Fibre Channel standard allowed SANs to be built that provided mirroring, redundant architectures, and scalability within the data center. Fibre Channel provided lots of bandwidth and very low latency in interconnecting storage systems. This architecture works well for many applications but falls short of our ultimate goal of providing continuously available data. When considered as one large system, the entire data center is vulnerable to natural disaster. For this and other reasons, we need to distribute our data geographically. The next section will discuss this need in greater detail.

The Need for Distributing Data

Since our new emphasis in the 21st century is on ensuring that data is safe and available in the location(s) in which it is required, we focus on two main reasons for data distribution: business continuance and content caching. The first reason covers all aspects of protecting the data of the enterprise and protecting the systems used to deliver data to the end consumer. The second reason addresses the economics and performance of caching data in disk systems local to the end user versus having all end users access the data from a centralized data center. This provides wideband access to data for all users by eliminating the latency and cost of pulling all data through the long pipes from a centralized source. We will address these topics one at a time.

Business Continuance

Quite simply, business continuance encompasses all aspects of data storage and system design that impact the safe storage and reliable delivery of data. Storage-system designers recognized long ago that a disk-drive failure constitutes a catastrophic loss of data. In response to that danger, arrays of two or more disk drives were deployed in which the data is written in multiple devices. If one drive failed, its data could still be found in one or more other drives. These mirrored storage arrays were typically located in the same facility as a convenience to the staff that managed the storage system. Soon, however, it was recognized that a catastrophic natural disaster could also destroy all of the data. Even though the data was mirrored within the data center, a flood or earthquake could still destroy all of the data in the entire facility.

To mitigate the threat of a natural disaster, storage-system designers created mirrored data centers that stored a copy of the data in a location that was physically separate from the primary data center. Thus, if an earthquake or other natural disaster destroyed the primary data center, the data would still be safe in the mirrored site. To date, these systems have been extremely expensive given the need to interconnect the sites with high bandwidth and low latency. They have typically been used by only the very high-end consumers of data who can measure the loss of data or the loss of service in thousands or millions of dollars per hour.

As the world has achieved better and more affordable network connectivity, more and more users are beginning to protect their data in this fashion. Some are deploying Fibre Channel over a higher-level protocol such as IP in an effort to take advantage of the prevalence of IP networking infrastructure. Others, seeking a higher level of performance, are deploying Fibre Channel directly onto low-level transport mechanisms such as synchronous optical network (SONET) or dense wavelength division multiplexing (DWDM).

Regardless of which method of networking is used, the interconnection of storage between remote sites will continue the pressure on carriers to provide a higher level of QoS.

Content Caching

We expect content caching to emerge as a new paradigm for storage networks. There are two reasons for this: performance and economics. Both reasons ultimately derive from the increased latency that results from locating data centers farther and farther apart from each other.

Let's consider the model of a Web hosting service. If they operated one data center (say in San Jose), then all Web pages served by them would be generated in San Jose and served to clients across the country or even the world. If the Web site contained a significant amount of data (for example, high-resolution photographs), then the server would have to push those large data files to every user (regardless of their location). As the number of users increases and as the distance between the server and the user increases, the distance-bandwidth product of the data in motion will increase dramatically. Ultimately, this drives the cost of providing data to the user, since it is a function of both bandwidth and distance. To complicate matters, the requirements for bandwidth will continue to increase as consumers seek ever-richer forms of media entertainment (streaming video, etc.).

Since we expect the demand for bandwidth to grow considerably, all that is left to us is to reduce the distance over which the data is served. In addition to decreasing the cost of the network infrastructure (distance-bandwidth), this has the added benefit of decreasing the time necessary for the server to respond to the user (less flight time for the packets in motion). This yields a more responsive system with greater throughput. All of these same issues will apply, whether the company is serving Web pages or just managing the distribution of wideband data. The Web-hosting company Akamai has developed an architecture that is based on these principles. Start-up companies such as Accellion are also developing architectures such as this to provide wideband, distributed data access at the edge of the network.

To implement a system such as this, the typical enterprise would need to deploy multiple data centers with identical (synchronized) content. Each data center would serve the region of the country in which it resides. It would provide wideband access to data via a much shorter link than had been used in the past. However, in implementing an architecture such as this, the storage system is faced with the challenge of maintaining synchronized content at different locations. By design, this represents less demand on the network than the centralized model, but nonetheless; it creates an increased need for block-level storage data to be moved across the network.

As we discussed, any time that block-level transport of data is involved, high bandwidth and low latency are crucial to maintaining high performance.

The Implications of Data-Centric Design on Security Infrastructure

Because storage was confined close to the computers where the data originated, storage has traditionally relied on physical security. As the networked storage emerges, this will no longer suffice.

There are three major types of storage networks that are evolving. First, the emergence of Fibre Channel–based SANs that provide low-latency, high-speed data transport between servers and the disk arrays located several miles away from each other using optical transport. Second is the iSCSI technology that allows carrying SCSI commands from the server to the disk arrays over traditional IP networks. Third is the future InfiniBand technology that is aimed at replacing current peripheral component interconnect (PCI) buses in the servers with high-throughput, low-latency switched networks. All three types of networks allow the storage to be extended beyond the data center through appropriate bridging with metropolitan-area networks (MANs) and wide-area networks (WANs).

As data makes its way out of the data center into public and private networks, security concerns become important. Storage networks will be subject to the same three main risks associated with other network-connected systems. The primary risk is that of a user gaining inadvertent access to unauthorized data. Another significant risk is an attacker who hacks the storage network or, more likely, one of its attached host servers and obtains administrator credentials. The third risk, applicable in the case iSCCI networks, is a denial-of-service attack that floods the storage network with more requests than it can handle.

First, let us look at the model of the potential threat that storage faces.

Since Fibre Channel is the most prevalent protocol used in the design of SANs today, we will concentrate on the vulnerabilities of Fibre Channel–based SANs. As Fibre Channel is transported over dedicated fiber-optic cables, it will remain relatively secure even as it travels out of the data center. The fiber-optic cables are not readily accessible, and it would be difficult, if not impossible, to perform passive monitoring without alarming the legitimate users of the fiber-optic cable. However, attempts extend the distance by combing Fibre Channel and IP protocols using Fibre Channel over IP (FCIP) expose the data to all of the same threats and attacks that have plagued IP for years.

As part of the FCIP request for comment (RFC), IPSEC is being added to protect the underlying Fibre Channel frames. This should provide cryptographic integrity as well as device authentication. Lately, proposals have started to emerge for end-to-end Fibre Channel security mechanisms (FCSEC). These would provide cryptographic data integrity and device authentication regardless of the physical transport used for the Fibre Channel data.

Security capabilities are also being incorporated into the storage fabric itself through logical unit number (LUN) masking and zoning. LUN masking creates subsets of storage within the SAN virtual pool and allows only designated servers to access the storage subsets. LUN masking provides the ability to create and manage virtual pools of storage, a capability essential for storage service providers (SSPs) to allow multiple customers to manage their own storage without the security risks. Fibre Channel zoning achieves a similar result at the switch by limiting access from a given device to only certain other devices in the fabric. To date, the zoning techniques that have been deployed have used soft zoning. In this model, a user device never discovers the existence of devices to which it should not talk. The system then relies on the integrity of the initiator to not seek to access other devices. With soft zoning, packets that are sent from a given device to an unauthorized device will still pass through the fabric. Emerging proposals for hard zoning will add packet filters to the switch fabric itself so that communication between unauthorized users can never occur.

With iSCSI protocol, data is carried over IP networks, and hence all the security concerns of the public and private networks will apply to storage over IP. These same concerns also apply to InfiniBand when extended over public and private networks.

The Implications of Data-Centric Design on Network Infrastructure

As the philosophy of data-centric design catches on, there will be a renewed emphasis on the availability of a high-performance end-to-end network infrastructure. As we have discussed, storage systems are particularly sensitive to maintaining high-bandwidth and low-latency interconnection. This can become a significant issue when storage networks are faced with the fundamentally different philosophies that have driven the architecture of the Internet as we know it today.

Today's Internet

Today's Internet was designed with scalability as the prime requirement. In this sense, guaranteed performance (even at a low level of QoS) was sacrificed so that the architecture could scale to enormous size. As of October 2001, almost 130 million hosts had been registered in the public Internet (see www.netsizer.com). The scalable architecture has clearly worked, but it has done so at the expense of guaranteed performance. The core element of today's Internet is the router, designed for the flexible, connectionless transport of IP packets. Through the clever design of hierarchical routing protocols, the router has proven its ability to interconnect millions of hosts. It accepts any and all packets regardless of its load and routes them to the appropriate port so that they can work their way to their final destination, one hop at a time.

In the event that a router reaches capacity, it has a very simple algorithm for managing that excessive load: It drops packets. It does so without any guilt or remorse, since every expectation of IP routed transport has been set to "unreliable." To compensate for the unreliable nature of IP transport, retransmission protocols such as transmission control protocol (TCP) are used to sequence and error-check data. Dropped or damaged packets are identified and then requested for retransmission. Unfortunately, the sensing process and the retransmission process take time. This can significantly increase the latency of the transmission. Further, the TCP algorithm will throttle back its transmission window, effectively lowering the transmission bandwidth as well. Since most applications that run over the Internet are asynchronous, they have do not have rigid requirements for latency or bandwidth. The TCP/IP protocol suite has repeatedly demonstrated its ability to provide scalability. Unfortunately, it is difficult to guarantee any set level of performance using TCP/IP over a lossy, routed infrastructure.

Tomorrow's (Storage Friendly) Internet

The interconnection of storage systems for business continuance or content caching may well turn out to be the "killer app" that will drive the Internet toward predictable, high performance.

In the near term, storage-system designers will compensate for the lack of guaranteed quality in public infrastructure by working around the data network. For example, storage networks will be extended using various technologies that allow direct transport of Fibre Channel over asynchronous transfer mode (ATM), SONET, or DWDM. These will mostly be deployed in point-to-point networks between mirrored data centers.

Many new data networking models are being tried. All seek to provide the "holy grail" of infrastructure: predictable, high performance. Among the models being tried are ATM (rapidly falling from favor), multiprotcol label switching (MPLS) (still on probation), and switched metro Gigabit Ethernet. All of these avoid the "drop when congested" behavior of the router. All use some form of flow control or flow-rate management to ensure that excessive data is not transmitted over the network.

Figure 1 shows the SAN interconnection through various options.

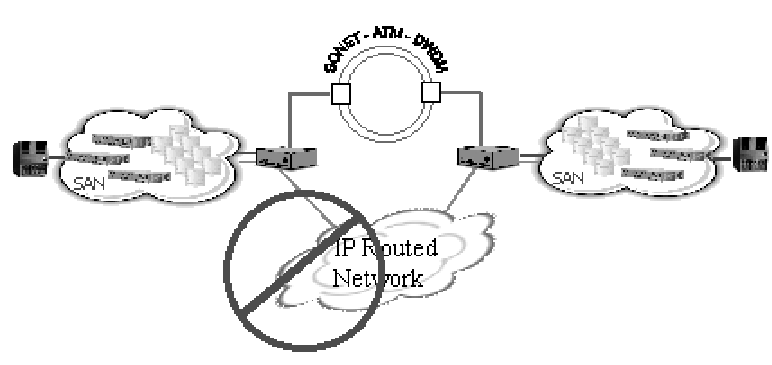
It is not clear which of these will emerge as the ubiquitous winner. However, it is clear that there is a tremendous need for predictable QoS in the next generation of data networks. Storage networking is at the front of the line demanding this quality.

Conclusion

The emerging "real-time enterprise" has created a demand for business that operates in a non-stop, on-demand fashion. This has created a need for business continuance solutions that also operate in a non-stop fashion. To meet this need, mirrored data centers will become more common. In addition, storage will become a truly networked asset that can be secured and managed. Networked, geographically dispersed storage, with synchronized content, will provide higher performance to end-users.

However, since storage systems have traditionally enjoyed very low latency and high throughput, there will be new demands placed on the new world of network interconnect to minimize the latency. There are two ways in which the

FIGURE 1



latency requirement will be addressed. Initially, there will be bypass networks deployed that provide point-to-point high-bandwidth, low-latency interconnection. These will be based on SONET or DWDM technologies. Later, interconnect technologies—such as ATM, MPLS, or more likely switched Gigabit Ethernet—will emerge to provide a more flexible interconnection without sacrificing performance. As these technologies stabilize within the world's network infrastructure and as their performance increases, storage systems will move to adopt them because of their ubiquity and lower total cost of operation (TCO).

Softswitch Is a Disruptive Technology

Frank Ohrtman
Telecommunications Consultant and Degree Candidate,
Interdisciplinary Telecommunications Program
University of Colorado

Introduction

The first deployment of the No. 4 electronic switching system (ESS) Class-4 switch[1] in the North American market was in 1976[2]. The performance and operational savings of the No. 4 ESS led to the replacement of all of the preceding technology, namely the No. 4 crossbar switch, within about a decade[3]. The replacement of the No. 4 crossbar switch by the No. 4 ESS is an example of a sustaining technology. A new technology known as Class-4 replacement softswitch is now entering the market and has the potential to displace the Class-4 switch in certain markets.

Definitions

In the mainstream circuit-switched telecommunications architecture, the Class-4 switch interconnects Class-5 switches. Class-4 switches provide traditional toll (long-distance) services.

A new technology has come on the market known as the Class-4 replacement softswitch. Softswitch seeks to surpass the functionality and performance of legacy circuit-switched Class-4 switches by providing lower cost (both in purchase and operations), smaller form factor, distributed architecture, and open standards (see *Table 1*).

In his 2000 business book, *The Innovator's Dilemma*, author Clayton Christensen describes how disruptive technologies have precipitated the failure of leading products and their associated and well-managed firms. Christensen defines criteria to identify disruptive technologies regardless of their market. These technologies have the potential to replace mainstream technologies and their associated products. Disruptive technologies, as defined by Christensen, are "typically cheaper, simpler, smaller, and, frequently, more convenient" than their mainstream counterparts. Furthermore, disruptive technologies "bring to market a very different value proposition than had been available previously ... disruptive technologies under perform established products in mainstream markets."[4]

What is a softswitch? As in the early days of any emerging technology, there is much confusion, if not conflict, over terminology. Currently, there are two popular uses of the term "softswitch." According to the International Softswitch Consortium (ISC), a softswitch (a.k.a. call agent, call server, or media gateway controller), is a device that provides, at a minimum, the intelligence to control connection services for a media gateway, the ability to select processes that can be applied to a call, routing for a call within the network based on signaling and customer database information, the ability to transfer control of the call to another network element, and interfacing to and support of management functions such as provisioning, fault, billing, etc.[5]

A softswitch *solution* is defined by its components. A softswitch solution is comprised of a media gateway controller (also known as a gatekeeper), a voice over Internet protocol (VoIP) gateway (also known as a media gateway), a signaling system 7 (SS7) signaling gateway, and an applications server. This paper will use the term "softswitch" to denote a softswitch solution.[6]

Markets

Over the past few years, dominant North American interexchange carriers (IXCs) have seen their respective market-shares erode. One reason for this is the lowering of the technology barrier to entry into their market. Previously, a long-distance service provider would have to invest great sums in Class-4 switches and nation-wide circuit-switched networks. The high cost of that technology reserved this market for only the very well capitalized. This lowering of the barrier to entry is made possible by new softswitch technology that is cheaper, smaller, and offers distributed architecture and open standards.

Service providers speak of a telecommunications market where voice and data are converged and the subscriber enjoys highly efficient Internet protocol (IP) services "desktop to desktop." This is called a *converged* network (see *Figure 2*). The vast majority of the Class-4 switch market was designed and installed before the advent of converged or IP networks, where voice and data were handled via separate channels. These are referred to as *legacy* networks (see *Figure 1*). For the purposes of this thesis, the author refers to the transition network as a *converging* network (see *Figure 1*). To define the markets for Class 4 and softswitch, it is important to understand that legacy markets applies to legacy networks, where voice and data are separate networks; that a converging market applies to converging networks, where, in most instances, the legacy infrastructure remains of Class-4 and Class-5 switches at the periphery of the network while the core of the network

TABLE 1

Comparison of Class 4 and Softswitch

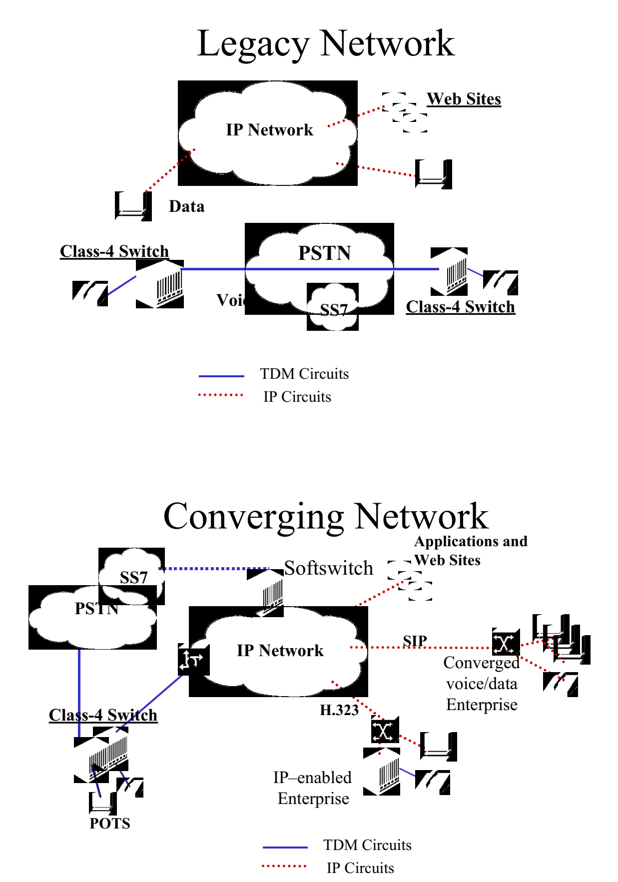
Class 4	Softswitch
Reliable (five nines)	Not as reliable as Class 4
Scalable (more than 100,000 ports)	Not as easily scalable as Class 4
Good quality of service (QoS)	QoS inferior to Class 4
Established features and applications	Features and applications not defined—possibly greater
Circuit-switched	Packet-switched
Expensive	Less expensive than Class 4
Centralized architecture	Distributed architecture
Large form factor	Small form factor
Proprietary standards	Open standards

is IP providing efficient long-distance voice transport (see *Figure 1*); and that a converged market applies to a converged network where voice and data are handled on one network (see *Figure 2*).

Softswitch is best suited for the converged market, where the majority of long-distance voice traffic is transported on converged IP networks and circuit switching is not present. Mainstream Class-4 technology was designed for legacy markets and is largely unsuitable for the efficiencies demanded in the converged market. Softswitch is gaining market-share at the expense of Class-4 in the converging market.

FIGURE 1

Legacy and Converging Networks with Class 4 and Softswitch



Advantages of a Class 4

Successful companies provide their customers with what their customers demand. In the author's experience in selling switching equipment, service providers demand reliability, scalability, QoS, and well-established features in their phone switches. Class-4 vendors have hybridized the product specifically for the North American legacy market. Its advantages are reliability, scalability, QoS, and well-established features.

Reliability

The focus of debate on this issue in the industry revolves around the question of how many "9s," or how much reliability, a product can deliver. The public switched telephone network (PSTN), or legacy voice network, boasts "five 9s," that is, 99.999 percent reliability. This equates to 5.25 minutes of downtime per year.

Scalability

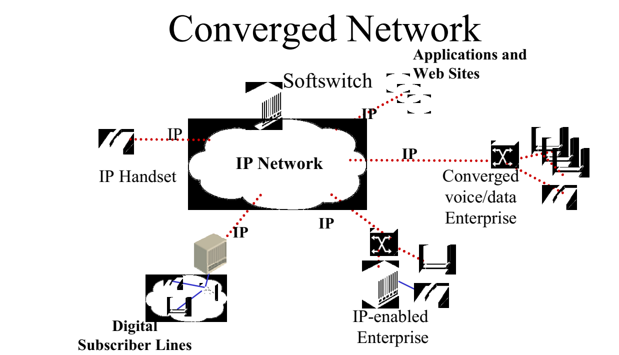
For a variety of reasons, a Class-4 switch must scale to the maximum possible at the upper end. Given the centralized architecture of the PSTN, "bigger is better." There are approximately 1,400 Class-4 switching offices in the United States. A switch with 100,000 ports delivers advantageous economies of scale. Nortel's DMS-250 Class-4 switch scales up to approximately 100,000 ports. The other matrix for scalability is the call processing power of the switch. The DMS-250, for example, can process 700,000 busy-hour call attempts (BHCA).[7]

Quality of Service

The voice quality of the North American PSTN is the standard for telephone service worldwide. The Class-4 switch was the first deployment of time division multiplexing (TDM) utilizing a 64 kilobit per second (kbps) circuit, which remains the standard to this day. Service on the PSTN is known for the absence of echo, crosstalk, latency, dropped or blocked calls, noise, or any other degradations of voice

FIGURE 2

The Converged Network
Note the absence of Class-4 and Class-5 switches.



for most long-distance service providers. Any technology that would challenge its dominance must match Class 4 in performance and offer advantages of its own.

Advantages of Softswitch

Softswitch Is Cheaper Than Class 4
Softswitch is cheaper than Class 4 in purchase cost and operations, administration, maintenance, and pProvisioning (OAM&P). A recent study by a major carrier found that packet equipment was 70 percent less expensive than traditional voice equipment, and data access lines were 60 percent to 80 percent cheaper than voice lines. The maintenance of packet networks was 50 percent less expensive, while provisioning was 72 percent lower.[9]

It is estimated that a service provider's largest cost is the ongoing expense of running the network and the switches themselves. Networks must be deployed, maintained, repaired, monitored, and upgraded. Aberdeen Group found that competitive carriers spend 60 to 70 percent of their overall expenses on OAM&P. The ability to manage the entire network via a softswitch solution (including adding and altering specific customer services, upgrading capacity, and fixing faults) from a centralized location leads to considerable time and cost savings.[10] Packet technology–based long-distance carriers maintain that their service-provider customers will be able to offer voice services at 20 percent off traditional rates and claim the underlying infrastructure can be 40 percent less expensive to operate.[11]

quality. Mainstream service providers in North America are unlikely to deploy equipment that offers voice quality at a lesser standard than the Class-4 switch.

The long-distance service providers have owned and operated their own proprietary networks over which they have had total control.

Class-4 Features
With almost three decades of development, the Class 4 has a well-established list of features. Custom local-area signaling services (CLASS) features are basic services available in each local access and transport area (LATA).[8]

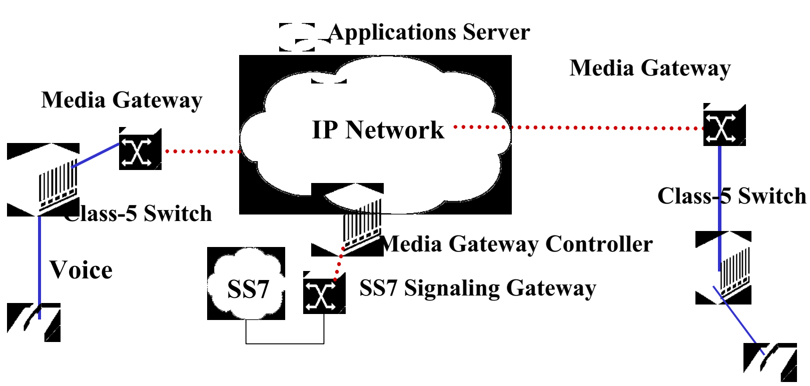
DMS-250 system long-distance features can be grouped under two major portfolios: basic and enhanced services. The basic services include such features as 1+, 800/900 service, travel cards, account codes, personal identification numbers (PINs), operator access, speed dialing, and automatic number identification (ANI) screening. Most of the aforementioned features have been standard on the DMS-250 and other Class-4 switches for many years.

In summary, the Class 4's reputation for reliability, scalability, QoS, and features has made it the preferred technology

Smaller Discrete Form Factor
Softswitch is smaller than Class 4. This is an advantage for softswitch. Due to the smaller "footprint," or discrete form factor (smaller size and shape), softswitch power consumption and cooling requirements are also less than the legacy switches due to their smaller size. Smaller hardware size also translates into lower "real estate" expenses. A Class-4 switch is usually located in a central office (CO), where space is a precious commodity and the cost of rack space is high. Softswitch components need not reside in a CO (see *Figure 3*). This opens many possibilities for locating the equipment in less expensive "co-loc hotels," that is, commercial co-location spaces located, in many cases, near COs.

FIGURE 3

Softswitch Solution in the Converging Market



Distributed architecture saves a carrier money in that its components need only reside somewhere on the IP network and not in a CO. Smaller softswitch components can be distributed around the network at less expense than large centralized Class-4 switches.

The smallest configuration for DMS-250 (Nortel's Class 4) is 480 digital signal (DS)–0s (20 T1s). For many locations and service providers, this presents a potentially expensive overabundance of capacity. Many media gateways scale by the T1 or E1 card allowing a greater flexibility in scaling down to capture certain markets and to take advantage of distributed architecture. If a service provider purchases and installs only what they need to get started in a given market and adds capacity only as it is absolutely necessary, then capital is not invested in equipment that cannot immediately generate revenue. The ability of a softswitch to scale *down* is an advantage for many carriers.

Advantages of Distributed Architecture

Long-distance bypass carriers were enabled by smaller gateways to roll out service in diverse markets and took market-share from large mainstream long-distance providers. Assume that service providers that were not traditionally voice service providers—that is, cable-television (CATV) operators, Internet service providers (ISPs), power companies, or digital subscriber line (DSL) providers—wanted to originate and terminate long-distance traffic for their existing customers. Following the long-distance bypass model, they could install media gateways in a number of points of presence (POPs) in tier 1 and 2 cities, and they could potentially take market-share from the legacy long-distance Class-4 carriers. This scenario points to the displacement of Class 4 by softswitch, a disruptive technology (see *Figure 4*).

Open Standards

A softswitch solution emphasizes open standards as opposed to the legacy Class-4 switch that historically offered a proprietary and closed environment (see *Figure 5*). A carrier was a "Nortel shop" or a "Lucent shop." No components (hardware or software) from one vendor would be compatible with products from another vendor. This usually results in less competitive pricing for those components. Softswitch open standards are aimed at freeing service providers from vendor dependence and the long and expensive service-development cycles of legacy switch manufacturers.

The absence of a robust feature list identical to those found on a DMS-250, for example, is an objection among service providers. Softswitch offers the advantage of allowing a service provider to integrate third-party applications or even write their own. While softswitch may have lacked a feature set directly comparable with Class 4 in the past, recent developments in the industry indicate that an ambiguous feature set might be an advantage rather than a performance deficiency. This is potentially the greatest advantage to a service provider presented by softswitch technology.

Softswitch Is a Disruptive Technology

Softswitch enables a lowering of the barriers to entry for service providers in the converging long-distance market. Compared to the Class-4 switch, softswitch, in the form of a Class-4 replacement, is a disruptive technology. Christensen's *The Innovator's Dilemma* sets parameters to compare and contrast the Class 4 and softswitch in the converging market.

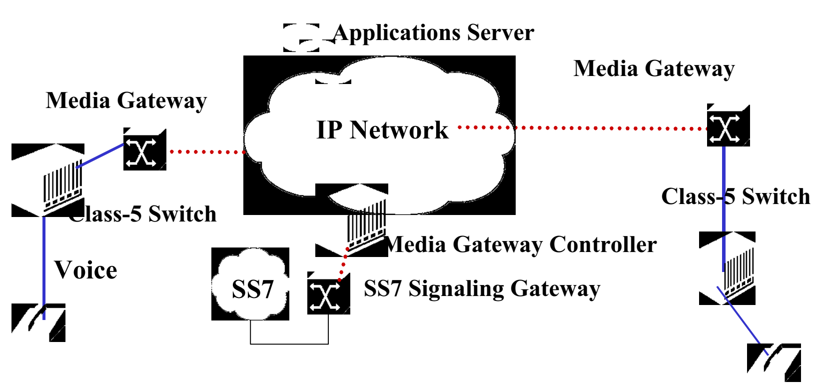
Softswitch has a number of technical deficiencies that hinders its growth in market-share in the converging market. They are scalability, reliability, QoS, and well-defined features and applications. Softswitch lacks the scalability of the Class 4 in that it does not yet match the density or call processing power of a Class-4 switch. Softswitch is not yet established as consistently delivering "five nines" of reliability.

Softswitch must overcome QoS issues to win trust in the converging market. Engineering improvements in the gateways and IP networks can accomplish this. Some media gateways can deliver voice quality that is indistinguishable from the PSTN.[12] The Class-4 switch offers service providers and subscribers many standard applications and features. The softswitch industry has yet to succinctly define applications and features, but its open architecture potentially allows it to offer *more* features than Class 4. Softswitch vendors are striving to correct the aforementioned deficiencies, and when they do, softswitch will replace Class 4 in the converging market.

Just as softswitch has quantifiable deficiencies, it also has a number of quantifiable advantages over Class-4 technology. Those advantages are that it is cheaper and smaller and offers distributed architecture and open standards.

FIGURE 4

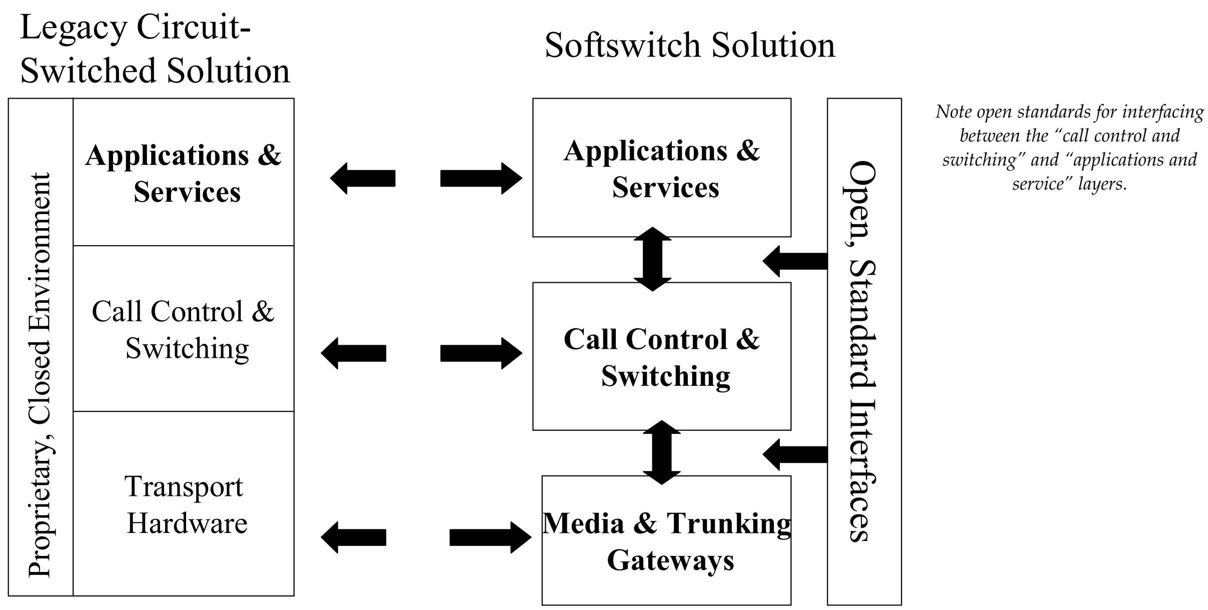
Softswitch Replaces Class 4 in the Converging Market



Distributed media gateways installed in or near COs would negate the need for large, centralized Class-4 switches in a converging market.

FIGURE 5

Three-Layer Softswitch Architecture Compared with Legacy Circuit Switching



It is cheaper than a Class 4 in both purchase and OAM&P costs. A discrete form factor smaller than a Class-4 switch coupled with distributed architecture gives softswitch the advantage of rapid roll out in markets that cannot be quickly or economically serviced by Class 4. Softswitch offers open standards as opposed to Class 4's proprietary standards. Open standards enable softswitch to offer expanded high-margin applications and services.

It is unlikely that incremental changes to the Class 4 will satisfy the converging market. A more likely scenario is that the incremental improvement of softswitch technology will over come the performance deficiencies of scalability, reliability, QoS, and features and applications while maximizing the advantages of its technology. As this occurs, softswitch will displace Class 4, making softswitch a disruptive technology.

Forecast

Using the disruptive innovation thesis, it is important to compare an existing technology set, the Class-4 switch, with a new set, the Class-4 replacement softswitch, in the converging market. Softswitch is deficient compared to Class 4 in reliability, scalability, QoS, and features and applications. Softswitch has some new capabilities also measurable (distributed architecture, lower cost, smaller form factor, and open standards) that appeal to the converging market in preference to the Class 4.

Either the Class 4 evolves to technology performance requirements of the converging market or softswitch, over time, is incrementally improved until its original performance deficiencies are erased while it still retains its advantages. In this way, the softswitch disrupts Class 4.

Conclusion

Softswitch, despite having technical deficiencies relative to the Class-4 switch, has enabled a number of long-distance service providers to lower the barriers to entry into the converging long-distance market. The advantages of the softswitch—being that it is cheaper and smaller and offers distributed architecture and open standards—made its initial entry in the converging market possible. In the converging market, softswitch vendors are correcting the technical deficiencies suffered by the softswitch regarding scalability, reliability, QoS, and features and applications. By virtue of competing in the converging market, being initially technically inferior to the mainstream Class-4 switch, and having certain advantages over the Class 4, softswitch is a disruptive technology that will replace the Class-4 switch.

Media Gateway Control Protocol: Providing Structure in Today's IP–Based Telephone Systems

Randy Salminen

Senior Systems Engineer

Integral Access, Inc.

Executive Summary

The Media gateway control protocol (MGCP) provides the call control necessary to allow wide-scale Internet protocol (IP) telephony over the Internet with interoperability between legacy telephone networks. Efficient and suited for growth and interoperability with legacy voice connections, MGCP is the number-one option for providing signaling over IP networks today.

1. Introduction

Voice over IP (VoIP) is here. Only a few short years ago, we learned about this packet-based tool called the Internet. This breakthrough technology initially enabled us to communicate data between remote locations; later, it allowed us to explore sites for knowledge, shopping, and entertainment. As technology evolved, graphics became more intense and lifelike. High-resolution graphics then led the way for video clips. Now we can even watch and participate in live voice and video connections across this worldwide packet-switched network.

1.1. VoIP Development

Unlike its circuit-based cousin (legacy telephone network), the Internet is packet-based. It was initially designed for worldwide data exchange but has outgrown the concepts and imaginations of its creators by leaps and bounds. The Internet is here to stay (and grow) for a very long time. In addition, VoIP will continue to evolve and grow as an important part of the Internet and other packet-switched networks. However, in order for both voice and video traffic to travel over a data-oriented network and arrive without any noticeable delay in sight or sound, improvements were necessary.

1.2. The Future of VoIP

Since IP and the Internet are ubiquitous, and because the existing public switched telephone network (PSTN) is extremely inefficient in its use of bandwidth, improvements are continually being made. Equipment vendors are quickly implementing protocols such as multiprotocol label switching (MPLS) to provide quality of service (QoS) and turn the Internet into a truly real-time, user-friendly atmosphere. As a result, VoIP is one of the fastest growing industries today (see *Figure 1*).

1.3. Why We Need MGCP

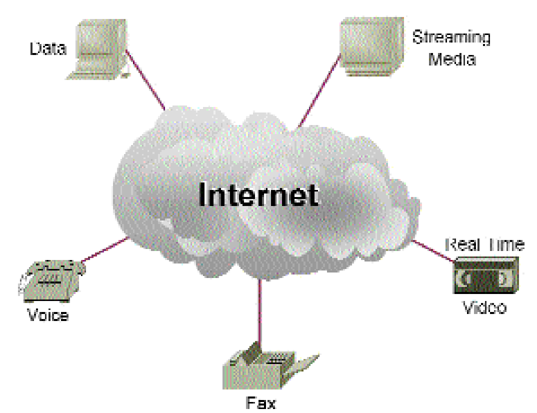
In order for the Internet to perform the functions of a full-fledged voice network (and beyond), it needs a structure that allows a user to make a call to any phone anywhere—whether the call is from an IP phone to a legacy phone, or vice versa. Of course, the resiliency of cellular phones, as well as the quality and features of landline-based legacy phones, is needed. MGCP provides the structure required in an IP–based telephone system.

1.4. What Is MGCP?

MGCP, an Internet Engineering Task Force (IETF) draft, has been chosen as the initial protocol to provide the call control necessary to allow wide-scale telephony over the Internet. MGCP also provides the interoperability between the Internet and legacy telephone networks. MGCP is American Standard Code for Information Interchange (ASCII)–based and resides in a user datagram protocol (UDP) packet, relying on a positive acknowledgment mechanism to deal with packet loss. As its basis, MGCP's stateless protocol was designed using a combination of Cisco Systems and Bellcore's simple gateway control protocol (SGCP) and the Level 3 Technical Advisory Committee's Internet protocol device control (IPDC) specification. Combining these two protocols facilitated a single specification, and, in turn, enabled faster deployment. To ensure security, MGCP uses the IP security (IPSec) protocol and has the ability to use encryption on the media streaming at the terminal equipment. MGCP works with several other protocols to provide the various functions that will be needed in the Internet for VoIP.

FIGURE 1

Internet Uses Today



2. Software Architecture

MGCP is used to communicate between a call agent and a gateway. Together, these help to make up the softswitch architecture (see *Figure 2*). The call agents (also referred to as media gateway controllers) are the brains of the operation, and the gateways are the muscle. You need both of them to complete a call over a public network using MGCP. The call agent sends commands to the gateway and receives an acknowledgment for each one. An advantage to call agent/gateway architecture is that new services can easily be introduced without having to swap or upgrade gateways. This model appears as if it is a single gateway, but it is actually distributed. This is commonly referred to as the decomposed gateway architecture. Putting the call-control functions in the call agent and the media streaming functions in the gateway allows for both greater scalability as well as more simple, inexpensive, and reliable local access equipment.

2.1. The Call Agent

The call agents, also called media gateway controllers or gatekeepers, are scattered about the Internet and act as telephony routers directing calls from place to place. The call agent is required for signaling within a call but is not involved in passing the voice traffic. Each call agent, responsible for a number of gateways, accepts event messages from them and tells them how to process calls via a relatively small set of MGCP messages and procedures. The call agents do not communicate with each other via MGCP. Call agents communicate via session initiation protocol (SIP) and H.323 (see Section 5 of this paper). Ideally, network providers will set up several gateways within their network to provide access for their users or customers. One or more call agents, or access to a call agent from another provider, should be set up. The call agents need to have the ability to route calls to and from the PSTN as well as the ability to route calls to and from customers of other network providers across other call agents and gateways. Call agents may also route calls to application or media servers.

2.2. The Gateways

A gateway is a device that is designed to join unlike elements (see *Figure 3*). A media gateway joins unlike media. In the case of MGCP, signals are joining or converting media between circuits and packets, and voice and packets. In MGCP, there are a number of different types of gateways performing different tasks. Each of these gateway types has a distinguishing name and allows voice to be encapsulated in packets. The gateways are primarily concerned with audio signal conversion and media streaming, while the call agents deal mainly with signaling functions. The gateways may be positioned at the customer premises where they can be directly connected to plain old telephone service (POTS) telephones, a private branch exchange (PBX), or a data network. They can also be found at a point of presence (POP) or co-location (colo) where they can service larger numbers of users as well as provide other high-level tasks. Gateways can be associated with multiple call agents to provide redundancy.

2.2.1. The Residential Gateway

The residential gateway may be found in the home or office. Its purpose is to connect the IP telephony subscriber to the packet network and accept events from said subscriber, passing them to the call agent for processing. This gateway also accepts commands from the call agent to set up, control, and tear down calls to and from the subscriber. Residential gateways may be digital subscriber line (xDSL), cable modems, and even broadband wireless devices.

2.2.2. The Trunking Gateway

The trunking gateway, which sits between the PSTN and the Internet, handles the conversion between a legacy telephone

FIGURE 2

The Basic Softswitch Architecture

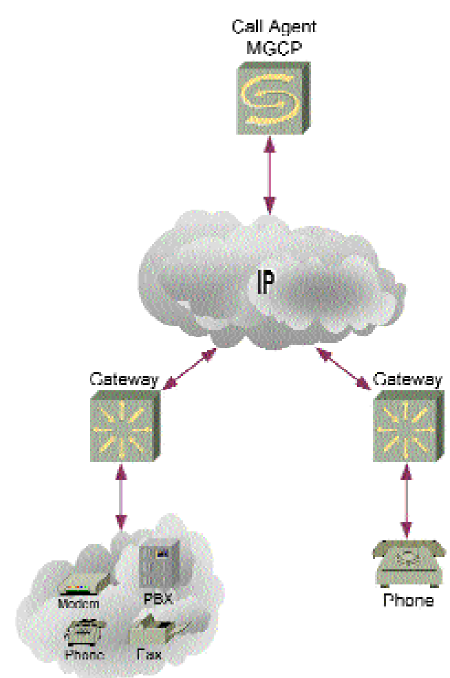


FIGURE 3

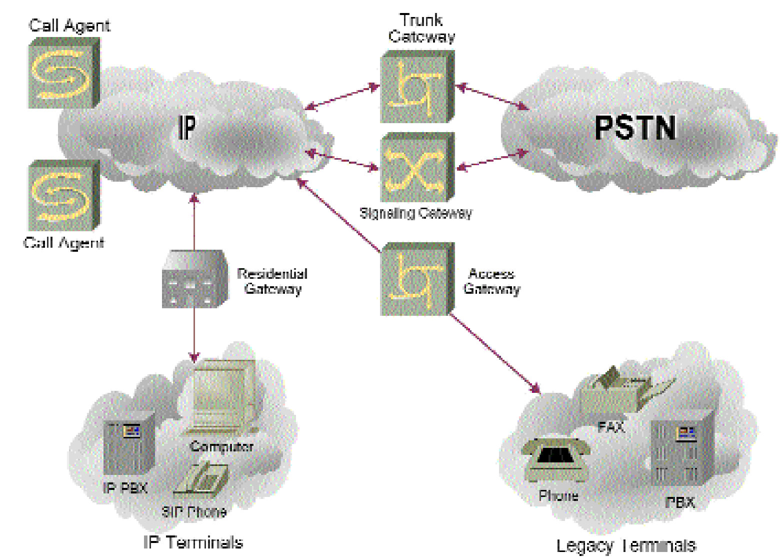
The Gateway Model



network and an IP network. The trunking gateways are large capacity devices capable of handling tens of thousands of digital signal (DS)–0 circuits, which they transform from time division multiplexed (TDM) voice channels into real-time transport protocol (RTP) or MPLS packets.

2.2.3. The Signaling Gateway

The signaling gateway is designed to handle the signaling conversion and forwarding between the PSTN and a packet-switched network. It has large capacity like the trunk gateway and supports a variety of signaling protocols, including signaling system 7 (SS7) and C7.

2.2.4. The Media Access Gateway

The media access gateway is used to aggregate end user traffic and call-control signaling. Operating under call-agent control, the media access gateway originates and terminates packet-based voice services, class features, and emerging multimedia communication services. While it is technically possible for call agents to directly control thousands of customer-premises devices directly, it is logically impractical. Aggregating MGCP sessions on a media access gateway vastly simplifies overall network management and offers the following advantages:

- Prevents malfunctioning, malicious, or over-enthusiastic customer-premises equipment (CPE) from overwhelming the call agent to have a negative impact on network performance and potential denial of service to others
- Provides a throttling mechanism for varied levels of service to others
- Provides a signaling aggregation to the call agent
- Helps prevent toll fraud, a significant issue for a service provider that wants to make money

2.3. The Connection Model

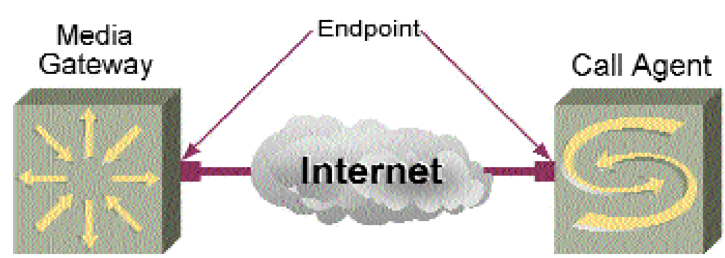
MGCP uses a connection model based on endpoints, calls, and connections. The connection model is a way to reference points and functions that are used to make a connection.

2.3.1. Endpoints

The term *endpoint* is used in MGCP to describe a physical or virtual port on a gateway or call agent (see *Figure 4*). Some

FIGURE 4

Endpoints



examples of endpoints are the termination point for a DS–0, an Ethernet, an audio server, or a POTS line. Media enters or exits through an endpoint. MGCP addresses these endpoints via endpoint identifiers.

2.3.2. Connections

A connection is an association of endpoints for the purpose of passing traffic between them (see *Figure 5*). Connections are typically formed dynamically, as in the case of a phone call. They are point-to-point, or point-to-multipoint. A multipoint connection is an association of multiple endpoints allowing for conference calls. Connections can be made between separate gateways or between different endpoints on the same gateway. They also have mode settings such as send-only, send-receive, and receive-only.

2.3.3. Calls

A call is a logical association of connections between two or more endpoints (see *Figure 6*). A three-way call contains two connections between three endpoints. Calls are managed by the call agent using domain names to identify each one individually. The call agent gives the call a name when it is created to allow greater versatility. The use of addresses as identifiers may restrict mobility.

2.3.4. Events

Events are occurrences in endpoints (e.g., a telephone goes off-hook). A call agent may ask to be notified of certain events and may also incur events such as telling a gateway to supply dial tone to an endpoint. Events are identified by names and are organized into differing name groups called packages. A package contains events for a specific type of

FIGURE 5

Connections

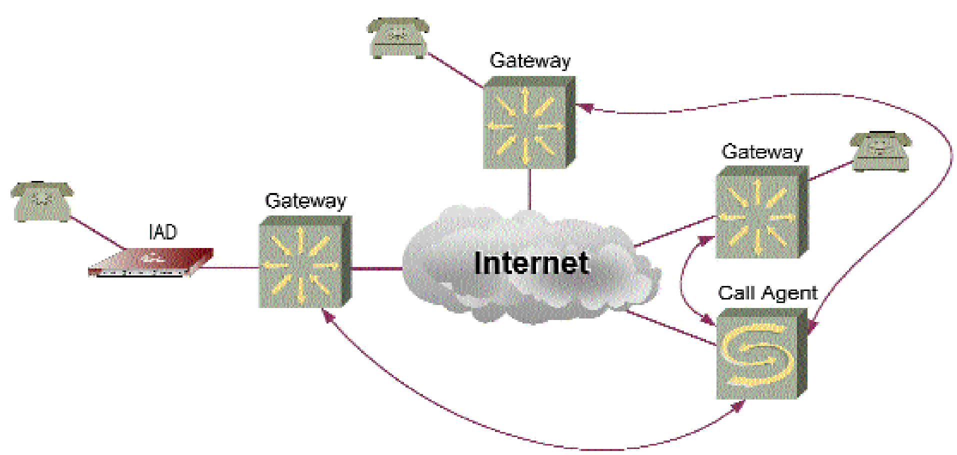


FIGURE 6

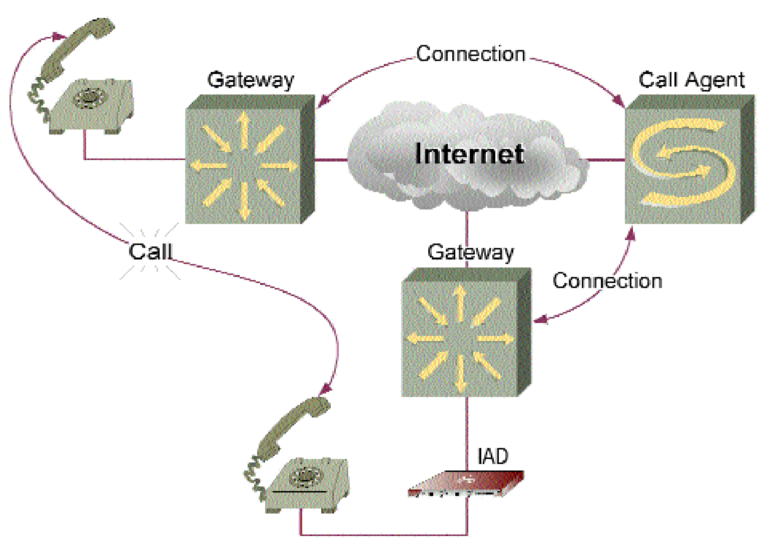
Calls



endpoint, such as an analog line. The names, made up of strings of letters, hyphens, and digits, have two parts: event and package.

3. MGCP Commands

Commands are issued from the call agent to the gateways for setting up and tearing down connections. The gateway sends back responses in return. Each command and response must be acknowledged by the receiver to ensure that none will be missed. Commands are also issued to keep the call agent informed of events at the gateways. There are eight commands defined in MGCP:

1. NotificationRequest
2. Notify
3. CreateConnection
4. ModifyConnection
5. DeleteConnection
6. AuditEndpoint
7. AuditConnection
8. RestartInProgress

3.1. NotificationRequest

The NotificationRequest is sent by the call agent to request notification about a particular event.

Example: The call agent wants to be notified when an off-hook occurs on an endpoint connected to a phone. Notification is necessary because an off-hook is an indication that a call will be taking place and that the call agent needs to take action. The call agent will tell the gateway to issue a dial tone and collect the dialed digits.

3.2. Notify

The Notify command is issued by the gateway in response to a NotificationRequest. The gateway includes a list of the events that it observed in the Notify. It also includes the identifier sent in the NotificationRequest so that the call agent understands the origination.

Example: A Notify could include the dialed digits that came from the phone attached to that endpoint.

3.3. CreateConnection

A CreateConnection is used to build connections on and between endpoints for the purpose of making calls. A CreateConnection is sent to each gateway involved, at which time an IP address and UDP port is associated with the endpoint. A CallId is specified to tie the connections to a call. More than one connection may share a CallId to accommodate situations such as when there is call waiting or conference calling. The CreateConnection includes both the parameters for the connection and the mode of the connection.

Some parameters include the following:

- Voice encoding
- Silence suppression

Some modes include the following:

- Send
- Send/receive
- Receive
- Conference
- Inactive
- Data
- Loopback
- Network loopback
- Continuity test
- Network continuity test

3.4. ModifyConnection

The call agent uses the ModifyConnection to change parameters in existing connections. The parameters used in the ModifyConnection are identical to the parameters in the CreateConnection. The ModifyConnection can also be used for activating and deactivating a connection and for providing information about the other end of a connection.

3.5. DeleteConnection

The DeleteConnection can be sent by the call agent or the gateway to delete an existing connection. The call agent may send the DeleteConnection because the other end of the connection has hung up, or it can be sent by the gateway if it can no longer sustain the connection for any reason. The gateway responds to a DeleteConnection by sending a list of parameters back indicating the final status of the connection.

The parameters include the following:

- The number of packets and octets sent and received
- The number of packets lost
- Inter-arrival jitter
- Average transmission delay

3.6. AuditEndpoint

An AuditEndpoint is a request from the call agent for details about the status of an endpoint or a number of endpoints. The gateway sends a response with audited information including the following:

- Requested events
- Dialing plan
- Connection identifiers

3.7. AuditConnection

The AuditConnection is sent by the call agent requesting information about a connection. The types of information that can be requested include the following:

- Call ID
- Local and remote connection descriptors

Local connection parameters and the mode of the connection

The gateway sends back a response with the information requested.

3.8. RestartInProgress

The RestartInProgress is used by the gateway to indicate the type and to tell the call agent that an endpoint or a group of endpoints has been put in service or taken out of service. The choices are as follows:

- *Graceful:* Indicates that the endpoint will be taken out of service after a slight delay
- *Forced:* Indicates that the endpoint is being taken out of service immediately

- *Restart:* Indicates that the endpoint will be placed in service, possibly after a specified delay

4. A Typical Call Flow

To understand MGCP in practice, we have to walk through a call.

1. A user decides to place a call.
2. The sending user picks up the phone and hears dial tone.
3. The sending user dials the number and hears the ringing.
4. The receiving phone rings to indicate an incoming call.
5. The receiving user picks up the phone and immediately hears the sender.
6. Sender and receiver converse.
7. When they are done, one of them will hang up the phone.
8. The other party then hangs up the phone.

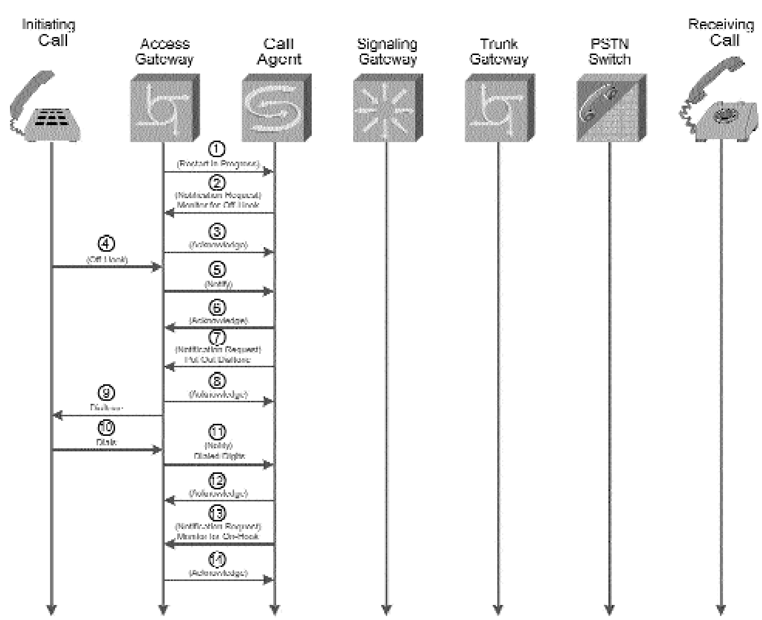
4.1. What Happens behind the Scene

Now let us see what is happening behind the scene. We will assume the user placing the call is using a phone connected to the Internet and that the receiver is connected to a phone on the PSTN. This means the calling party is behind an access gateway, a trunking gateway, and a signaling gateway connecting the Internet and the PSTN.

1. The first message is a RestartInProgress, which is sent by the access gateway, indicating the availability of its endpoints.
2. Before the phone goes off-hook, the call agent had sent a NotificationRequest to the access gateway, telling it to monitor for off-hook conditions.
3. The gateway acknowledges the command.
4. The calling party picks up the phone.
5. The off-hook condition causes the gateway to send a Notify to the call agent.
6. The call agent sends back an acknowledgment.
7. A NotificationRequest is sent by the call agent, telling the gteway to put out a dial tone and collect digits.
8. The gateway responds with an acknowledgment.
9. Dial tone is put out on the line connected to the calling party.
10. The calling party dials the phone.
11. The gateway sends a Notify to the call agent with the dialed digits.
12. The call agent sends the gateway an acknowledgment.
13. The call agent then sends a NotificationRequest to the gateway telling it to stop collecting digits and to monitor for an on-hook condition.
14. The gateway acknowledges the call agent (see *Figure 7*).
15. The call agent sends a CreateConnection to the gateway to create the connection.
16. The gateway sends an acknowledgment that contains all of the necessary information about the endpoint.
17. The call agent determines where to route the call, then sends a CreateConnection to the receiving gateway.
18. The gateway sends an acknowledgment along with its relative information.
19. The call agent then sends an SS7 ISUP initial address message to the signaling gateway that will allow the signaling to be hooked into, and understood by the PSTN.
20. The signaling gateway forwards the message to the proper local-exchange carrier (LEC).
21. The PSTN returns a set-up complete message to the Signaling Gateway.
22. The signaling gateway forwards the message to the call agent.

FIGURE 7

A Call Set-Up—Phase One



23. The call agent sends a NotificationRequest command to the access gateway to tell it to start ringing.
24. The gateway acknowledges the command and puts ringing on the line.
25. The called party picks up the phone.
26. The PSTN sends an ISUP answer message to the call agent.
27. The call agent sends a NotificationRequest message to the access gateway telling it to take off the ringing.
28. The gateway sends an acknowledgment to stop ringing.
29. The call agent sends a ModifyConnection command to the gateway to put it into a send/receive mode.
30. The gateway sends an acknowledgment and goes into send/receive, and the call is established. The parties can now converse (see *Figure 8*).
31. When they are done, one of the parties will hang up first. Assume it is the called party.
32. A release message gets sent to the call agent from the LEC.
33. The call agent sends a DeleteConnection to the gateways.
34. The gateways will respond with an acknowledgment and include the final status of the connection.
35. The calling party hangs up the phone.
36. The access gateway sends a Notify to the call agent.
37. The call agent sends a NotificationRequest back to the gateway, telling it to monitor for off-hook.
38. The access gateway sends back an acknowledgment that the call is finished (see *Figure 9*).

This is how MGCP works.

5. Other Signaling Protocols

In addition to MGCP, there are a number of other protocols that are possible alternatives or complements to MGCP. Two of the most prominent are H.323 and SIP.

5.1. H.323

H.323 is an umbrella protocol consisting of a number of different sub-protocols that are used to support audio, video, and data applications. There are three versions of H.323:

- The ITU specified version 1 in 1996.
- Version 2 in 1998.
- Version 3, the mature signaling protocol

Version 3 shall be used for this discussion.

The H.323 suite was designed to do the following:

- Provide video, audio, and data across various network types
- Do point-to-point and multipoint conferences
- Handle call control, multimedia environments, and prioritization
- Function across a local-area network (LAN) or wide-area network (WAN)

Its model is similar to MGCP in that it uses gateways to do the media conversion and gatekeepers (the H.323 term for

FIGURE 8

A Call Set-Up—Phase Two

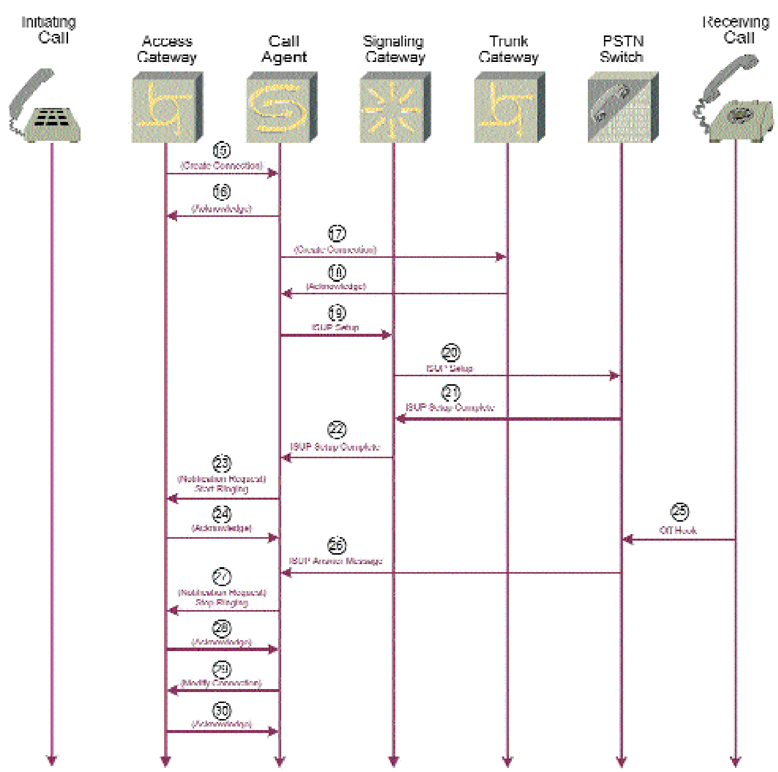


FIGURE 9

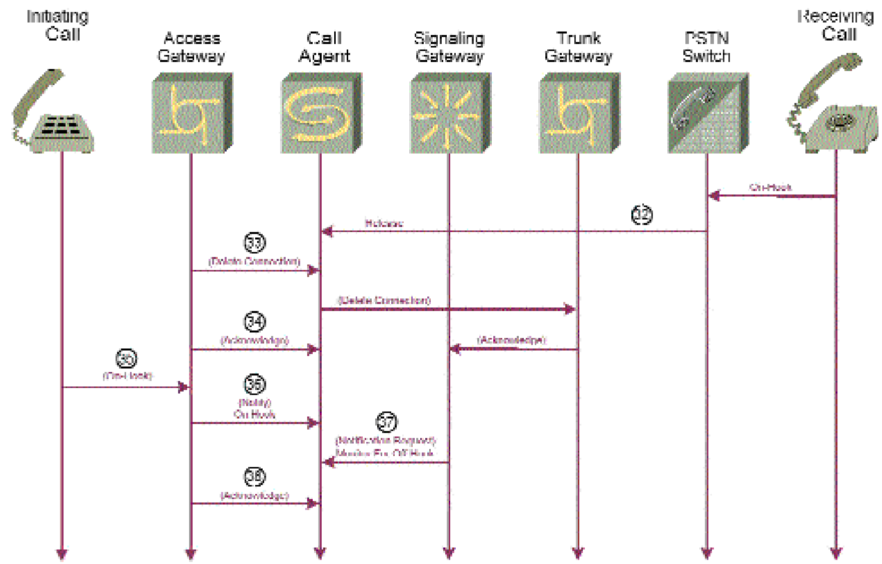
A Call Set-Up—Phase Three



call agents) to do the signaling. The main difference, however, is that unlike MGCP, H.323 was designed to work primarily with intelligent endpoints (such as IP–based telephones), whereas MGCP was intended to function with integrated (intelligent) access devices (IADs) and simple, dumb, endpoints (such as a normal telephone).

H.323 is a complex protocol with a heavy code base. This makes it a very intelligent protocol, but it also causes it to be more expensive to build gateways, and it makes it more difficult to build a simple, reliable gateway. H.323 has a concentrated peer-to-peer architecture that does not allow easy scaling—a key concern to large network providers that need millions of connections. Other shortfalls include the following:

- H.323 is based on transmission control protocol (TCP)/IP, which can cause too much delay to make it practical.
- It will connect over LANs that have no QoS control—an unacceptable solution when you are connecting to the PSTN (which does not tolerate delays).
- Neither H.323 nor SIP was designed to interface with the PSTN—a drawback to using either as a full-scale solution.

5.2. SIP

SIP is a signaling protocol for Internet conferencing, telephony, presence, events notification, and instant messaging. SIP is a text-based protocol, similar to hypertext transfer protocol (HTTP) and simple mail transfer protocol (SMTP), for initiating interactive communication sessions between users. Such sessions include voice, video, chat, interactive games, and virtual reality. SIP is basically the next generation of H.323. It is less complex and better designed than H.323 and is well suited for connection set-up and media mapping. It is designed similarly to H.323, as it communicates with intelligent endpoints. SIP was brought about to dethrone H.323, but since H.323 is pretty well entrenched, most likely the two will coexist for some time.

5.3. H.248/MEGACO

H.248 is the name given to this protocol by the International Telecommunication Union (ITU), and MEGACO is how it is recognized today by the IETF. This is the first time that these two groups have worked on a standard together and is indicative of the future meshing of telecommunications and the Internet. H.248 has a lot of similarities to MGCP and is typically referred to as the protocol that will eventually supersede it. H.248 uses the gateway/call-agent architecture and also handles the call set-up much like MGCP; however, the naming of the parts and functions differs. H.248 also adds enough complexity to allow it to support video traffic (see *Figure 10*). Though there has been successful testing of H.248, it is still an infant in the world of signaling protocols.

6. Surrounding Protocols

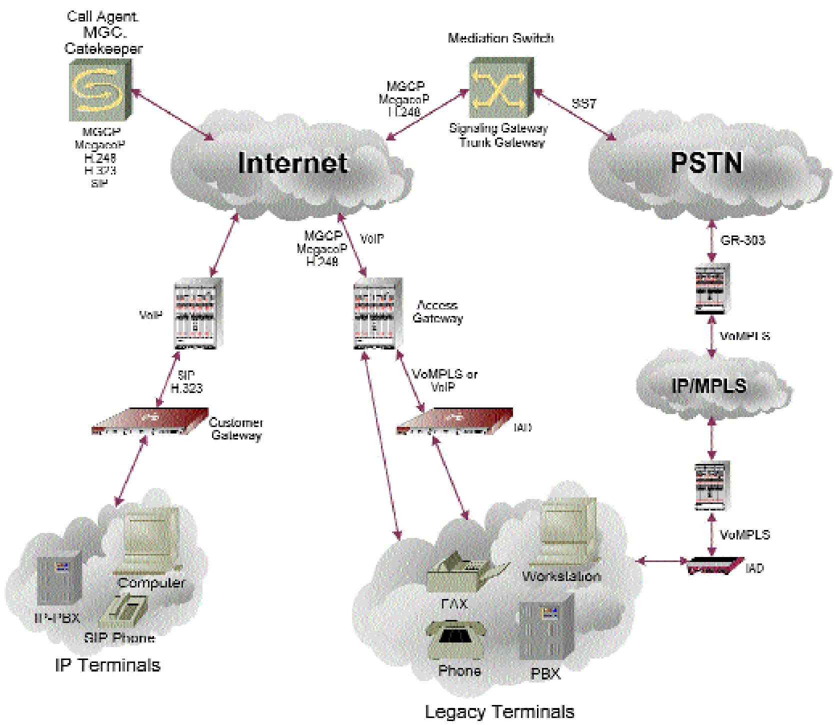
As stated earlier, MGCP is a protocol that works together with others to perform the feat of delivering voice over packets. The protocols that surround it are many and varied. We will touch on several of the most important and prevalent surrounding protocols.

6.1. SDP

The session description protocol (SDP) is used to help set up a connection. Defined in RFC 2327, its job is to hand the endpoints the information needed to be compatible with the network (i.e., the type of call being made and its opposite endpoint). The call agent that is associated with the gateway on which that endpoint is located uses SDP. SDP commands will be sent from the call agent at the time of call set-up or modification. Some examples of descriptors are IP addresses, payload types, and RTP port numbers.

FIGURE 10

The Complete Solution



6.2. RTP

RTP is used for transporting real-time audio or video streams over packet-switched networks. MGCP is only used to set up, modify, and tear down the calls; it needs a protocol like RTP to handle the actual voice traffic. RTP does not reserve bandwidth; it can only send information to the receiver. The receiver has to be able to act on the information through things such as jitter buffers. Some of the information provided by RTP includes the following:

- Time stamps, so that the receiver can determine if there is any delay
- Sequencing numbers, so the order of the packets is preserved
- Payload identifiers, used to express what type of encoding is being used for the media

This is important because bandwidth allocation in the Internet may adjust the encoding to conform to the available bandwidth.

6.3. RTCP

The real-time control protocol (RTCP) works with RTP to help ensure QoS. It will send information to users upon request, providing them with information on round trip delay, jitter, and lost packets.

6.4. MPLS

MPLS has emerged as the preferred technology for providing QoS, traffic engineering, and virtual private network (VPN) capabilities on the Internet. MPLS contains forwarding information for IP packets that is separate from the content of the IP header, such that a single forwarding paradigm (label swapping) operates in conjunction with multiple routing paradigms.

The basic operation of MPLS is to establish label-switched paths (LSPs) through the network into which certain types of traffic are directed. MPLS provides the flexibility of being able to form forwarding equivalence classes and also being able to create a forwarding hierarchy via label stacking. All of these techniques facilitate the operation of QoS, traffic engineering, and VPNs.

Once an MPLS enabled network is established, additional routing protocols or extensions of existing routing protocols can be used to activate the MPLS capabilities. For example resource reservation protocol–traffic engineering (RSVP–TE), a control/signaling protocol, can be used to establish a traffic-engineered path through the routed network for high-priority traffic.

Voice is one of the most important types of traffic carried on today's networks. For an IP network to be truly considered "multiservice," it must accommodate voice traffic and its unique transmission requirements. Unlike data traffic, voice traffic needs to travel consistently through the network without being subject to delay or packet re-ordering. A standard IP network, operating on a best-effort basis, is unable to guarantee such preferred treatment. An MPLS enabled network, on the other hand, is able to provide low-latency and guaranteed traffic paths for voice. Using MPLS, voice traffic can be allocated to a forwarding equivalence class that provides the differentiated service appropriate for this traffic type.

7. Summary

MGCP is a required protocol to allow the proper growth of VoIP. Efficient and suited for growth and interoperability with legacy voice connections, MGCP is part of the signaling-protocol evolutionary process.

Prior to MGCP was H.323, but its design limits it to functioning in niche areas. Also, it doesn't perform optimally. Next is SIP—more simple and efficient then H.323. SIP is suited for environments where the end device has the intelligence to interact with the SIP server and where interaction with legacy switches is not required.

The next evolutionary step is MEGACO, or H.248, which is designed to be optimal for both voice and video. Smart MGCP product vendors are preparing for the next step by building their devices to be ready to turn on MEGACO when it is finally deployed.

Developing a Distributed Internet-Based PBL Environment Using Java Beans, CORBA, and JDBC

Mohammed Samaka

Associate Professor of Computer Science and Director of the Computer Science Program, College of Information Technology

United Arab Emirates (UAE) University

Abstract

Problem-based learning (PBL) is a student-centered learning method that provides students with problem-solving, self-directed learning, and collaborative learning skills. PBL has become an increasingly popular method of learning in many professional fields—for instance, in industrial training and in university education that require group management. This research project involves the design, development, and implementation of an instructional software system that runs on the Internet. The system provides a distributed-based multimedia environment that supports the PBL approach. The design is a complete three-tier client/server application for the Web using Java Beans, common object request broker architecture (CORBA), and Java database connectivity (JDBC). It provides synchronous and asynchronous communication services that allow students in one group to communicate remotely either with each other or with the course instructor. This application is being proposed to university and industrial courses that involve projects management, instructor supervision, and group work.

1. Introduction

PBL is an educational format that is centred around discussion and learning. It is a method that encourages independent learning and a deeper understanding of the material rather than superficial coverage (Gallow, 2000). With this approach, students are more involved in their own learning and group work and take responsibility for solving professional problems. The instructor creates a problem situation for the students and then acts as an observer and an advisor while the students work out a solution. A problem used in the PBL approach can be a research project, a case method, or a design project. The small group setting used in PBL encourages an inquisitive and detailed look at all issues, concepts, and principles contained within the problem. The time spent outside of the group setting facilitates the development of skills such as literature retrieval, critical appraisal of available information, and the seeking of opinions of peers and specialists (Thomas, 1995).

The traditional classroom teaching pattern views the teaching process as transmission of knowledge that relates to students' future professional role, while the learning process is an acquisition of that knowledge (Bridge & Hallinger, 1995). This pattern was based on the assumption that learners are able to recognize when it is appropriate to use the acquired knowledge. However, it was noticed that the context in which knowledge is learned has little input on subsequent recall or use in analysing and solving a problem situation. On the other hand, PBL rests on an entirely different set of assumptions. PBL founders assume that the knowledge and the ability to use that knowledge are of equal importance. They also assume that the problems that students are likely to encounter in their future professional practice provide a meaningful learning context for acquiring and applying new knowledge.

PBL is a newcomer to the field of educational administration. It has been used for more than a decade by McMaster University to prepare future physicians and other professionals. It was then incorporated as a curriculum component into a number of institutions in United States and Canada. Nowadays, PBL has become an increasingly popular method of learning in many professional fields as well as in university education (Cameron & Barrows, 2000; Yip, 2000; Pross, 2000).

There is a growing trend for universities to use the World Wide Web (WWW) in direct support of teaching and learning. Various universities around the world are using the WWW as an instructional environment, as both a primary means of information delivery and a supplement to classroom teaching (Harasim, 1999; Hiltz & Wellman, 1997). The use of the Web as a teaching resource can benefit students (Milheim & Harvey, 1998; Sloan, 1997). It is more advantageous when the pedagogical process of PBL is supported by technology to foster teaching and learning. Although learning and teaching courseware is available (Blumenstyk, 1999; Frederickon, 1999) and some universities have been using WebCT as the teaching platform, the available features may not be able to support interactive facilities, various on-line facilities, project planning and controlling, and private discussion facilities for collaborative learning. All are important facilities within PBL.

The project described in this paper concerns with designing, developing, and implementing an instructional application program that supports the PBL approach over the Web. This application is called distributed-based PBL and is abbreviated to DPBL. The DPBL application is an integrated multimedia environment that provides students and instructors with synchronous and asynchronous communication services across heterogeneous computing platforms over the Internet. The DPBL is a complete three-tier client/server application for the Web using Java Beans, CORBA, and JDBC. In this environment, the client beans from the Internet browser invoke operations on CORBA middle-tier server objects via an object request broker (ORB). The server objects provide the application logic, and they store their persistent data in a JDBC–compliant structured query language (SQL) database.

2. DPBL Modeling

During the analysis and modeling processes for the DPBL system, the method of the data-flow model was implemented. This method reflects the end-user understanding of the system and contributes directly to object identification and the identification of operations on the objects. For that reason Oracle-Power Designer-7 was used for composing the data-flow diagrams and the conceptual data module (CDM) for the system. The CDM represents the overall structure and describes the conceptual relationships of different entities and their relations. The power designer was then used to translate the data types specified in the CDM into the physical data types, which the target database supports.

The context diagram in *Figure 1* shows the users that the DPBL system is serving and their relationships over the functions that the system performs. The external entities are students and instructors that are interfaced to the DPBL system through a friendly client interface.

The main DPBL client interface, as shown in *Figure 2*, is a Java frame that is composed of Java Beans. It runs inside a Web browser and provides the friendly interface that allows users to run a PBL facility available in the server via method invocation on the server's object implementations using CORBA infrastructure. The frame shows that two sets of

FIGURE 1

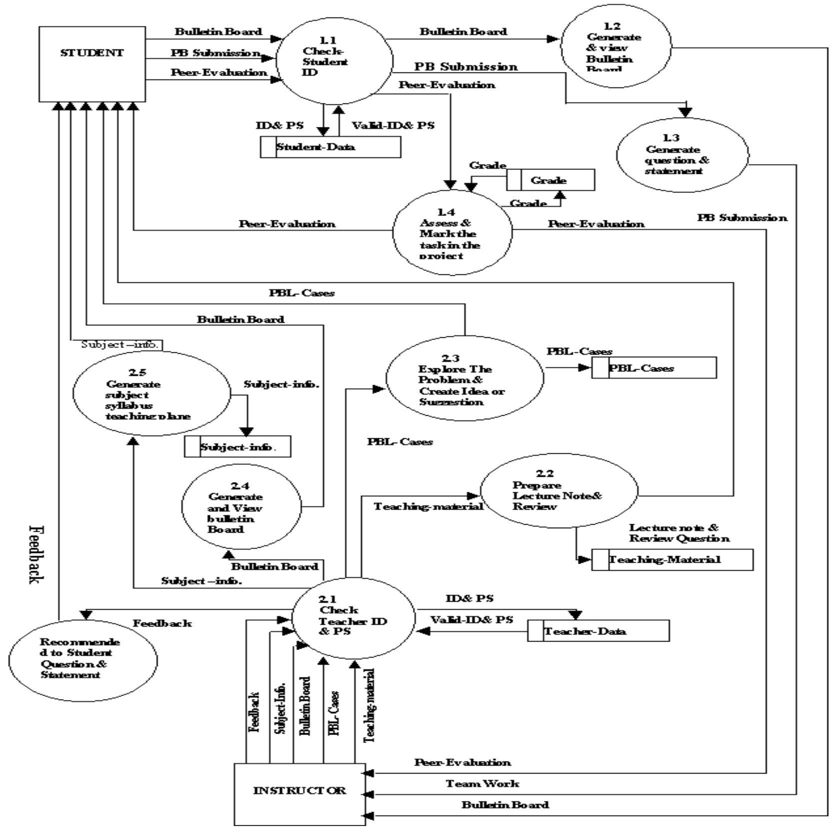

FIGURE 2

The Main Frame of a DPBL Showing the Class Room Facilities

PBL facilities are provided for two Web-based rooms: class rooms and group rooms, respectively.

The DPBL facilities are shown in more detail in *Table 1*. The classroom facilities are provided to every student in the class. Each group of students has a group room. The group-room facilities are accessible only by the members of the group, using a password to log onto the appropriate Web site where the facility is available.

The facilities provided by the DPBL application create the environment for implementing the major PBL components: the realities of the workplace, the content, instructional process, and evaluation. These facilities also sup-

port the PBL goals in developing students skills in a) problem solving, that is defining, analysing, and solving problems; b) self-directed learning; c) working collaboratively within groups; and d) project management, organizing, and planning.

In the PBL approach, the problem cases that are given to students cover the course learning elements and motivate them to work collaboratively in groups. Using postings on the Web of the information given by the instructor regarding the problem cases, the students will then be responsible for preparing for a meeting session with the instructor. This exercise stimulates the students to focus on the essential elements of the subject and comprehend the subject thoroughly, especially when they revisit the conceptual materials.

Also, each group is responsible for decomposing the problem into its components and assigning a task to each person. Then the group draws up a project-management plan and puts it on the Web. The plan includes task sequence and description, a time schedule, and the allocation of tasks to the group's individuals. This exercise permits the students to learn project-management skills and to play a more active role in their learning. Consequently, their critical-thinking and problem-solving abilities will be further enhanced.

3. Web-Distributed Technology

During the development process, several distributed Web-based learning sites were evaluated to determine which hardware and software might be of use for developing and implementing the DPBL application. For the process of identifying the technologies involved in implementing the DPBL, two main objectives were considered. First, the project has to be restricted to technologies that are available to most potential DPBL students and instructors. Second, students working on different computing platforms across the Internet should be able to use the DPBL. To meet the second objective, a Web-distributed framework should be in use. A Web-distributed framework allows developers to create distributed software that can run across a heterogeneous computing environment through the Internet. It integrates Web computing across different boundaries of different computer machines, operating systems, and programming languages. In commercial sectors, the most prominent frameworks for distributed computing are CORBA, common gateway interface (CGI), distributed component object model (DCOM), and, to a lesser extent, Java RMI. For DPBL development and implementation, CORBA, in particular, was chosen as being the distributed client/server framework that is reasonably suitable. This was based on a previous research project, which involved courseware development that was conducted by the principal investigator of this research work (Samaka & Godfrey, 2000). CORBA is one of the newer technologies in distributed client/server computing. It was introduced and is still being controlled by the Object Management Group (OMG) (Object Management Group, 1996). CORBA now is the leading industry standard for communication between distributed objects. It has already been successfully deployed in a variety of information systems application domains. It allows client and server objects written in different languages and running in different hardware platforms to interoperate.

It also provides operating systems and programming languages independent interfaces. This is because CORBA specifies a language-independent object-oriented architecture and an interface definition language (IDL) for connecting heterogeneous components (Orfali & Harkey, 1998). The IDL compiler generates client/server stubs in the desired target language, which together realise the interconnectivity between an object and remote client.

Furthermore, CORBA provides a suite of high-level services, relieving programmers from having to implement them from scratch, such as, transactional services, security, and a few others.

Finally, it was stated in the literature (Evans & Rogers, 1997; Leippinen & Pulkkinen and Rautianen, 1997) that Java, WWW, and CORBA could be used together in developing highly sophisticated and efficient distributed information systems applications.

4. DPBL Development and Implementation

The DPBL application creates a three-tier client/server environment using Java Beans, CORBA, and JDBC. The client/server environment is chosen because remote communication is required between remote clients over the Internet. In this application, the PBL client beans, which implement the first tier, invoke operations on CORBA middle-tier server objects. The server objects that implement the PBL facilities, in turn, store their persistent data in a JDBC compliant SQL database—Oracle.

The tools used to develop the DPBL system were the Java Development Kit 1.2 (JDK) and Netscape Communicator. The Java ORB used in this development is the Visibroker 4.0 product from the Visigenic. The later product was used for pre-compiling the DPBL IDL interfaces into Java using the idl2java pre-compiler and for providing tools for running the DPBL system over a distributed environment— tools such as OSAgent and the Internet Inter-ORB Protocol (IIOP) with Gatekeeper.

The WebGain Visual Cafe 4 Enterprise edition was used to develop the graphical user interface (GUI) for the DPBL application. Each GUI was implemented using the JFrame component of the Java Swing package. The JFrame is a top-level window that provides the basic attributes and behaviours of a window. Swing components are often referred to as lightweight component, since they provide a uniform appearance across all platforms. On the other hand, the original GUI components, AWI, are called heavyweight, since they are tied directly to the local platform and may cause different appearance in different Java platforms (Deitel & Deitel, 1999).

During the development stage, the front-end frame program was coded in isolation to the server program to reduce the time spent on testing and debugging. The server program was also coded and developed in a similar manner. Once the client frame and the server program worked satisfactorily, CORBA was then implemented between them. The DPBL main IDL interface was coded and pre-compiled into Java using the Idl2java pre-compiler. Also, the function "bind" was included within the frame code to allow client objects to locate objects that implement the DPBL interface, as shown in the following Java statement:

```
try { // Initialize the ORB.
    showStatus("Initializing  the  ORB,  Please
Wait");
    org.omg.CORBA.ORB  orb  =  org.omg.CORBA.ORB.
    init(this, null);
    // Bind to the Course Object
    showStatus("Binding to Course Object");
    course  =  DPBL.CourseHelper.bind(orb,  "My
    Course");
    } catch(org.omg.CORBA.SystemException e){
    showStatus("Applet Exception" + e);
    e.printStackTrace(System.out);
    }
```

To run the DPBL application, you need first to run the server application that requires a Java VM and an ORB (Visibroker 4.0). Once the server application is running alongside the Web server, the client frame can then perform requests on the server objects.

When the client frame is downloaded and bounded to the server, students and instructors can then choose a DPBL facility from the menu. In the DPBL, each facility is normally front ended with a frame, as shown in *Figure 3*.

5. Discussion and Conclusion

By the time this paper was submitted, most the asynchronous facilities provided by the DPBL were implemented and tested. However, further work is needed to complete the other asynchronous facilities (refer to *Table 1*) that provide real-time interactivity between the DPBL participants.

The DPBL application can now be used in university and industrial courses that involve projects, instructor supervision, and a group-work application area. The technology of the application provides facilities to both teachers and students to facilitate learning and teaching. These include posting teaching materials on the Web to support on-line information retrieval, a discussion area for brainstorming, a facility for project planning and monitoring, a private group area for the purpose of discussion, a facility for the submission of development work and learning resources, and a posting area to display good work to motivate students. The students' progress can also be monitored, and their instructor can give feedback to students in regard to their progress.

Mesh Fabric: Next-Generation Interconnect for Next-Generation Network Equipment Platforms

Rob Shaddock
Director, Gateway and Wireless Application Unit
Motorola Computer Group

Paul Virgo
Director of Product Marketing, Telecommunications Business Unit
Motorola Computer Group

As the communications market evolves, there is increasing convergence of voice, data, and multimedia applications in telecom networks. Toprovide new applications or services, various types of access devices are being deployed at the edge of the network. The proliferation of these new devices has lead to interoperability and configuration-management issues at the network edge. These issues have in turn escalated the need for a scaleable platform family solution, which can provide powerful processing and storage capabilities for control applications plus a high throughput bearer architecture that supports multiple services on circuit-switched and packet networks.

Telecom equipment manufacturers can realize a significant step forward in network convergence by developing platforms that accommodate differing protocols such as Internet protocol (IP), asynchronous transfer mode (ATM), and frame relay without unnecessary conversion and overhead.

Bearer Protocols

There are numerous protocols within the network that must be addressed by telecom original equipment manufacturers (OEMs) to offer the greatest availability of services for customers. Among the more popular as the following:

- ***TDM (Time Division Multiplexing)*** is the basis for the existing public switched telephone network (PSTN). It uses hierarchies of multiplexed channels with a specific amount of fixed bandwidth. This fixed nature is the biggest drawback for data—rather than voice—transmission, as time slots are allocated based on the amount of users, not on the amount of user traffic being carried.
- ***ATM*** comprises much of the packet-based network backbone. It uses small, fixed-sized packets and supports a variety of different qualities of service routing mechanisms. ATM also supports different types of traffic and optimises network utilisation.
- ***P*** is a simpler protocol than ATM that reduces the cost of network deployment. IP networks are commonly used in local-area networks (LANs) in homes and businesses.

In contrast to traditional networks, packet-based networks use routing and switching to efficiently transport data as demand increases or decreases, rather than using fixed resources based on the number of users. This more efficient use of the network coupled with the much larger amounts of data transport caused by the explosive growth of the Internet are the driving forces behind the need for flexible telecom solutions that address communications between different networks and offer migration to a packet-based world.

Standardization of Platform Architectures

As the industry continues to evolve toward packet-based switching architectures, there has been significant momentum toward standardizing equipment architectures. This standardization will encourage third-party development efforts and enable telecom companies to reach economies of scale for the reuse of technology across various platforms. One of the most significant standards to date that specifically addresses switching fabrics in CompactPCI® systems is PCI Industrial Computer Manufacturers Group® (PICMG) 2.16, which was ratified in September 2001.

The PICMG 2.16 standard for CompactPCI Packet Switching Backplane (CPSB) architectures overlays an embedded Ethernet switching fabric on the backplane in CompactPCI systems. The architecture is based on two concepts: an Ethernet infrastructure is embedded in the CompactPCI backplane and is accessed via the J3 connector, and all subsystems operate as standalone systems on a card, interfacing through a network stack on top of Ethernet. PICMG 2.16 is most useful in the control planes at the edge of the network, where applications are processing intensive, but is also suited to bearer applications that use IP. Typical applications most suited for applications with this type of architecture include voice over IP (VoIP), media gateways, integrated access devices, and embedded service clustering.

A potential use of PICMG 2.16 is to provide an all packet infrastructure with IP as the core packet transport. The architecture provides up to 1 gigabit per second (Gbps) er board of bandwidth for a system capacity approaching 20 Gbps (in large systems). The limitation of this architecture is that the 2.16 standard only supports IP transport, thus limiting its scope largely to metropolitan-area networks (MANs) and LANs. Generally, the core of the network currently uses TDM and ATM for public switching, although there is movement toward gigabit IP transport in the core.

The growth of the converged network has consequently led to several key issues for telecom OEMs:

- How can an OEM efficiently address the high bandwidth, speed, and multiple protocol requirements that occur in networking applications?
- How does a telecom OEM migrate from a traditional circuit-switch network to the all packet networks based on current and emerging technologies?
- How can the OEM leverage the open industry standards regulated by PICMG to ensure that there is the greatest extent of third-party products available for integration into a system-level solution?

We will attempt to answer these critical questions, but first we need to understand the difference in transport topologies.

Star versus Mesh Topologies

There are many topologies for wiring together boards and systems to transport information. They differ in factors such as cost (pins to connect, speed, logic costs, etc.), reliability, and complexity.

Star Topologies (see *Figure 1*) use a point-to-point configuration in which each device uses a dedicated link to send/receive data from a central resource. This resource provides the data distribution for the system. Ethernet networks are a hierarchy of star networks. Each subnetwork is a leg on a star of the next layer in the hierarchy.

Star topologies require redundancy to provide reliability. Reliance on a single central resource can cause a loss of all elements below the failure point. The topology of the PICMG 2.16 specification is a dual star configuration.

Mesh Topologies (see *Figure 2*) are a superset of star topologies and also use point-to-point connections. As interconnects are added to eliminate "dead branches" in a star network, a point is reached where all nodes have connections to all other nodes. At this point, the hierarchy disappears. Each node can be an endpoint, a router, or both.

Meeting the Needs of the New Network

An ideal solution to meet the ever-changing needs of the telecom industry is the creation of an extremely flexible platform that can allow for a variety of protocols and services integrated into a base platform. The infrastructure of the platform must have sufficient bandwidth to meet the current and future needs at the network edge, where the industry will experience significant growth in the foreseeable future.

To meet the high bandwidth and speed requirements of the edge and access portions of the network, telecom OEMs must be able to efficiently process large amounts and different types of traffic.

FIGURE 1

Star and Dual-Star Topologies

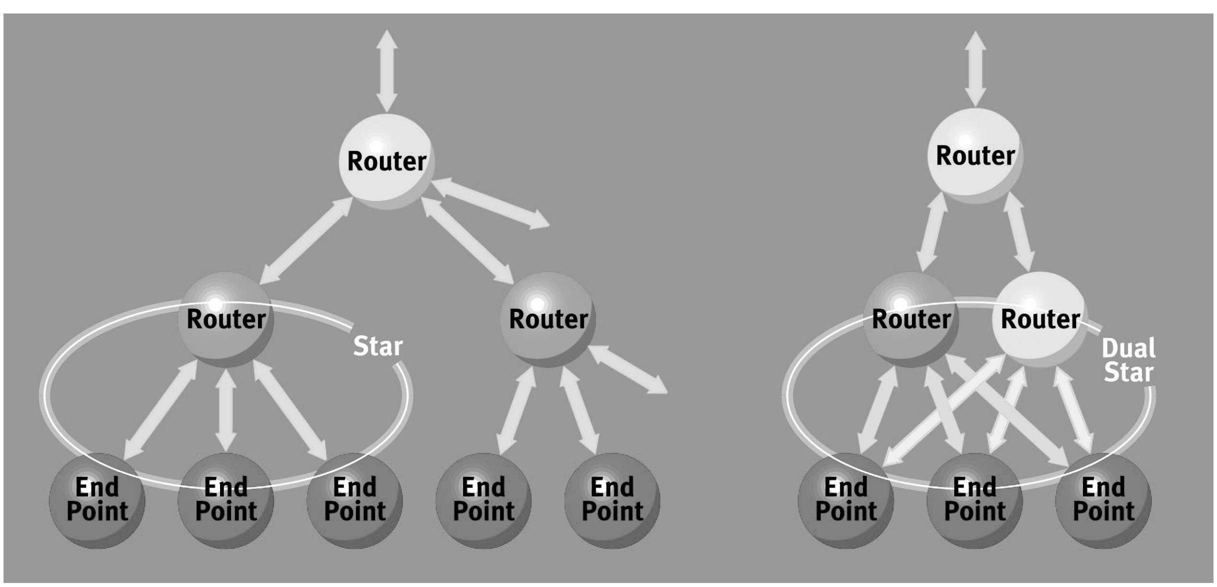

FIGURE 2

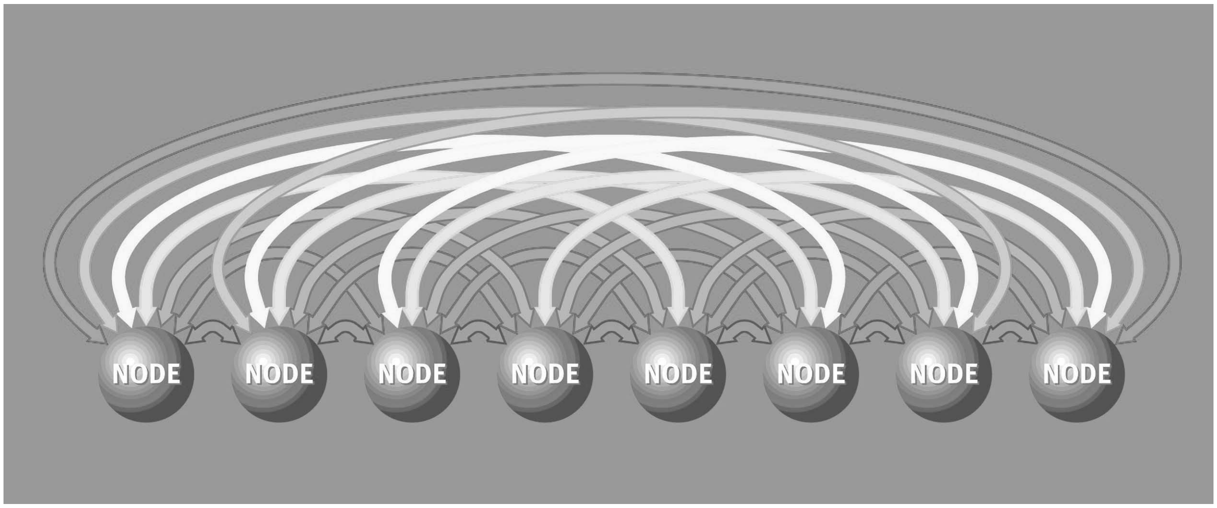
Mesh Topology Example



A key strategy to meet these high bandwidth and speed requirements while leveraging the move toward open standards is to add a high-speed mesh data fabric to augment the PICMG 2.16 Ethernet packet switching backplane standard. This fabric could be used for distributed processing, distributed storage, and bearer plane applications.

The high-speed mesh data fabric fills a void not just for bandwidth, but also for protocols and quality of service (QoS) that are not supported by IP. This creates a multicomputing environment that can compete with higher-end symmetric multiprocessing systems.

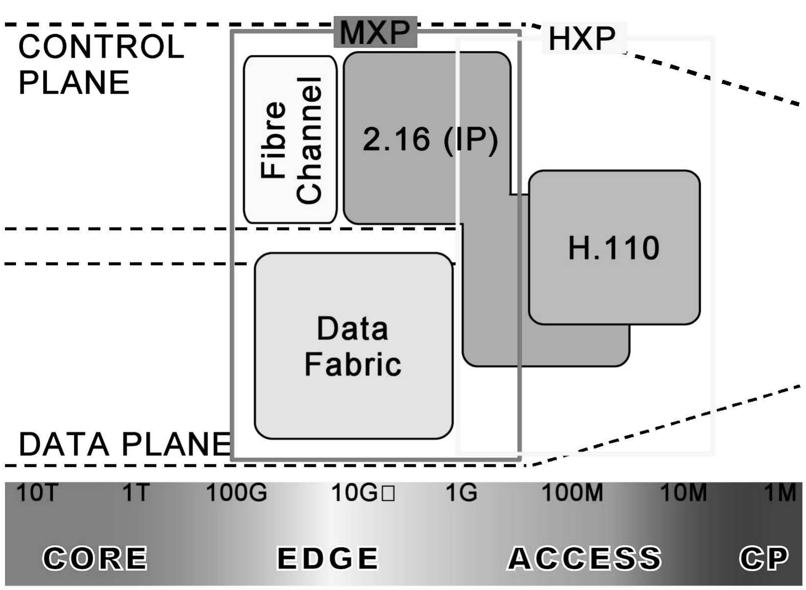
Combining all of these features in a single data transport platform allows the entire spectrum of edge applications to be addressed (see *Figure 3*). The resulting multi-service platform delivers the best of all worlds—delivering optimum performance in data plane, control plane or integrated data and control applications.

What About TDM?

Clearly, a large portion of the industry has significant investments in circuit-switch networks. To protect these investments, OEMs must seek a solution that combines

FIGURE 3

Adding a High-Speed Mesh Fabric in a Flexible Platform Addresses the Entire Spectrum of Edge Applications



TDM compatibility with a packet transport architecture. One solution to address this need while still leveraging open industry standards is to combine the PICMG 2.16 architecture with PICMG 2.5 (H.110) to create a mixed TDM and IP system. This allows the data traffic to be carried on the IP network and the voice traffic to be carried on the TDM network. In this manner, telecom OEMs are offered a migration strategy that addresses traditional network architectures, while also addressing the needs for packet-based architectures.

Next-Generation Solutions

Motorola Computer Group has addressed the changing needs of the packet world with the introduction of two new architectures, the Multi-Service Packet Transport Platform (MXP) and the H.110 Packet Transport Platform (HXP).

Built to adhere to open industry standards regulated by PICMG, the MXP is a highly flexible platform that can provide fast throughput (more than 700 Gbps) as well as the flexibility and scalability needed to deliver multiple services that can connect to different networks—IP and ATM.

The MXP multiservice architecture takes advantage of the mesh topology to offer a more resilient solution that needs no dependence on a central resource. The mesh architecture, which is being submitted to PICMG for consideration as an open industry standard, enables a more scalable solution than that presented merely by a star network.

While the networks continue to evolve to all packet-based, there remains the need to protect OEM investment in circuit-switched technology. To address this market need, Motorola has augmented its packet transport platform series with the introduction of the HXP. This product provides a clear migration strategy for telecom OEMs by supporting TDM and IP in the same platform.

Comprehensive Packet Solutions for Current and Future Networks

Standards-based systems provide access to compatible products from a broad range of vendors, maximizing the OEM choice. Standards can only be generated from existing technology, however, and in fast-evolving markets, need to be augmented with forward-looking new ideas and technologies.

By developing architectures that adhere to open industry standards regulated by PICMG, while integrating value-added features from Motorola, the telecom OEM is well equipped to meet the needs of a changing marketplace. The packet transport platforms offer the necessary open architectures and speed and flexibility requirements to meet the needs of today's network while providing the foundation to evolve into next-generation solutions.

IP Telephony

Michelle Specktor

Co-Founder and Vice President, Business Development

Gallery IP Telephony, Inc.

Internet protocol (IP) telephony is the emerging communications technology arising from the convergence of the worldwide data infrastructure and the telecommunications networks. The evolution of the public network from a circuit-based infrastructure to a packet-based infrastructure introduces new software-based Class-4 and Class-5 switch alternatives that will enable service providers to reap the benefits of the next-generation network (NGN) IP–telephony revolution with great flexibility in rolling out new revenue-generating opportunities, low overall cost of ownership, platform scalability, and enhanced price-to-performance ratios.

While the IP telephony opportunity is huge and most promising, the mass deployments of softswitches and the transition to an all–packet-based network will take a long time to complete. Before IP telephony becomes a major growth market, the softswitch market needs to mature. Both service providers and vendors face key issues that need to be first resolved, then developed and implemented, before the softswitches and IP–telephony markets could meet their exponential growth forecasts.

The key issues for service providers are demand for selectivity in choosing best-of-breed end-to-end solutions, low overall cost of ownership, enhanced price-to-performance ratios, flexibility and scalability to ever adapt to business growth and new competitive strategies, an increase in quality of service (QoS), and an ability to create new revenue-generating opportunities and support fast rollout of new services.

While the key issues for service providers are in terms of profitability and competitiveness, the equipment and software vendors face a lack of standardization in key areas; hurdles in comprising voice, data, and software development specialists; difficulty in balancing between reliability and scalability; dense interoperability testing and performance testing; financing struggles; and, given the new marketplace circumstances, a more difficult overall sales environment.

The IP–telephony revolution challenge is to combine software advantages with sophisticated telecommunication architecture to create the ultimate highly reliable IP–telephony solution, which in time will replace the traditional circuit switch and will provide a strong economic advantage to service providers offering bundled communication services and enhanced services.

While the traditional voice switching market was dominated by a very small number of vendors (five vendors account for approximately 85 percent of the global public switched telephone network [PSTN] switching market), the vendor environment of IP telephony is vastly different. Historically, each technology revolution has set the stage for new players. Likewise, many new start-up vendors will aim to address the evolving IP–telephony market opportunities, yet, most likely, just a few "right players" meeting the demanding criteria of the teir-1 service providers will be able distinguish themselves as the leading IP-telephony vendors (e.g., Sonus, Gallery IP Telephony, Telcordia Technologies).

A softswitch is a pure software-based switching and control solution that runs on general-purpose industry open platforms to provide the functionality of the traditional time division multiplexing (TDM) switch in a modular, distributed fashion and based on industry standards. The softswitch's key performance criteria are reliability and scalability. It combines the functionality of the traditional Class-4 or Class-5 switch (see the following descriptions), yet its open architecture supports extendibility and scalability, and use of standard complementary components. The softswitch delivers the benefits of cost reduction, service differentiation, and the leveraging of existing networks while migrating to IP–based networks.

The traditional switches are split into two distinct types of switches:

1. Class-5 switches reside at the edge of the PSTN, providing the local exchange/central office (CO) functionality, serving subscribers through local-loop connections, and handling call control as well as attributing special subscriber features and service requirements. Traditionally owned by the local-exchange carriers (LECs) and service providers.
2. Class-4 switches, also known as tandem toll centers, reside at the central part of the network. Essentially, these interface with either other tandem switches or Class-5 switches to complete calls outside of the local area. The role of these tandem switches is simply to control the relay of information from one (geographical) network to another. Traditionally owned by long-distance/international carriers and service providers.

In converged networks, computers are becoming part of the network, and traditional proprietary switches are replaced with standard-based softswitch environments that are composed of software-based ambiguous switches, gateways, application servers, and complementary network components.

The core component of the converged network is called the "call agent," "media gateway controller," or "softswitch."

Class-5 softswitches are infinitely more complex in their design and operation and will account for the majority of added value associated with deploying IP–based networks. "The Class-5 market represents more than 80 percent of the total market opportunity for voice switching and presents the greatest opportunity for services innovation and differentiation."[1]

Although Class-4/tandem softswitches and gateways could be found already deployed by Internet telephony service providers (ITSP) and long-distance/international carriers, generating revenues for players in this niche (e.g., Sonus, ipVerse), they have become somewhat of a commodity. Clearly, it will be the deployments of Class-5 softswitches that will support the service differentiation and costs reductions that next-generation telecommunications companies are seeking, and thus the Class-5 softswitch together with a flexible robust services platform is the ultimate technology required for reaping the greatest benefits of IP telephony.

In summary, these are challenging days for next-generation service providers and carriers, as well as for equipment and software vendors. Never before has there been so much demand for new technologies, and never before has there been so many vendors' offering. But making the right decision has gotten harder. The new IP–telephony infrastructure is not yet fully spread out, and the softswitch technology is not yet mature. However, once the key issues of both the carriers and vendors are resolved, the right vendors with the right technology, partners, strategy, and paths to the market will not only dominate the market, but also drive and accelerate IP–telephony market growth.

Notes

VoIP in the Enterprise: Opportunity or Threat for Service Providers?

Laura Thompson
Vice President, Corporate Marketing
Sylantro Systems Corporation

Internet protocol (IP)–private branch exchanges (PBXs) are quickly gaining market-share among recent communications system purchases by enterprises, according to Phillips Infotech and other analyst firms. Large distributed enterprises, such as Household International and Dow Corning, and institutions, such as the University of Arkansas, have made the switch to these newer, IP–based in-house systems. This growing trend toward IP–PBXs presents both an opportunity and a threat to service providers.

The IP–PBX has the potential to further extend and consolidate the powerful hold that customer-premises equipment (CPE) has maintained over enterprises since the mid-1980s. Over the course of 20 years, service-provider–based Centrex offerings were inexorably squeezed out of the enterprise market—and later, the small- to medium-sized–business markets—by feature-rich CPE products that far exceeded the limited functionality, features, and ease-of-use of traditional Centrex.

The IP–PBX trend is just beginning and is likely to follow an easier, faster adoption curve than that of the PBX. Three years from now, according to Gartner, 44 percent of lines shipped will be IP–PBXs if current trends continue.

As a newcomer to the CPE space, the IP–PBX poses an additional, more ominous threat to service-provider revenues and viability. In addition to providing a rich set of features, the IP–PBX also allows businesses with geographically dispersed offices to route interoffice traffic via a data network, consolidating trunks and lines and significantly impacting service providers' toll and long-distance revenues, as well. Thus, the IP–PBX has the potential to effectively blockade service providers from the enterprise market forever in terms of service offerings, increased access lines, and their associated usage revenues.

Enterprise users who purchase IP–PBXs are simply making the best choice that they can among current offerings—and who can blame them? The IP–PBX effect is predicted to continue to grow in strength unless a more compelling service-provider–based offering is provided. A recent study by Research First, a telecommunications market research and consulting firm, found that outside of the small office/home office (SOHO) market, about 90 percent of businesses have installed an in-house phone system. In-house systems such as these are typically replaced every four to seven years. Without a viable service-provider–hosted alternative, much of this opportunity will be lost to the IP–PBX.

With the penetration of on-premises systems at more than 90 percent, traditional Centrex is clearly not perceived by businesses as a viable alternative. In fact, in a study of the Centrex market by Frost & Sullivan, it was found that most businesses view Centrex only as a stopgap measure to use until they can make a decision on an in-house phone system. Other reports have indicated that, due to favorable tariffs, Centrex lines are often less expensive than other access line alternatives—and thus many deployed Centrex lines are in actuality used only for trunking rather than features such as call transfer, park, and pick-up. Traditional Centrex has not and will not be a viable competitor to the IP–PBX.

The Service-Provider Impact

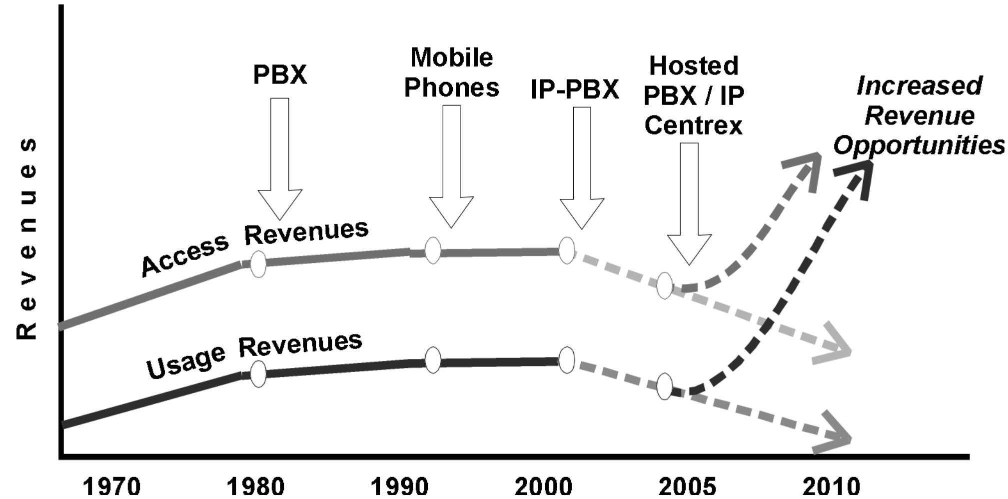
Before the introduction of CPE telephony systems in the early 1980s, service providers were seeing access line growth in the 10 to 12 percent range. After PBXs and key systems became entrenched in the enterprise market, providers' access line growth dropped to 3 to 4 percent in the late 1990s as a result of these on-premises systems' ability to allow multiple users to economically share lines. This decline in growth and revenues has continued due to the rise of other technologies—such as wireless communications, e-mail, and instant messaging—which have diverted even more traffic from service providers' wireline networks. If service providers are to generate new revenues to offset these losses and produce a healthy balance sheet, they must diversify beyond traditional product and service offerings and offer compelling new enterprise-oriented services.

A New Opportunity

Many of the technologies and market forces that have engendered the IP–PBX have also given rise to a new type of products and services that are uniquely designed for service-provider networks and business models. These products, called hosted PBX or IP Centrex, provide a strong alter-

FIGURE 1

New Technologies Impact Access Lines



native to customer-premises solutions and can compete effectively against the rising IP–PBX tide. Residing in the service provider's network as application or feature servers, these new products work with existing time division multiplexing (TDM)–based (Class-5) networks and operations support system (OSS) infrastructures and can support a smooth, phased migration path to next-generation softswitch-based networks if that is the ultimate goal.

As the name implies, hosted PBX, or IP Centrex, is based on the same type of deployment model as traditional Centrex. However, by virtue of its IP–based architecture, hosted PBX, or IP Centrex, shares many of the same advantages of IP–PBXs while providing additional benefits that premises-based systems can't offer.

IP–PBXs provide feature delivery, switching, and other functionality over a data network. These systems reside at the customer premises and require internal information technology (IT) staffing resources for day-to-day management, as well as vendor support for major changes. Calls within the premises and interoffice off-premise calls are typically routed over a wide-area network (WAN) or other data network, bypassing the public switched telephone network (PSTN) (and service-provider access charges) entirely. According to Probe Research, up to 70 percent of an enterprise's traffic is inter-employee, especially for large enterprises, so the savings for users—and lost revenues for service providers—quickly become significant.

Hosted PBX, or IP Centrex, is based on a service-provider network-based model, much as traditional Centrex, but offers feature parity as well as cost parity, along with advanced new local and remote management capabilities. With these types of hosted services, all calls, switching, features, and other functionality are distributed to the customer location(s) via broadband services such as T1 or digital subscriber line (xDSL). Just like the IP–PBX, calls are delivered via an internal data network to users within a single premises or over the service provider's network (a virtual WAN for the enterprise) for calls between multiple enterprise locations. However, with IP Centrex services the customer no longer has to invest in or manage a PBX or IP–PBX—they need only to IP–enable their existing business phones with a simple adapter or use new IP phones. No other CPE is needed.

For businesses with multiple sites, interoffice calls can be routed across the service provider's managed data network—retaining these access revenues for the service provider. The business customer benefits, as well. By using these service-provider network resources, business customers gain the advantages of a network without the upfront capital expense of building one or the management headaches and costs associated with maintaining their own network.

End-User Benefits

Hosted solutions such as hosted PBX, or IP Centrex, offer business users the same wide-area dialing advantages and savings as IP–PBXs, without requiring internal IT resources to manage the system. The communications services and the broadband facilities used to deliver hosted PBX capabilities are managed instead by the service provider, simplifying deployment and management for the business customer compared to an on-site IP–PBX. In addition, a service-provider–managed network typically provides a level of voice quality that is indistinguishable from traditional PSTN–based services.

Hosted PBX, or IP Centrex, systems can also meet requirements for telco services such as E-911 and caller ID. These capabilities are identical to, or supersede, those available with traditional TDM–based voice services. Hosted PBX, or IP Centrex, services are offered at a monthly service fee per user, much like traditional Centrex, allowing businesses to avoid large capital outlays of $25,000-plus to upgrade existing PBXs or $75,000-plus to purchase a new on-premises IP–PBX. Through disruptive pricing strategies, service providers can easily compete with, and win against, IP–PBXs.

In addition, hosted PBX and IP Centrex features far exceed those provided by legacy CPE products and easily match those offered by IP–PBXs. The advanced features offered by hosted PBX and IP Centrex are key to driving adoption, because they are far more intuitive than traditional PBX features. Furthermore, the outsourced model employed by IP Centrex reduces both capital expenditures (CAPEX) and operational expenditures (OPEX) in a significant way for business users, which is very attractive in the current economy.

But Will They Outsource?

How willing are businesses to outsource their telephony services? Outsourcing has become a standard practice for many business services such as Web hosting, payroll, and e-mail. Furthermore, the Research First study referenced earlier concluded that business users are extremely frustrated with managing their current phone systems and exhibit a strong interest in outsourcing their telephony services. Outsourcing was viewed not only as a way to reduce the management and maintenance headaches associated with their current CPE phone systems, but also as a means to avoid CAPEX.

Outsourcing allows businesses to focus on their core business, rather than devoting personnel and expense to their telecommunications systems. In the study, focus groups were conducted in several locations across the United States in which generic sample screen shots of a hosted PBX, or IP Centrex, solution were presented. The samples included advanced features such as click-to-call and inbound/outbound/missed call logs, and new browser-based management tools. After viewing the examples, 60 percent of the focus group members expressed a willingness to outsource their telecommunications. Said one survey respondent, "Get me out of the phone business—please!"

In addition, respondents indicated a strong willingness (a "5" on a sale of 1 to 7) to switch to an outsourced model if that was the only way to get some of the advanced features and management capabilities they were shown. All of this explains why outsourcing solutions such as IP Centrex are being well received in the market—and post-study field experiences have reaffirmed the research project's results.

The IP Centrex Advantage

Technology providers such as Sylantro Systems have used the flexibility of IP to incorporate customer-pleasing new applications into their hosted PBX, or IP Centrex, products. Compelling features such as popular mobile phone-type features including click-to-call and call logs, Microsoft Outlook integration, and hosted directories proved very desirable to business users in the Research First study and in deployments.

These new hosted PBX, or IP Centrex, systems support newer IP phones or IP–enabled legacy phones and offer user-friendly features via new uses of the phones' liquid crystal displays (LCDs) and soft keys. Other user interfaces are offered via browsers Microsoft Outlook, or WAP–enabled mobile phones. Customizable call treatments allow users to set up find me/follow me scenarios for different types of callers, such as VIPs, family, or friends. A call queuing and distribution option helps businesses manage peak call volumes on a temporary or permanent basis—a much more affordable option to buying and managing an in-house automatic call distributor (ACD) system.

While the service provider maintains the servers, some hosted PBX, or IP Centrex, solutions offer a rich browser-based portal that allows office receptionists or managers to perform moves, adds, and changes (MACs) quickly and easily. The Yankee Group estimates that businesses spend almost $6 billion per year on phone-system maintenance, including MACs. Through portals such as these, businesses can largely eliminate these expensive outlays and gain control over MACs themselves—without the frustration of depending on outside service contractors.

These routine tasks have historically been a major source of frustration, delays, and expense for users of premises-based telephone systems. The self-administration capabilities offered by hosted PBX and IP Centrex solutions are attractive to business users because the capabilities allow fast responses to changing business needs and conditions without a lengthy wait for an expensive service call (typically a minimum $200 charge per call). Furthermore, the portal allows administrative staff—rather than expensive IT staff—to manage routine changes.

Browser-based portals also allow end-users to easily access, manage, and control their communications options on the fly, without star codes or other complicated programming gymnastics. These portal interfaces help users, for the first time, to take full advantage of communications features that enhance productivity and increase accessibility and flexibility.

Unlike premises-based telephone systems, hosted solutions are easily upgraded. Service providers can allow customers to change service packages at any time they choose and to upsize or downsize the services as needed or as their businesses flex in number of employees or services needed. Premises-based solutions such as IP–PBXs simply don't offer these same advantages. The ability to "right-size" communications services to fit changing needs is critical in today's economy and allows businesses to use only the resources they need, without incurring unneeded expenses.

Building New Revenues

During the next few years, service providers have a unique opportunity to generate much-needed new revenues and recover some of the business that they lost to premises-based solutions over the last two decades. Through the added flexibility afforded by hosted PBX and IP Centrex, service providers have a powerful set of tools that will allow them to easily compete with and outsell IP–PBX offerings.

Many of these advantages are a function of the service provider's market presence. For example, the study by Research First found that the first company most businesses think of when considering a new telephone system is their phone company. Service providers have built extensive brand recognition and customer awareness that can quickly translate to sales opportunities for a compelling new service offering such as IP Centrex.

Most service providers also have a knowledgeable sales force in place that is already selling traditional PBXs and Centrex and that can easily transition to selling new services such as IP Centrex. Some innovative service providers with IP Centrex offerings are signing up former traditional Centrex resellers to market these services, with great results.

Interestingly, field experience has shown that, while hosted PBX and IP Centrex solutions might be useful for migrating Centrex users to IP–based telephony offerings, the biggest opportunity is in replacing traditional PBXs and key systems. This market segment is a true incremental opportunity for service providers.

Summary

For all of these reasons and many more, IP Centrex has emerged as a viable, competitive alternative to IP–PBXs and other CPE solutions. The innovative service providers offering hosted PBX and IP Centrex today are winning sales away from IP–PBXs. Oftentimes, end-users are replacing their phone system much sooner than the average (typically four to seven years), since there is no CAPEX penalty for replacement, and they gain access to the extensive features and easy manageability offered by these hosted services. Through hosted PBX and IP Centrex, users receive all of the new call-management functionality that IP–PBXs offer—and new usability and control that traditional PBXs never offered—all without the up-front expense of a premises-based solution.

For the first time in years, Centrex—in its IP–based form—is fully competitive with CPE solutions, and where businesses have the choice, these new services are winning hands down against IP–PBXs. Hosted PBX and IP Centrex solutions are proving themselves in the market and have amassed solid evidence that they can combat the IP–PBX trend and help reverse the decline in access lines and revenues for service providers. IP Centrex has come into its own, but the window of opportunity, before the IP–PBX reaches critical mass, is now.

Requirements for the Next-Generation Intelligent Data Network

Eric Von Gonten
Senior Internet Architect, Internet Architecture
Genuity

This paper will discuss requirements for the next-generation intelligent data network, providing an overall view of the network, including backbone and metropolitan areas. This paper does not pertain to Genuity's network in particular, but rather networks in general.

Backbone Network Architectures

Current backbone network architectures primarily consist of 10 Gigabit per second (Gbps) dense wavelength division multiplexing (DWDM) transport systems that were deployed between 1997 and 1999. These networks were built with passive, point-to-point (PTP) DWDM technology with anywhere from eight to 32 lambdas of transport capability. In addition, these networks were overlaid with state-of-the-art 10 Gbps synchronous optical network (SONET) four-fiber bidirectional line-switched rings (BLSRs) to ensure reliable architectures for service providers and their customers.

Cost Concerns

Four-fiber BLSR architectures are highly reliability. However, they are very costly, include many complicated components, are difficult to provision, and require long build times. Significant capital expenditures (CAPEX) must be made to purchase the equipment necessary to support this level of reliability. Four-fiber rings are designed so that half the bandwidth is dedicated to working traffic and the other half is dedicated to protection, and the architecture requires the deployment of many redundant transmitters. All of this adds up to a significant cost disadvantage.

Revenue Concerns

Under four-fiber BLSR architectures, traffic can be provisioned on only the working path of the ring, while the protection path sits idle, without generating revenue for the carrier. If service providers had access to the unused protection bandwidth, the network efficiency would be improved. Without the ability to provision on the protection path, service providers have spent large amounts of money for optical components to build protection, without generating additional revenue.

In a network where multiple layers of rings are deployed across a large geographic area, provisioning traffic across numerous rings becomes quite challenging. Because rings can be anywhere from hundreds to thousands of kilometers in circumference and must be completely built out before they can be used, build times are generally long. The business issues associated with four-fiber BLSR rings are cost, excessive equipment, ineffective use of bandwidth, complex provisioning, and long build times.

Reliability Concerns

There are also concerns about the reliability of four-fiber ring systems due to the inherent operational complexity. The DWDM transport portion of the network tends to be very reliable, as it is primarily composed of amplifiers and passive filters. DWDM systems of the past required signals to be de-multiplexed, regenerated, and multiplexed every few hundred kilometers. On a large network, this resulted in many fiber patch cords and connections between the DWDM layer and the active transmitters of the SONET four-fiber rings. Additionally, this type of regeneration required service providers to install SONET bays and numerous optical-to-electrical-to-optical (O–E–O) cards to regenerate both the working and protection channels of the many already deployed four-fiber rings. The requirement for so many patch cords, connections, and electrical interfaces increases the opportunity for an outage to occur either by equipment failure or user error, which can impact the reliability of network.

Architectures of the past used Internet protocol (IP) over asynchronous transfer mode (ATM) over SONET over DWDM. This architecture utilized four different network layers to offer services to customers. The more layers that were deployed resulted in more required components for providers to purchase and provided more opportunity for failures due to the large number of components installed. As technology continues to advance, new transport mechanisms and architectures will arise and will reduce some of these concerns.

Routers Plus Photonics Architecture

Other architectures under current consideration by the industry use only two layers: an optical layer and a service or IP layer. *Figure 1* is an end-to-end view of the service layer of the future resulting in Layer-1 to Layer-3 convergence. The vision here is to take 10 Gbps IP traffic directly over route-diverse optical wavelengths bypassing both the ATM and SONET equipment and relying on the optical layer and IP routers to provide the protection. With the recent development of 10 Gbps interfaces on routers and with optical layer support for 10 Gbps transport, the requirement to use SONET equipment to aggregate lower-speed signals up to a 10 Gbps signal is no longer necessary. This architecture will continue to evolve and use high-speed terabit routers, which can have dozens to hundreds of interfaces with speeds from 10 Gbps to 40 Gbps and faster on each interface. To support this architecture, the network must use a highly scalable optical layer that supports terabits of capacity and has the ability to provide bandwidth on demand.

The use of ultra-long-haul (ULH) DWDM technology to provide city-to-city connectivity can be used for this type of architecture with improved overall network reliability. In the past, a signal sent from Los Angeles to Miami would require electrical regeneration at many locations. However, with an ULH DWDM system, little or no intermediate electrical regeneration would be required. Therefore, ULH DWDM technology may actually increase the reliability of the network by reducing the number of patch cord, connections, electrical interfaces, and intermediate regeneration sites compared to previous DWDM transport systems.

The use of ULH technologies to transport IP directly over wavelengths is the first step toward the next-generation intelligent optical network. The benefits associated with this architecture include a cost-effective transport, reduction in O–E–O requirements, higher reliability through reduction of components, operational simplification resulting from bypassing higher-order network layers, and improved provisioning intervals.

Metropolitan Network Architectures

Current Metropolitan Network Architecture

The current industry-standard metropolitan network includes fiber, limited DWDM, SONET, and a service-aggregation component. There are many different hardware platforms, components, and software platforms that coexist in today's metropolitan networks. All these complexities result in many opportunities for inefficiency (see *Figure 2*).

Reliability Concerns

The more components that exist in a network, the higher the possibility that a failure may occur. In addition to multiple hardware and software platforms, a complex metropolitan architecture consists of many patch cords, electrical cables, connections, and interfaces that increase the opportunity for an outage due to equipment failure or user error, thus impacting the reliability of the metropolitan network

Hardware is not the only item that can affect the reliability of a network. Software upgrades have many complexities; time and careful planning must be taken when they are performed. Over the years, there have been more than a few carriers that have had outages associated with software upgrades. Outages could be associated with people following incorrect procedures, an upgrade of one system not interoperating properly with another system, or even a bug in the software. Regardless of the problem, when carriers experience outages, customers and revenue are potentially impacted.

FIGURE 1

Routers Plus Photonics Architecture

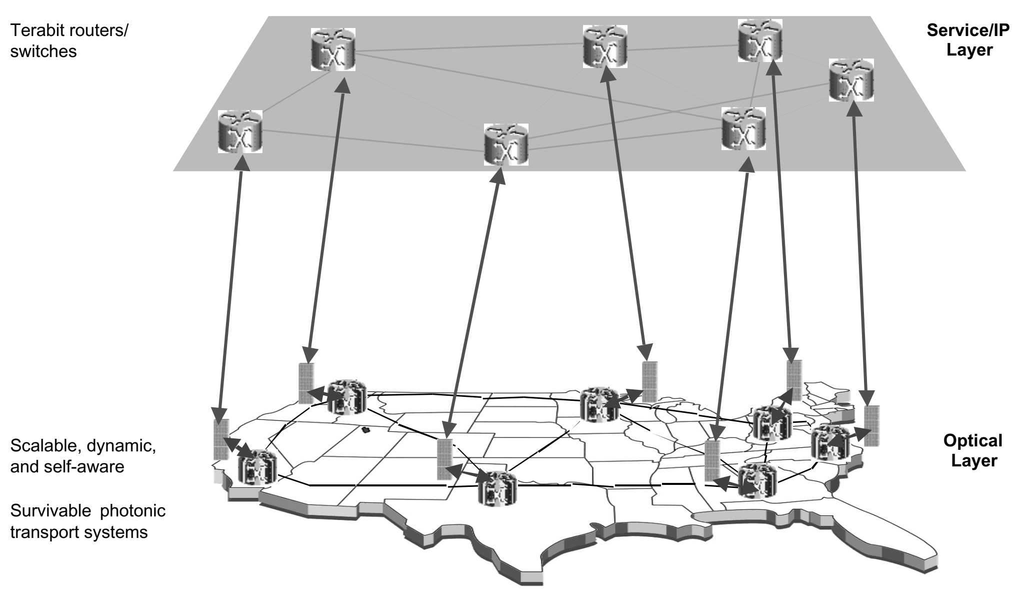


FIGURE 2

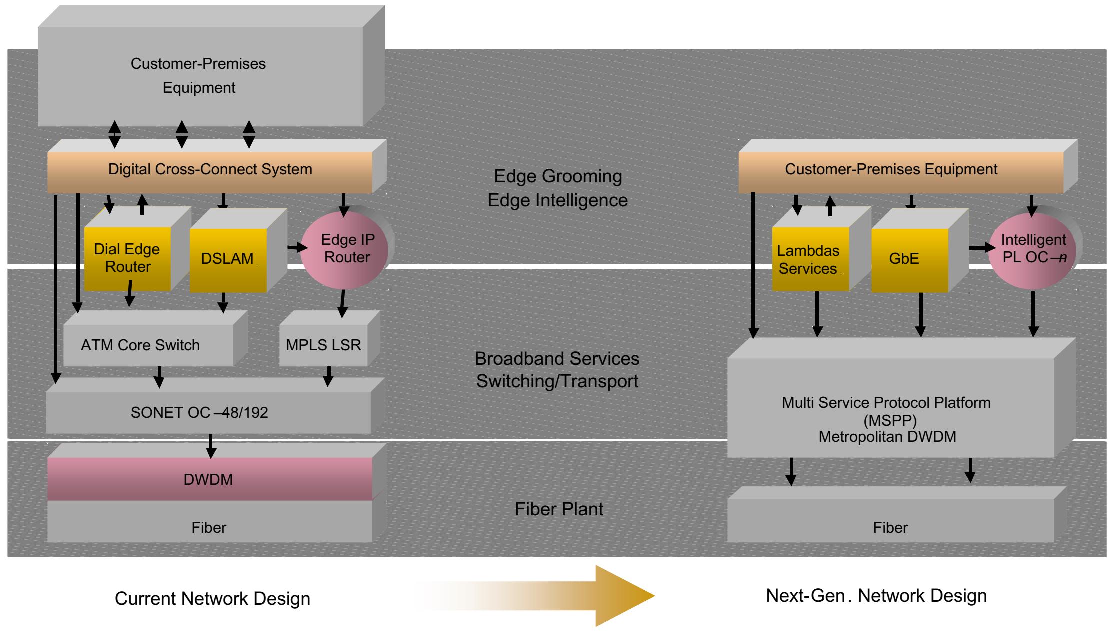
Metropolitan Network Migration



The more components in the network and the more software upgrades you perform result in a higher risk of a network outage. Current complex metropolitan architectures, with many components and management systems, present operators with many opportunities to make slight mistakes that could cause network outages.

Next-Generation Metropolitan Network Architecture

The next-generation metropolitan network will be a consolidated network where a single integrated access device (IAD) or multiservice protocol platform (MSPP) will replace many of the components of previous architectures. These MSPPs will offer a variety of service interfaces such as SONET, IP, Ethernet, ATM, etc., along with test-access in one platform resulting in simplified network architecture. MSPPs seem to be very popular, although the operational aspects of this approach present some challenges that need to be considered in detail.

In the metropolitan environment, we must consider churn. When a customer requests a service upgrade (optical carrier [OC]–3 to an OC–12) there are many things that occur. A technician is required to drive out to a site, install a new interface card, connect patch cords from the interface to a demarcation patch panel, coordinate the interconnection with the customers technician, provision the circuit, and finally test the circuit. All of this takes time and money. While this process is taking place, the customer is not without service, as they are still utilizing the original OC–3 circuit. When the customer has accepted the new circuit, the old OC–3 circuit must be decommissioned through a process that includes removing the old OC–3 interface card, removing the patch cords from the card to the patch panel, and removing the provisioning information from the database of record. This manually intensive process of turning up new circuits and decommissioning old circuits presents many opportunities for operator error, which may result in a customer outage.

Providers can minimize opportunities for outages and simultaneously offer more cost-effective services to customers by immediately providing the most cost-effective, highest bit-rate interface possible. This could be a Gigabit Ethernet connection or a single interface card that supports multiple bit rates, and service upgrades to the customer can be completed by remotely increasing the data rate of the multirate card. This method lessens the field work associated with ordering and installing new cards, running new patch ports, removing old cards, and removing old patch cords—ultimately reducing the possibility of errors that could degrade network reliability. In addition, this eliminates the cost of purchasing new cards for upgrades and reduces the need for old cards to be returned to the carrier's inventory.

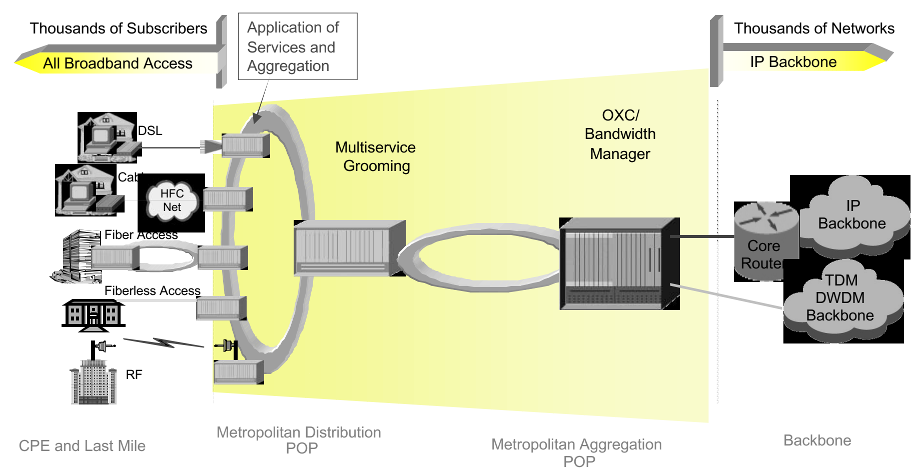
The Metropolitan Network Is about End-to-End Services

Figure 3 shows the technology of the metropolitan network. The IP backbone is on the right, the metropolitan aggregation and distribution is in the middle, and the last mile (thousands of subscribers with customer-premises equipment [CPE]) is on the left.

An additional driver for this MSPP technology is the huge demand for reliable end-to-end services offering broadband delivery of content and services. Services that were not even envisioned only three to four years ago are now a reality. Some examples include broadcast video over IP, voice over IP (VoIP), interactive gaming, collaborative services, and the huge growth in time-sensitive traffic, such as on-line trading. MSPPs also provide a way to aggregate many different

FIGURE 3

The Metropolitan Network Is About End-to-End Services



types of traffic into high-speed connections (data or TDM) that can easily be handed off to the backbone network.

When providing an end-to-end service for customers, the reliability of the service depends on the combined architectures of the metropolitan and backbone networks.

Standards and Protocols

Networks of the future must be able to provision bandwidth dynamically through the network based on machine-to-machine signaling. This is just beginning to happen due to Layer-3and Layer-1 convergence. However, it will not work without standards-based protocols. Guidance for building these networks of the future can be found in the legacy telco networks' signaling system 7 (SS7).

Signaling and routing protocols that will enable better management of the network are currently under development. Some key protection and recovery protocols that are currently used are open shortest path first (OSPF), intermediate system–to–intermediate system (IS–IS), border gateway protocol (BGP), and service-location protocol (SLP).

Some other emerging standards and protocols are generalized multiprotocol label switching (GMPLS), optical user-to-network interfaces (O–UNIs), optical network-to-network interfaces (O-NNIs), optical label-distribution protocol (OLDP), and automated switched transport network (ASTN). Some of the forums currently working in this area consist of the Optical Domain Service Interconnect (ODSI), Optical Internetworking Forum (OIF), Internet Engineering Task Force (IETF), and International Telecommunication Union (ITU).

These standards will enable service providers to provision and manage services in multivendor environments. A large network can consist of a very large backbone built with equipment from two or three different vendors connected to numerous metropolitan networks that may have equipment from five to 10 different vendors. With one vendor in one portion of the metropolitan network, another vendor in the backbone, and even a third vendor in another metropolitan portion of the network, signaling and routing protocols and standards are required to make it possible to manage and dynamically provision end-to-end circuits across the network.

End-to-End Network-Management Capability

Today, only carriers that have end-to-end visibility of both the metropolitan and backbone networks can easily accomplish customer network management (CNM) for end-to-end service delivery. CNM and bandwidth-on-demand services will enable over-subscription of the network, thus increasing revenues for service providers. CNM will also provide customers with instantaneous capabilities, such as performance monitoring characteristics and the circuit reliability.

CNM and future signaling and routing protocols (e.g., GMPLS) will enable bandwidth to be provisioned dynamically through the network based on machine-to-machine signaling. This will allow customers to pay for the network as they use it (dynamically), rather than as it is manually provisioned. Signaling and routing protocols will allow bandwidth to be provisioned dynamically and allow CNM capabilities over a multivendor and/or multicarrier network. This end-to-end network must be operationally friendly, accommodate service-level agreements (SLAs), and be able to scale with the network.

Services and Performance Characteristics of the Future Network

Intelligent software and standard protocols that enable bandwidth on demand are also the primary developments that will enable many new protection mechanisms and classes of service (CoS).

Premium Service: Dedicated Mesh for Near Real-Time Traffic Restoration

The premium service is the real-time traffic restoration (< 50 ms). This service level is appropriate for traffic that is intolerant of delays, such as voice, VoIP, video broadcasting, interactive gaming, and collaborative services.

Today, premium service is accomplished using SONET four-fiber BLSRs. As previously indicated, large amounts of equipment are required to provide this level of service using traditional four-fiber BLSR systems. The next-generation routed photonic network will enable mesh architecture and near real-time traffic restoration to be accomplished by use of dedicated 1+1 optical protection, similar to a tail-end switch or hot standby capability.

The advantage of using a mesh to provide near real-time traffic restoration is the ability to provide higher utilization of network resources than the four-fiber BLSR system. As a result, other services cannot be offered throughout the mesh by utilizing the protection bandwidth.

Gold Service: Predefined Traffic Protection

Gold service uses mesh protection to provide longer restoration times (300 ms to five seconds), and gold service traffic uses predefined protection in the mesh. This service level is appropriate for traffic that can tolerate some delay within defined SLA boundaries. This level provides M-for-N mesh-protected service with no degradation in the CoS. M-for-N protection with guaranteed priority and predetermined routes provides greater reliability, faster restoration, and a deterministic behavior. M-for-N protection with best-available routes, strictly determined by the state of the network, provides recovery that can still be sub-second but that may exceed that based on the state of the network. Throttled-down service at the optical layer ensures that the data layer does not have to deal with loss of adjacencies and associated issues.

Silver Service: Best-Effort Traffic Restoration

Silver service is enabled from a network that searches tables for the best route of recovery. This service may tolerate delays in the seconds to minutes range. Applications include e-mail, store-and-forward traffic applications, storage-area networks (SANs), and IP over DWDM (where IP provides the protection).

This service can be sold to carriers who want to establish IP over wavelength connections on different carriers networks with diverse fiber routes from their own, thus offering Layer-3 protection and physical network topology diversity.

Bronze Service: Unprotected Traffic

Bronze service has no recovery mechanism. Applications include IP over this service and swapping bandwidth with other carriers to provide network topology diversity (different transport networks with potentially different fiber routes) where another layer of provides the protection (Layer 3).

Lead Service: Pre-Emptible Traffic

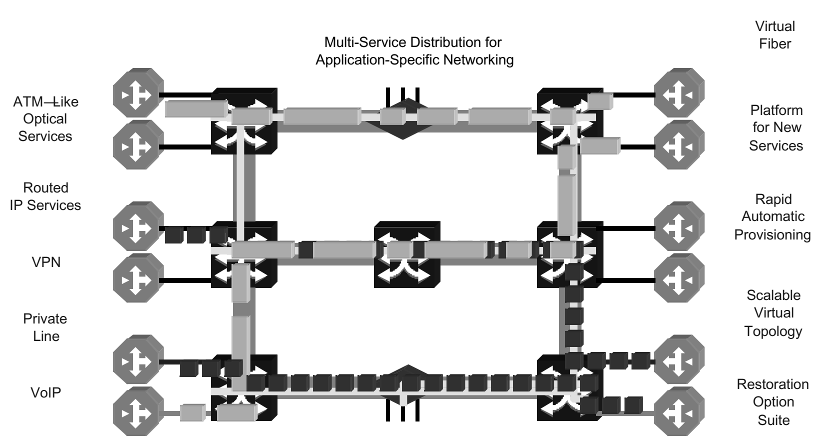
Pre-emptible traffic is the lowest level of service available. Like unprotected traffic, this service provides no recovery. Here, traffic may actually be dropped to provide protection to other traffic. This service is generally up and running but in the event of a network outage, will be dropped as other traffic uses this capacity for protection. Applications include swapping bandwidth or wavelengths with other carriers for protection and low-priority locally stored data. The benefit of this service for the carrier is the ability to generate new sources of revenue off of the existing operational equipment.

Next-Generation Backbone and Metropolitan Network Architectures Combined: Routed Photonic Network

Signaling and routing standards enable a next-generation network that provides intelligence and automated capabilities. The network, which starts with the physical fiber infrastructure, manages traffic in a routed photonic network. A DWDM layer with both long-haul and ultra-long-haul capabilities is placed on the fiber, providing virtual wavelengths or optical virtual private networks (VPNs). Optical switches are then placed at junction locations to provide switching and routing capabilities. Then there is the multiservice distribution, or metropolitan network (see *Figure 4*), which aggregates services from the edge to be transported on the backbone.

FIGURE 4

Routed Photonic Network



Software, signaling and routing protocols, and standards provide the network with intelligence, which allows the metropolitan and backbone networks to be self-aware of their resources and to operate together to dynamically allocate bandwidth, offer CNM capabilities, and provide end-to-end services to each customer based on the customers individual SLA.

All of these components will enable the future routed photonic network to exist. Many new protection mechanisms and service offerings will arise through this network and will benefit service providers and customers.

Making Next-Generation Networks Possible

Ultimately next-generation networks must deliver end-to-end services to customers cost-effectively. They must be scalable, flexible, and provide for end-to-end network management.

To achieve cost-effective next-generation networks, the telecommunications industry (service providers and vendors) must work together to succeed in delivering business solutions that meet and exceed the constantly changing expectations of a bandwidth-intensive, service-focused customer base.

Parlay API Specifications: An Overview

Avni Wala
Software Engineer, Telecom Applications Group
Future Software Limited, India

Abstract

A number of groups are currently developing technologies aimed at evolving and enhancing the capabilities of intelligent networks (INs). This paper describes one such technology developed by the Parlay consortium, namely Parlay API. This paper describes the Parlay application programming interface (API) specification, its architecture, its advantages, and its place in the current scenario, as well as means of deploying APIs and an example illustrating the use of APIs.

Introduction

Recently, immense exposure to the Internet has raised customers' expectations of the service features that should be offered by the public telecommunications infrastructure. The users expect that the services should support a mix of media types, allow easy customization, and be available on demand, regardless of the location or the capabilities of their terminal equipment. To meet these demands in a cost-effective manner and to survive in a volatile marketplace, the challenge is to deploy the technological components required to realize these services. As the level of interconnection between fixed, mobile, Internet, and enterprise networks increases, a key component in ensuring these services will be the availability of a common platform for their development and delivery. Of course, the platform should leverage the existing systems as much as possible—to enhance the service-delivery capabilities, rather than totally replace them. One such platform, specified by a Parlay industry working group, aims to provide an object-oriented service-control API that is independent of underlying communications technologies (e.g., public switch telephone networks [PSTNs] as well as wireless and Internet protocol [IP] networks). The APIs are specified in unified modeling language (UML) and are designed to support all major middleware technologies (e.g., distributed component object model [DCOM], common object request broker architecture [CORBA], Java platform, etc.)

What is Parlay Group?

The Parlay Group is a nonprofit entity. It is incorporated in California and managed by Enterprise Ventures.

Parlay Members

The following companies are a part of the Parlay consortium:

- Aepona
- Alcatel
- AT&T
- BT
- Cisco Systems
- Ericsson
- France Telecom
- Fujitsu
- High Definition Systems, AB
- IBM
- Lucent Technologies
- Microsoft
- NEC Corporation
- NET4CALL
- Nokia
- SBC–TRI
- Siemens AG
- SS8 Networks, Inc.
- Tundo Communications
- Ulticom, Inc.
- Westwave Communications

Aims of the Parlay Group

The Parlay Group has generated an API specification providing access to network information and control of a range of network capabilities. The API is specified in UML and is designed to support all major middleware technologies. The Parlay Group aims to specify an object-oriented service-control API that is independent of underlying communications technologies to encourage the widest possible range of market players to develop and offer advanced telecommunications services.

Current Scenario

Currently, intelligent capabilities in conventional switched networks are exclusively under the control of network operators because of incompatible standards, network security, and integrity. Hence, we have two scenarios:

FIGURE 1

1. Network-centric communications-service delivery mechanisms (e.g., advanced intelligent networks [AINs], INs, etc.), which run "inside" the network domain. Such a mechanism is easily manageable and robust, and hence is good for simple mass-market applications. But the problem with such a mechanism is that it cannot access data in the enterprise domain for domain-specific decision-making.
2. Edge-of-network service delivery mechanisms (e.g., enterprise computer telephony integration [CTI]), which run "outside" the network domain. Such a mechanism is good for creating services that meet the specific needs of a customer but generally cannot access critical information and capabilities within the core network.

Figure 1 shows a typical network-centric scenario:

- The top layer represents applications.
- The middle layer represents service components that are reused by many applications.
- The lower layer represents different network technologies.
- All the three tiers of this architecture are owned and operated exclusively by network operators.

Disadvantages
The major disadvantage is the difficulty in achieving the flexibility to deploy many customized versions of services to different customer groups, as the network operator is responsible for the creation and operation of all applications. Also, application development and integration testing take a long time, thus the time to market for new applications is long.

Introduction of Parlay

The advantages of both network-centric and edge-of-network mechanisms have been incorporated in Parlay specifications. Parlay is an umbrella architecture that provides network independence and application portability. Parlay APIs enable a new generation of off-the-shelf network applications and components (e.g., messaging, mobility, end-to-end quality of service [QoS], etc.) to be developed by application providers (e.g., independent software vendors [ISVs], application service providers [ASPs]) independent of the underlying voice/multimedia network. Parlay APIs are platform/vendor/technology independent to ensure the implementation of multiple technologies. The Parlay Group, working together with standards bodies, directs the industry to design and develop new services and allows those services to actually drive information technology (IT) networks.

Where Does Parlay Fit into the Existing Architecture?

As shown in *Figure 2*, the Parlay APIs can be implemented on top of the middleware, which can be any implementation of CORBA, DCOM, or the Java platform. Some of interfaces will be implemented on the client side (i.e., the application side) to collect the responses given by the interfaces that are implemented on the server side (i.e., the network provider's side). The Parlay server-side interfaces will collect the information from the underlying network, and then will present the required information to the client application using the call-back mechanism.

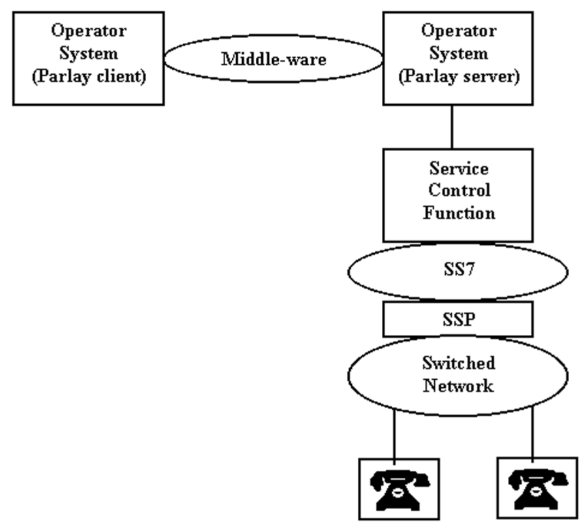
How Can the API Be Deployed?

The main specification is defined in technology-independent UML. Deployment of the API can be via technologies such as DCOM, CORBA, or Java. Technology-dependent interface definition language (IDL) specifications in Microsoft IDL and CORBA IDL also exist. APIs can be implemented using any of the languages that support object-oriented characteristics.

A Conceptual View of Parlay APIs

As illustrated in *Figure 3*, the API resides between the application layer and the service-component layer. By enabling access to network capabilities via an API, service providers,

FIGURE 2



ISVs, and other developers in the IT and telecommunications industries are empowered to generate a new range of applications that benefit from, and add value to, functionality resident in public and private communications networks. These services can then be used within the enterprise or are sold to other enterprises.

The Parlay API Architecture

As illustrated in *Figure 4*, the Parlay APIs consists of two categories of interfaces:

1. Framework interfaces
2. Service interfaces

Framework Interfaces
Framework interfaces provide supporting capabilities necessary for the service interfaces to be open, secure, and manageable. The framework can be considered as a number of functional building blocks and is independent of any of the Parlay services.

Functions provided by framework interfaces include the following:

- Service registration, subscription, and discovery
- Authentication and authorization
- Integrity management

Thus, the framework should authenticate the users of the API, prevent non-authenticated users from accessing both the service and the framework interfaces, and provide the users with means to ensure the integrity of their transmissions.

The framework interface can be divided into the following categories:

1. ***Trust and Security:*** It enables the application to contact the framework, mutually authenticate, and sign for use of services.
2. ***Discovery:*** It supports properly qualified searches for services available to the application.
3. ***Event Notification:*** It allows asynchronous event passing between the application and the gateway.
4. ***Integrity Management:*** It performs various functions to monitor and control the operations of the gateway and application, and assists in recovery from faults.
5. ***Subscription Management:*** It allows enterprise applications to explicitly subscribe to new services and makes them available for use.

Benefits of framework interfaces:

- Common security, service location, and registration framework to which application developers can write. These applications would use the services presented by the Parlay API.
- Provides service brokering, security, billing, and operation support and maintenance (OS&M) capabilities consistently across any Parlay-enabled framework.

Service Interfaces
Service interfaces contain mechanisms by which applications access underlying network capabilities and information.

Functions provided by service interfaces include the following:

- Allowing access to traditional network capabilities, such as call management, messaging, and user interaction.
- The service interfaces also include generic application interfaces to ease the deployment of communications applications.

The service interfaces are divided into five categories:

1. Call-control service
2. User interaction service
3. Messaging service
4. Connectivity manager
5. Mobility service

FIGURE 3

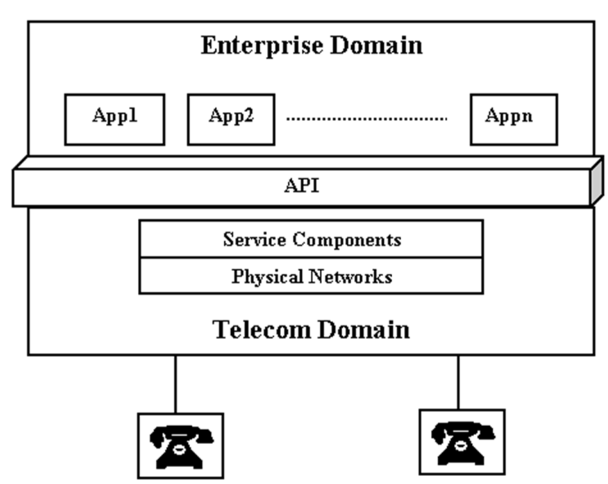


FIGURE 4

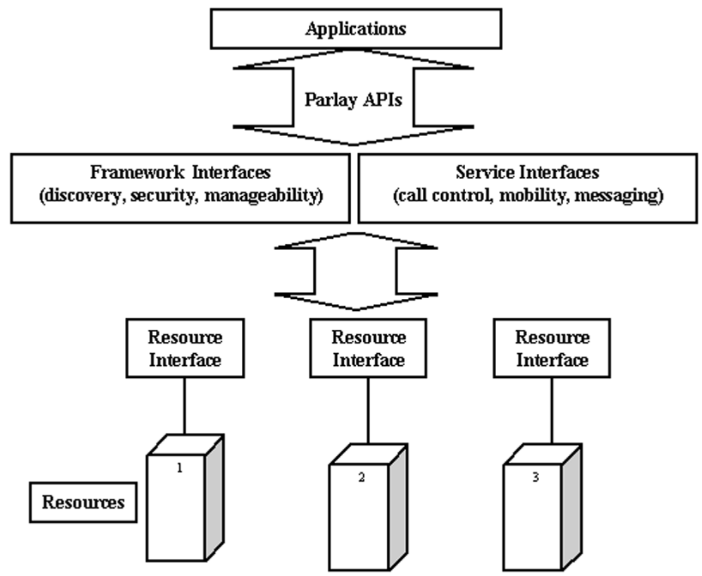


Call-Control Service
This API creates applications that use centralized call routing for services that span PSTN, mobile, and voice over IP (VoIP) networks. It has tiered capabilities from very basic call control to multiparty multimedia, so that applications use only the appropriate complexity.

The call control can be a simple call control, multimedia, or conferencing.

Benefits of call-control service APIs include the following:

- Multimedia applications can signal across all network-specific protocol mediums, hiding underlying protocols.
- The APIs enable multimedia services development that span multiple networks.

User Interaction Service
User interaction service, when used in conjunction with call control, enables applications to control interactive voice systems, specify prompts, and collect user input. It is used to send and receive information to and from the user. Any responses that will go from the application to the user, and vice versa, will make use of the user interaction service APIs.

Messaging Service
It has capabilities to send, retrieve, and store messages. It explores limited functionality to store-and-forward messaging systems for voice and e-mail messaging.

Benefits of messaging service APIs:

- They simplify developers' abilities to write applications for messaging that integrate other services.
- Service providers can offer cross-service messaging applications and ensure application portability.

Connectivity Manager
A connectivity manager enables applications to provision QoS–specified pipes across IP networks. It will allow an application to be developed to configure virtual circuits (VCs) and selectable QoS levels on an IP–based network.

Benefits of a connectivity manager include the following:

- It enables user-configurable QoS multiservice applications across IP networks.
- Configurable QoS levels on IP backbone can be integrated with other applications.

Mobility Service
Mobility service presents mobile user-location information through APsI to be used to develop applications for network services. Using the mobility-service APIs, applications can obtain the geographical location and status of fixed, mobile, or IP–based telephony users. Also, the location information based on the network-related information, rather than geographical coordinates, can be retrieved via these APIs.

Benefits of mobility service include the following:

- It provides APIs for the location of mobile users for emergency, geographical, and other applications.
- Mobile-user location information adds unique functionality to various applications.

An Example Using Parlay APIs

A company, ABC Repairs, offers a product support service for its customers. The software system that it uses comprises a workflow engine that integrates a fault-logging system, home-based diagnostic experts, and a mobile repair fleet.

A typical workflow for the support service is shown in *Figure 5*, and the states through which it will go are numbered from 1 to 12. The descriptions of the states are given as a business scenario:

The business scenario:

1. A customer phones the 0800 support line.
2. The call-control API sends a message to the application identifying the calling-line identity (CLI).
3. If the CLI is not recognized as belonging to a customer, the application instructs the call-control API to route the call to the interactive voice response (IVR) system.
4. The prompts played to the customer and the responses are all passed across the user-interaction Parlay API.
5. When the customer and site location are recognized, the application uses its customer database to ascertain the product type and the level of service for which the customer has paid.
6. If the service call is to be dealt with immediately, the application releases an IVR and routes the call using the call-control API to an available agent qualified for the particular product.
7. The agent takes the customer through a basic diagnosis system and logs the report into the workflow databases.
8. The workflow engine identifies an appropriate mobile repair technician to send to the customer site, using the staff skills database.
9. The mobility APIs are used to locate the best-fit technician for the job, and the completion time for the technician's current job is estimated.
10. The agent receives the technician's estimated arrival time and name.
11. The customer is informed of the same.
12. The mobile technician is informed and the fault report is downloaded to the technician's computer.
13. The calls that the employees are unable to answer are diverted to the voice-mail system.
14. When the caller leaves a message, the messaging API will alert an application that may send an alerting e-mail to the staff member.
15. The connectivity manager API is used by the training and conferencing applications to schedule guaranteed QoS pipes between the distributed offices for the duration of high-bandwidth, real-time conferences.

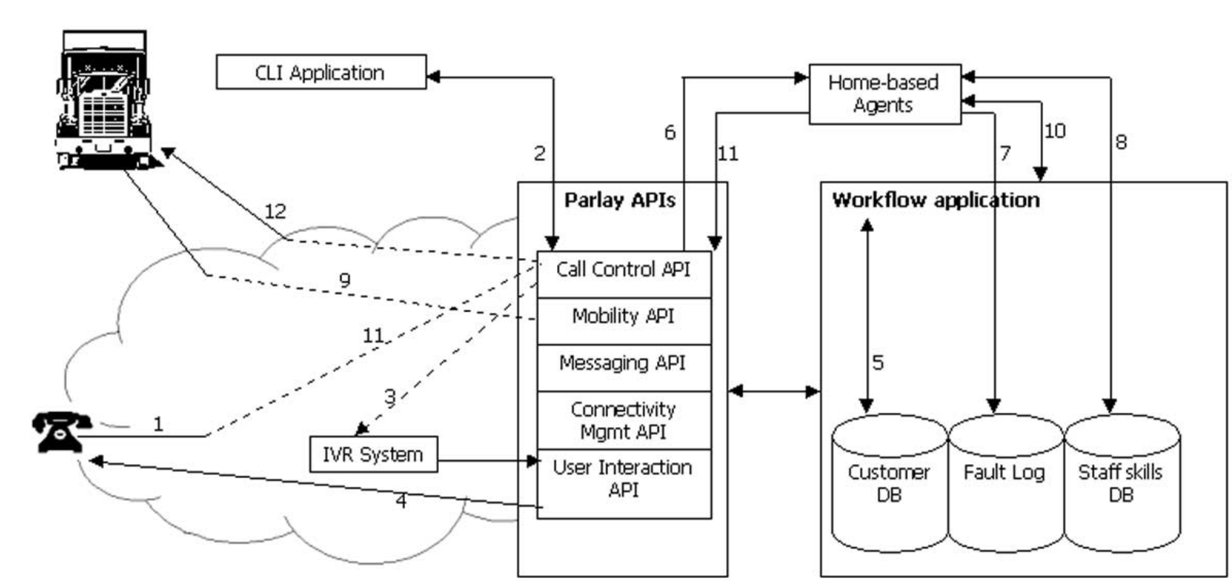
Conclusions

The focus of the Parlay Group is on producing an API specification that enables enterprises outside of the network operator's domain to access network information and control a range of network capabilities. The Parlay Group believes that there is a tremendous growth opportunity for network operators, service providers, and application developers through the adoption of the Parlay API. Customers will benefit as business needs are met more cost-effectively and quickly using the capabilities offered via the Parlay API.

The following is a summary of the major goals of the Parlay Group:

- Define an API specification that provides application developers a consistent, network-independent view of functionality that they can employ.
- Ensure that the API specification provides security and integrity for the network as well as enterprise domains.
- Encourage IT and telecom industries to implement and deploy the Parlay API globally.

FIGURE 5



- Encourage application developers to create new and innovative applications using the APIs to solve customers' needs.
- Work with the IT industry to encourage the production of software development kits (SDKs) that make the process of developing applications exploiting the Parlay API straightforward and efficient.

SIP–Based Call Centers: A Vendor-Independent Architecture for Multimedia Contact Centers

Neill Wilkinson
Senior Consultant
Quortex Consultants Ltd.

The current call-center market is populated with vendor-specific solutions, making the decision for the telecom manager on functionality very difficult. Finding the best fit and being able to combine components from different vendors can quickly become a major systems-integration project.

This paper outlines the possibility for a vendor-independent architecture that will allow best-of-breed components to be combined and allow for a close integration of systems without performing a major integration project. The architecture proposed also has the ability for rapid development of new applications for call centers by skilled Web developers (not systems integrators or expensive software houses) and provides a framework for eCRM products.

1. Introduction

During the last decade, computer telephony integration (CTI) has rapidly become the way in which call centers have achieved the benefits of being able to combine telephony services with information technology (IT) systems.

While this growth in CTI has improved customer care and call-center sales capabilities, the industry has been marred by proprietary systems and nonstandard interfaces, creating spiraling system-integration costs.

In the background to this has been the rise of the Internet revolution and the emergence of Internet protocol (IP) as the way to connect systems.

The growth of the World Wide Web (WWW) from Tim Berners Lee's original idea of a hyperlink information store to that of a powerful tool for application development has allowed for dynamic content to be generated and constructed based on inbound context.

Now that Internet telephony is becoming mainstream, the major telecommunications operators are looking to replace their circuit-switched infrastructures with packet-telephony networks [1].

This is allowing CTI, the WWW, and Internet telephony to be combined to create a new breed of call-center system, presenting an opportunity to utilize the open nature of Internet telephony for call centers and to move away from proprietary protocols and vendor implementations.

The call-center market has seen significant growth during the last decade. Recognition of the need to handle customers efficiently has lead to the ideas of customer-relationship management (CRM).

While the idea of customer relationship is not that new, the linking of customer relationship to the realization that retaining customers is more cost-effective than trying to win new ones is one that has captured the call-center industry.

The recent growth in the so-called e-economy has created a new area for customer contact, that of the Web and e-mail. While this has created a new channel to market, it has also created a new need to ensure good customer care through this medium. This has led to the growth in the eCRM market.

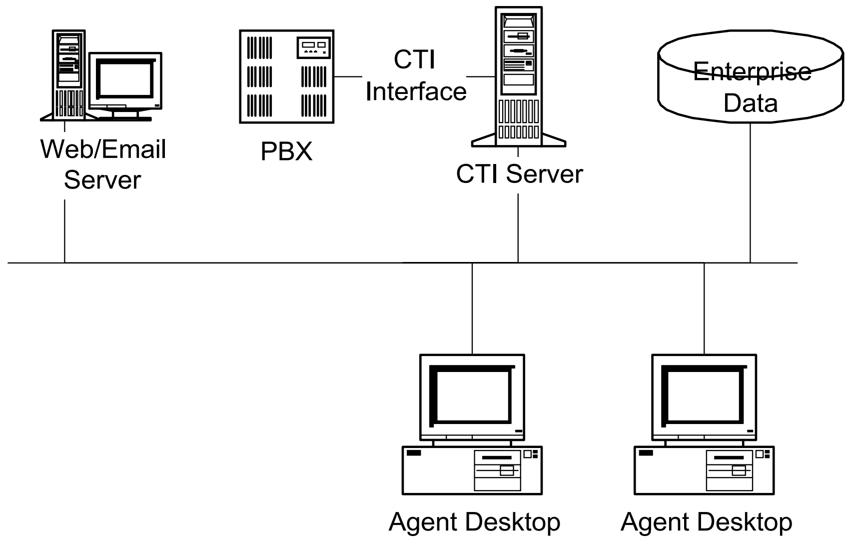
2. Evolution of CTI Architectures

The de facto architecture for computer telephony (CT) third-party call control is shown in *Figure 1*.

This architecture involves a CT server communicating with a private branch exchange (PBX) or automatic call distributor (ACD) system via a proprietary (vendor-specific) interface, and a proprietary interface between a workstation application and the CTI server.

The back office enterprise database is accessed through open database connectivity (ODBC), Java database connectivity (JDBC), or a direct structured query language (SQL)

FIGURE 1



interface, either by workstation applications or by the CT server. This enterprise data is fed from marketing and other channels, and areas such as on-line analytical processing (OLAP) and data mining are very important in extracting value from this data. However, this is outside the scope of this paper.

This ends in a complex integration project of all the disparate systems through a plethora of interfaces and middleware, some of which is vendor-specific. This is clearly not an environment for rapid application development.

The Rise of the UnPBX

A little over three years ago, the use of NT as an operating system (OS) for call-center applications emerged as an opportunity to move away from proprietary PBX/ACD systems. "*We are total believers in the concept of Windows NT based UnPBXs. We fully expect that over time, smaller phone systems (PBXs and Key Systems) will be replaced by UnPBXs.*"[1]

A number of vendors seized this opportunity[2] and started to produce hardware and software alternatives to the box-based ACDs/PBXs. The UnPBX was born [3].

The rise of the UnPBX was the birth of the movement away from circuit-switched proprietary ACDs to a more open IP–based solution. However, three years ago (and to an extent now) proprietary call-control protocols still reigned supreme[3].

The current trends in open ACDs owe a lot to these UnPBX vendors. The telecom world has moved on from there, and a more open carrier-sized upgrade is taking place.

3. Next-Generation Networks

A lot of words have been printed about voice over IP (VoIP) and IP this and IP that. The plain fact is that IP has become the de facto standard for multimedia communications. This means that ways have been sought to carry voice *reliably* over IP. This has lead to the emergence of what are known as the next-generation networks. What this means for call-center technology is that there is a greater opportunity to capitalize on the changes in the core network.

The New PSTN

Conventional circuit-switched time division multiplexing (TDM) networks are slowly being replaced by packet-switched networks carrying both voice and data. These networks are being created from new access techniques, such as digital subscriber line (xDSL) and hybrid fiber/coax (HFC) cable modems, and core carrier network technologies such as media gateway controller (MEGACO) [4]. The mobile networks have not been left out, and the Universal Mobile Telecommunications System (UMTS) standards are based on an asynchronous transfer mode (ATM) transport, with increased focus being placed on data services (general packet radio service [GPRS] and enhanced data rates for GSM evolution [EDGE]; and wireless application protocol [WAP] and i-Mode).

While this creates the opportunity for more integrated applications, it will also force the telecom operators to consider redesigning all of their conventional telecommunications services.

Since most (if not all) major telecom carriers operate separate voice and data infrastructures, major consolidation will be required to efficiently move the voice network from TDM to the packet infrastructure of the data networks. To get real value (read revenue) from this infrastructure investment, without pricing the services out of everyone's reach, the telecom operators will need to look at technologies such as virtual private networks (VPNs) for creating virtual segregation of customer traffic.

There is a major market opportunity for a new breed of telecom operator to emerge, the *IP telco*. This operator could emerge from an existing network operator or could be launched from a global Internet service provider (ISP) like AOL. The IP telco could operate in a model similar to that of the mobile virtual network operator (MVNO) or switchless resale company.

To capitalize on the VNO model, incumbent and competitive global telecom operators could deliver telecommunications services on a wholesale basis from their networks, rebranded by VNOs completing the evolution of the switchless resale model.

The cost of entry for a new player to come into the market place as a global IP telco is relatively small, and the potential for large revenues is huge[4]. The revenue is rapidly becoming derived from the services offered, not the cost of access to the services[5].

This means a new entrant could enter the marketplace without having to own any network, they *just* have to negotiate peering access to a number of key points of presence (POPs) around the world and piggy-back their service on other incumbent networks. Clearly, new peering arrangements that include quality of service (QoS) and service-level specifications will have to replace the current ISP peering model.

Voice-Based Information Services and the New Answering Machine?

A number of the main vendors of interactive voice response (IVR) systems are looking to add packet voice interfaces to their products.

This is being augmented with extensible markup language (XML)–based scripting in the form of VoiceXML[6]. This allows voice prompt scripts to be written in a platform independent language that also allows a close integration with Web servers.

Unified communications (UC) is an application that has received a great deal of press recently. UC is unified messaging (UM) come of age. It provides the ability to integrate voice-mail, e-mail, fax, short message service (SMS), and paging into a single inbox. Work has been done on the use of SIP and real-time streaming protocol (RTSP) for a UM platform [5].

UC looks set to replace company voice-mail systems and to provide a new answering-machine service to users of in-net services via an application service provider (ASP) delivery model. British Telecom (BT) offered an early version of an in-net answering machine with their CallMinder™ product.

A number of ISPs are starting to offer UM services for combining fax and e-mail integration and allowing customers to dial in and listen to their e-mail. The problem with these at the moment is that they require their users to have another access number.

4. The Vendor-Independent CTI Architecture

Building on the foundations of the UnPBX, the softACD has appeared, and companies such as CosmoCom[7] are successfully utilizing software frameworks—such as Microsoft distributed component object model (DCOM), J2EE, and common object request broker architecture (CORBA)—to develop conventional ACD functionality and combining Web server capability to deliver eCRM.

These first-generation softACDs are creating a new opportunity for vendor-independent CTI capability by combining the CT server and ACD into a single platform built from open software frameworks.

The architecture of a truly vendor-independent solution is available now through products such as Sun Microsystems' J2EE, Oracles' 8i or IBM's Websphere, and BEA's Weblogic.

What vendors will do is to write code on top of these application frameworks, providing the value-add for call-center applications. Application frameworks such as this are also big business, and companies such as BEA Systems have made significant inroads into this market segment.

The Open-Source Movement

By combining open-source H.323 and/or session initiation protocol (SIP) stacks, anyone with software engineering skill can develop a softACD and provide Web integration to deliver an eCRM solution. The biggest challenge is adding the value through reporting tools and remote maintenance capability and combining these with sound back-office integration.

This is creating an opportunity for Web developers to create new services, building on top of platform libraries without having to resort to help from systems integrators. This also means that small businesses need not worry about large bills from system integrators and can take services from network-based vendors for a fraction of the cost.

This also opens up the possibility for large telecom operators to take the code developed by the new entrants to the market and transport it the large network-based call servers, thus delivering large-scale, feature-rich, network-based softACDs. This also creates the opportunity for ASP delivery of customer contact systems for the new e-economy.

It also opens up the way for systems/software houses to enter third-party development and partnership agreements with large operators to allow for the rapid delivery of new differentiated services.

While the traditional role of systems integrators is diminishing, their role is evolving from technology integration to business integration—moving them up the value chain.

All of this software is of course nothing without the call-control protocol. SIP [6] is emerging as the favorite to fill this space. However, H.323 is probably currently the most prevalent implemented call-control protocol. For comprehensive comparisons of these protocols refer to [DALGIC].

Sun Microsystems is working on a Java-based model called Java APIs for integrated networks (JAIN) that incorporates these architectural ideas, including a SIP and H.323 stack for intelligent network (IN)–based services.

The protocols responsible for converged communications are best viewed as a layered model [7]. This model consists of the call-processing protocols, user protocols, and support protocols.

Call-Control Protocols
The call-control protocols have been highlighted as SIP, H.323, and MEGACO.

Of these, SIP is arguably the most versatile and extensible, as it is text-based and designed around simplicity. This, however, does leave out a lot of embedded feature capability.

Why Use H.323?
H.323 is actually a collection of protocols, and H.245 is actually the call-control protocol (based on Q.931) combined with H.225. This framework has evolved from the work on the H.320 videoconferencing standards, which means a lot of capabilities and features are supported by the H.323 family of protocols.

Also, H.323 is important because of its prevalent implementation by Microsoft in its Netmeeting' product and in the TAPI 3.0 implementation on Windows 2000.

SIP's Attractiveness for Call Control
One of the key issues of any Internet-based service is security. SIP can support security through the use of any encryption standard. For example, the widely available pretty good privacy (PGP) package could be used to encrypt the signaling payload. One of the potential issues with SIP is that IP addresses are carried in the header message; this can be overcome with a SIP–network address translation (NAT) module (a version is available for Linux under the GNU license). Solutions to this are far from elegant—yet [8], and it may be necessary in a network operator's environment to implement a firewall control protocol.

The SIP architecture has two key components that provide for load balancing and service transparency, namely proxy servers and redirect servers for load balancing.

SIPs openness and extensibility allows for easy extension. The SIP INFO method [9] for in-call messaging is an example of this and is a perfect candidate for in-call communication between an agent desktop and a proxy server softACD.

Support Protocols
The list of support protocols is endless, as this is essentially the list of all the specifications of the Internet Engineering Task Force (IETF). That said, the protocols of most significance are IP multicast for agent monitoring and third-party call connect; the IP security (IPSec) specifications for the creation of IP–VPNs and multiprotocol label switching (MPLS) for the same purpose; the RTSP and real-time conferencing protocol (RTCP) for playback of recorded messages; and finally the Internet relay chat (IRC) client protocol for real-time chat between customers and agents.

One could bundle in the plethora of Web protocols, such as hypertext transfer protocol (HTTP); however, these are more related to the Web-server delivery of content, rather than collaborative interaction.

Application Frameworks
A word of caution on the title of this section: Application frameworks are an area of study relating to the use of object-orientated techniques for the production of domain-specific software components. I do not intend to expand on this here, as this is a massive topic area in its own right. If application frameworks interest you, I suggest you refer to [MOHAM].

This section highlights some of the middleware frameworks that are available from the development of the collaborative applications necessary to support an eCRM service.

Firstly, Sun Microsystems' J2EE coupled with its iPlanet Web server. These products build on Sun's Java 2 virtual machine for the rapid development and deployment of component-based applications and create an environment for the creation of an integrated ACD call server.

The BEA/Nokia and Motorola (MIX) platforms use the same capabilities as Java server pages and Java servlets to create an integrated environment for wireless platform application development. These could be used as the basis of a wireless communications server.

Finally, dynamicsoft's proxy server products utilize CPL and SIP CGI for call control in a SIP environment. It is a small mental step to enhance this to a Java servlet environment to provide softACD functionality on top of this platform and to link these platforms to Web servers to provide multimedia integration. Queue and agent skill scripting could be provided by CPL [10,11].

Call Servers
The evolution of the public switched telephone network (PSTN) from a collection of circuit switches to a distributed call server (media gateway controller) and gateway (media gateways and signaling gateways) architecture, and the use of proxy servers in the SIP architecture, has created the opportunity to deliver all services from call servers.

This might be considered as an issue with "all your eggs in one basket," but that is not the case, because the call servers are in their own right fault-tolerant, distributed platforms.

What is key is that the call servers are being constructed from *standard* IT hardware. This opens up the possibility for these servers to be used for network-based softACDs.

Billing for Network Services
Clearly, from a network operator's perspective, being able to charge for the use of a service is very important. Billing for next-generation network services will be performed by the call servers (media gateway controllers, softswitches, SIP proxy servers, H.323 gatekeepers). The difficult arises from the fact that once an endpoint has discovered the other party's endpoint, there is theoretically nothing stopping the originating endpoint from passing the call server, thus creating the opportunity for fraudulent use of network resources.

To prevent this in, for example, an SIP situation (a similar solution would work for H.323 endpoints), the SIP user agent must contact the SIP proxy via a NAT firewall, thus preventing any visibility of the "internal" network [12]. This of course leads back to the issues involving the use of firewalls.

5. Conclusions

Firstly, let's start with areas not covered by this paper: business models (marketing/sales/service sale cycle, when things go wrong, order tracking, workflow) and delivery models (ASP, customer-premises equipment [CPE]). These areas are papers in themselves, and the author suggests that the reader look elsewhere for discussions of these topics.

Telecom operators need to be looking at platform vendors rather than mega-software vendors.

The mega-software vendors will develop functionality based on what the mass market wants, and customization and differentiation will be more difficult than with a platform solution.

The platform solution has the advantage of allowing for vertical market products on a common architecture. The scale of product offering required by a telecom operator makes the platform solution the obvious choice. For wholesale delivery of services to different customers, telecom operators will also need to consider the ability to segment the services in a secure fashion.

Watch out for consolidation in this market space. The market is still young, and vendors such as Cisco Systems, Alcatel (Genesys products), Siebel, and Clarify (a Nortel Networks company) have the power to swallow new entrants. The author has specifically steered clear of the CRM products provided by companies such as Siebel and Clarify, purely because the space that these vendors occupy is currently the area of product and system integration. This white paper's whole premise was to discuss the framework that will underlie these vendors' products.

Also watch out for the platform people (BEA, Vignette, and Art Technology Group) and for the architecture vendors (IBM [Websphere], Sun Microsystems [J2EE and iPlanet]. The other big boys keen to push this opportunity are, of course, Oracle and Sybase. Oracle's 8i and 9i products could form the core of many eCRM offerings.

Another company in this space that will later emerge as an eCRM candidate is dynamicsoft. dynamicsoft is the leader in SIP–based products that will underpin the voice side of softACDs. (The company's chief scientist, Jonathan Rosenberg, is very active in this area and has recently proposed application architecture that may go someway toward achieving this [13].) All of the other vendors mentioned are firmly from the IT and data-management camp. So far these IT vendors have not integrated the voice portion of customer interaction, arguably the most important channel.

Voice over Internet Protocol Quality of Service

Bruce Young
Engineering Vice President
Telverse Communications, Inc.

Philip Repino
Publications Manager
Telverse Communications, Inc.

An opportunity to use data networks for voice over Internet protocol (VoIP) telephone traffic holds great appeal because VoIP can reduce the business expense of long-distance calls and offer enhanced features. Today, VoIP is an evolving technology that is gaining in popularity and application. VoIP is evolving toward real-time conferences, presentations, and video streaming. However, as more companies deploy VoIP, more Internet protocol (IP) networks will have to carry time- and jitter-sensitive packets. A circuit-switched public switched telephone network (PSTN) and a packet-switched Web network hold different challenges. IP networks require testing and monitoring for call set-up, voice quality, and packet analysis. Additionally, while bandwidth consumption may be relatively low, VoIP poses stringent demands for low latency and consistent arrival of voice-related datagrams. Each voice carrier and enterprise should calibrate its network for optimal VoIP performance.

VoIP Simplified

As stated, VoIP eliminates long-distance telephone charges by sending voice signals over the Internet. Previously, the use of the PSTN incurred time-based, long-distance charges. By using VoIP, packets of digitized voice can now be sent over the Internet to a distant point within the VoIP Internet, or a call can be switched upon receipt to the local PSTN and onward to any digital or analog telephone.

Data can travel over a packet-switched network in packets that arrive at varying times. They are simply reassembled back into their correct sequence when received. However, for real-time voice transmission, hearing packets of digitized voice in anything but the correct order is unintelligible. Re-assembly techniques do not work for voice packets.

Quality of service (QoS) can be improved by using software to compensate for many of the problems of sending voice over packet-switched networks, such as delay, jitter, and random or recurring lost packets. With this new software and other tuning adjustments, packets of digitized voice can be sent successfully over a data network.

The Inherent Parts of VoIP: Delay, Jitter, Echo, and Packet Loss

Delay and Jitter

Because network congestion can be encountered at any time within a network, buffers can fill instantly and cause packet delays. Jitter is the difference between when a packet is expected to arrive and when it actually is received: the end-to-end delay. (Jitter refers to *packet* jitter, not bit jitter). To compensate for delay variations between voice packets in a conversation, VoIP endpoints use jitter buffers to store incoming packets and release them in a more constant stream and thus turn the delay variations into a (unperceivable) constant value. This damping allows a voice to be delivered to a handset smoothly. A suggested goal is to keep jitter at less than 20 ms, ideally at 5 to 10 ms.

As jitter buffers hold voice packets, they add latency. And, compounding the jitter problems somewhat, packets can get lost if a jitter buffer overflows. Thus, the size of a jitter buffer can affect both jitter and latency. If voice traffic has enough jitter to annoy users, increasing the size of a jitter buffer will reduce jitter to acceptable levels. Too large a buffer, however, may cause latency to increase to where it is again annoying to users.

There is no optimal size for a jitter buffer, and buffer size varies within the network. A typical jitter buffer delay is 20 ms but can reach 80 ms. Increased bandwidth and proper tuning can reduce network congestion, which in turn will reduce packet loss and jitter.

Several considerations and possible actions exist to counteract delays. Many types of delay can present themselves in today's network, such as jitter buffer (as mentioned), network-appliance transport, propagation, and packetization. To compensate for delay added by appliances, the number of hops and the delays within the worst-offending appliances can be reduced. Propagation pitfalls can be reduced by making the network path as direct as possible. Packetization delay can be reduced by using a coder-decoder (CODEC) compression scheme that induces only a small packetization delay. Finally, not allowing changes from one CODEC to another along a path and avoiding complex, time-consuming CODECs will reduce delay.

Latency

Designs for VoIP transmission have to measure the amount of latency that an appliance will add to a network. By knowing the latency of each component, you will know what each component contributes most to the total latency. That information can help you to decide if the size of buffers is sufficient to deliver acceptable QoS.

If network latency is too great, VoIP conversations degrade. Typically, users can tolerate delays of no more than about 200 to 250 ms before a conversation becomes annoying. Delays of 400 ms to 500 ms make conversations impractical. The suggested goal is to keep latency less than 150 ms for one-way traffic between endpoints.

Echo

In a voice telephone call, echo occurs when you hear your own voice repeated. An echo is the audible leak-through of your own voice into your own receive (return) path. Echoes arriving before 20 ms are generally imperceptible—those arriving after 20 ms are audible.

Some things that can be examined to reduce echo include the following:

- Check speakerphones or headsets. If the destination telephone is a speakerphone or headset, it is probably the source of the echo. Replace the speakerphone or headset with a new or better-quality handset and see if the echo vanishes.
- Telnet to the destination voice gateway and check that the echo canceller is enabled and that the coverage is set to maximum.
- Test for normal echo canceller. If the echo persists and you have verified that the echo canceller is working properly, the echo canceller cannot fix the echo because it is too loud (called a *loud echo*) or if it is too delayed (called a *long echo*). Most persistent echoes are loud echoes. Delayed echoes are common, however, when the end circuit involves a long-distance PSTN link, a series of alternating digital and analog links, or any other link with high latency.
- Match output impedances and levels with the analog telecom equipment attached to the adapters and gateway analog voice ports.

Today, echo cancellers, built to the International Telecommunication Union (ITU) G.168-2000 standard, can provide rapid (< 500 ms) training and some degree of real-time echo cancellation for telephony applications.

Packet Loss

Heavy traffic loads are a primary contributor to network delay, jitter, and dropped packets. When a router overloads with traffic, it may intentionally drop packets to relieve congestion. A voice packet that arrives late might as well have not been transmitted at all. Retransmission is of no value. And, excessive packet loss affects the QoS of a VoIP system. Because lost packets cannot be recovered, they show up as gaps in a conversation. Small gaps are acceptable, but a consistent high rate of loss is not acceptable.

Typically, more than 5 percent of lost packets will annoy users. Burst packet loss is more obvious to users than random packet loss for the same rate of loss. If the average packet loss rate is 1 percent, but the dropped packets are widely dispersed, quality can be perceived as quite good. Gateways that provide packet-loss monitoring but do not consider the difference between burst and random loss will give misleading results.

VoIP using G.711 CODEC delivers 55 packets per second. With a 5 percent loss of packets that results in a reception of about 52 packets per second (pps), an acceptable value still exists. Protocol analyzers will display the number and percentage of lost packets, and analyzers can tell you when lost packets occur in bursts. For example, if you lose every 20th packet (5 percent), the conversation is still understandable. The goal is to keep random packet loss well below 1 percent, ideally at approximately 0.2 percent.

One clever practice to reduce the effect of random packet loss is called *packet-loss concealment* (PLC). This masking technique interpolates a portion of the information from the last good packet and substitutes it for the missing packet, making the loss unnoticeable to the user.

Firewalls

Getting session initiation protocol (SIP) and media gateway control protocol (MGCP) through firewalls and network address translations (NATs) is particularly troublesome. Generally, firewalls are configured to not let user datagram protocol (UDP) packets in or out. (The fields related to real-time transport protocol [RTP] are inside the UDP.) Transmission control protocol (TCP) packets are not allowed in unless they are destined for specific servers designated to handle the protocol. Some UDP–entry solutions are based on having a proxy server control the firewall/NAT with a control protocol. This protocol can open and close holes in the firewall and obtain NAT address bindings to use in rewriting the session description protocol (SDP) in a SIP message.

Firewalls are beginning to appear that operate on a protocol-inspecting basis and allow IP telephone signaling control of the firewall, IP telephone file transfer protocol (FTP) configuration, and NAT look-ups. In yet another approach, application-layer gateways can serve as external voice gateways to forward voice on a separate access network. The ALG functions as a proxy and acts as a firewall. The ALG must assume a limited set of router capabilities to support registered network appliances. This simplifies QoS and legacy firewall issues that present themselves in a shared data and voice deployment.

RTP Header Compression

RTP is widely used to encapsulate video and audio frames because it is designed to send audio quickly in one direction without acknowledgement. Each RTP header contains a timestamp that enables the receiving end to reconstruct the timing of the original voice data and deal with duplicate, missing, or out-of-order packets. RTP header compression, known as cRTP, can reduce a 40-byte RTP header by 90 percent and thus reduce bandwidth use. As with jitter buffering, cRTP adds latency and is best used on links with 500 kilobits per second (kbps) bandwidth or less.

Differentiated Service for VoIP

Because VoIP has strict requirements for packet loss, delays, and jitter, it makes sense that it be treated with a high QoS. One method is to add the differentiated services (DiffServ) tag to VoIP packets for expedited flow (EF). DiffServ is a QoS tuning technique that assigns a high priority to RTP packet streams and is intended to improve handling as the packets pass through routers, switches, and other network appliances. This technique, however, does not always deliver guaranteed results. Handling methods and policies can vary among network devices, and what began as a voice stream bearing a higher setting than best effort can sometimes be downgraded or re-queued with other high-priority traffic. Remember, too, that inserting packet tags introduces delay with an accompanying jitter.

Other QoS Issues

The greater part of this paper has focused on the factors that can affect voice transmission using VoIP once a call has been placed. There are other endpoint QoS issues that need to be considered. Call–set-up time, set-up rates, dropped calls, and success ratios while using VoIP present performance challenges and need to be measured and maintained.

Voice-Quality Standards

Standard groups, such as the ITU, address the issue of voice quality and have published two important recommendations: P.800 (mean opinion score [MOS]) and P.861 (perceptual speech quality measure [PSQM]). P.800 defines a method to derive a voice-quality MOS, which is scored from 1 (bad) to 5 (best). A MOS of 4 or higher is considered carrier-grade. P.861 defines an algorithm that a computer can use to derive a score that has a close correlation to a MOS score. PSQM does not consider factors such as jitter or frame loss. Keep in mind, though, that intrusive snapshots that gather voice-transmission averages can actually impair quality by using valuable bandwidth themselves.

Another standard has emerged for VoIP from British Telecom called the perceptual analysis measurement system (PAMS), which produces a good correlation between itself and manual MOS results. The European Telecommunications Standards Institute (ETSI) is another organization that produces speech-quality standards.

In the final analysis, the quality of VoIP hinges on a positive perception of subjective people using telephones.

Summary

Most likely, your data network will have to be tuned to carry VoIP traffic. The majority of data networks contain points of congestion and jitter, but with today's network-testing tools, it is easy to test a network's readiness or locate bottlenecks by merely simulating VoIP traffic. This allows you to make needed network changes to assure VoIP success. Examine the network frequently under varying conditions until you are convinced it is ready for voice. Later, re-examine performance as you add services.

Section V:

Wireless

Safety Standards for Wireless Optical Networks

Jim Alwan
Manager, Electro-Optics Group
AirFiber, Inc.

Introduction

Wireless optical networks (WONs) are beginning to emerge in the telecommunications market as a strategy to meet last-mile demand, enabling reliable high-bandwidth connectivity previously available only to customers directly connected to fiber. Open-air or free-space beams used by WONs to transmit data are not a new concept. Historically, such free-space systems were used in point-to-point (PTP) connections in some campus settings and by the military and the aerospace industry. Expanding into the commercial sector, this technology has evolved into systems with back-up and redundant optical links, providing high reliability and fiber-like bandwidth to customers located up to a kilometer away from buried fiber. Such systems are being deployed to commercial buildings in urban areas, breaking the so-called "last-mile" bottleneck. These WONs provide a unique solution that provides higher bandwidth than radio frequency (RF) wireless systems and is considerably less expensive than laying additional fiber. Additionally, there are no complex licensing requirements when implementing WONs.

The use of wireless optical networking technology enables carriers to offer low-cost, high-bandwidth services that can be deployed within a short period of time. However, implementing these systems in public spaces provides new safety challenges. Understanding existing eye safety standards, as well as the factors in the WON environment that impact eye safety, is essential in addressing these challenges.

Equipment makers, laser-safety professionals, and telecommunication service providers are working together to build safe and reliable systems that deliver the next generation of broadband connectivity. This whitepaper presents a review of laser ocular hazards, present and upcoming safety standards, and eye-safe WON architectures. Additionally, the paper highlights considerations when evaluating the eye-safety of wireless optical networks and uses the AirFiber OptiMesh Network as an example of a Class 1–compliant WON.

Light, Lasers, and the Human Eye

The human eye is a sophisticated and sensitive optical detector with a peak visual response to light in the visual range (400–700 nm)[1] that has evolved over time to correspond to the peak of the solar spectrum. Like any other living tissue, the tissues of the eye are susceptible to damage under extreme conditions. Because different tissues absorb some wavelengths more strongly than others, different parts of the eye are variably susceptible to damage at a given wavelength. The cornea (glassy front of the eye), the lens (behind the cornea and in front of the retina), and the retina (the back surface of the eyeball that detects light) are all in the path of light entering the eye and therefore may be subjected to dangerous light levels.

Many factors combine to result in the potential for laser-induced ocular injury. The anatomy of the eye, physiology of vision, and laser-tissue interaction are important factors. Laser-tissue interaction is strongly dependent on wavelength, power, and pulse duration. Damage can occur by several mechanisms including photochemical, thermal, and thermo-acoustic. *Photochemical* interactions are those in which an absorption of a photon by a molecule results in a chemical reaction. *Thermal* interactions refer to the deposition of heat to a local area, whereas *thermo-acoustic* refers to transient phenomena where the rapid deposition of heat results in a damaging shock-wave. In terms relative to the human eye, a thermal interaction might result in a slow burn at the irradiated site, whereas the thermo-acoustic interaction could cause additional physical damage beyond the burn site, such as detachment of the retina.

As described, specific tissues in the eye interact strongly with different portions of the optical spectrum. The cornea and lens are transparent to the visible wavelengths and near-infrared, as they are intended to focus visible light onto the retina. However, ultraviolet (180–400 nm) and mid-infrared (1400 nm–3 µm)[2] to far-infrared (3 µm–1 mm)[3] exposure to the cornea and lens can cause photokeratitus and cataracts, respectively. *Photokeratitus* (also known as welder's flash or snow blindness) is similar to sunburn on the cornea. This condition, while painful, does not normally result in permanent damage. *Cataracts* refer to the formation of cloudy regions in the otherwise clear lens, compromising vision as they prevent light from reaching the retina. Visible and near-infrared light is of particular hazard to the retina as this is the range of light to which the eye is intended to be sensitive and thus has a high absorption. Hazardous exposure to radiation in this range can result in retinal burn resulting in compromised vision at the damaged site.

Lasers are potentially hazardous as a result of their high brightness (also known as radiance, W/m^2 sr). A handheld laser pointer (~630–650 nm and visibly red) is many times brighter than intense lamps or even direct sunlight. Although a lamp or the sun may have a larger total output of light, it is generally spread into a large solid angle. For example, the sun shines in all directions around it and is thus said to be radiating into 4 steradians (sr) of solid angle. In direct contrast, a laser can produce a beam of light that spreads very little and radiates into a solid angle several thousand times smaller; thus the brightness is several thousand times higher. It is the collimated, beam-like quality of laser output that results in very high irradiance (also known as power density, W/m^2), because lasers can be focused to a much smaller spot on the retina than conventional light sources. *Figure 1* provides a comparison of the retinal irradiance of a variety of sources.

Laser Safety Standards

The eye-safety hazards of lasers were recognized within a year of the first demonstration of a laser device. As some of the first adopters of laser technology and research, military agencies issued the earliest laser-safety guidelines. In the 1960s and '70s, biomedical research regarding laser-tissue interactions established the first physiological basis for safe exposure limits. In more than 40 years of research and development, the variety of lasers now spans the spectrum from the vacuum ultraviolet to the far-infrared, with pulsewidths as short as femtoseconds (10^{-15} s). The task of providing laser-safety guidelines and regulatory codes that adequately address such a broad field of devices and diverse applications has become significant. Just as the capabilities of laser systems have expanded, so has the complexity of safety standards derived to address them.

There are a number of regulatory, governmental, and educational organizations that have developed and published laser-safety standards, three of which are discussed in the following paragraphs. The standards generally have the following main functions:

- Classification of laser systems
- Safety measures for manufacturers
- Guidelines for safe operation by users

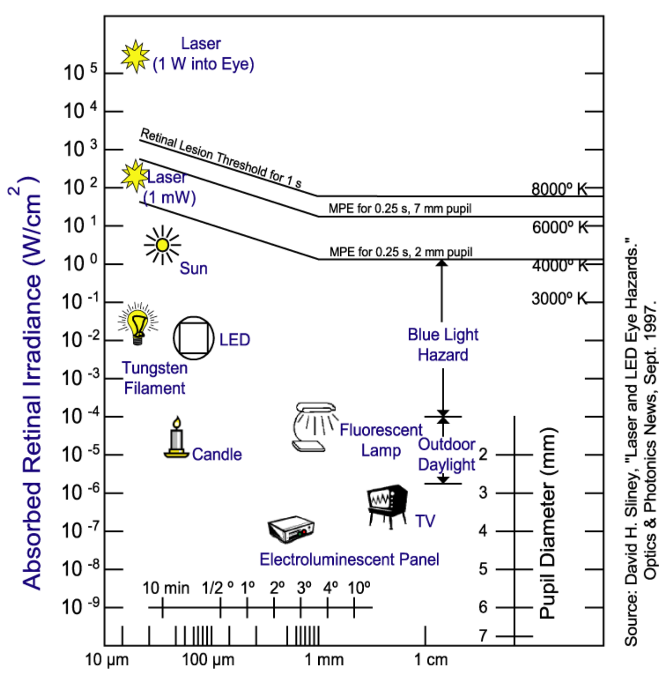
Some standards are for manufacturers of laser systems providing regulatory codes on how laser products can be made, classified, and labeled, for example. Other standards are considered user standards and address how individuals and organizations should deploy and safely use laser systems in the community and the workplace.

ANSI Z136.1–1997 The Safe Use of Lasers

One of the earliest standards that has undergone continual revision since its inception in 1973 is American National Standards Institute (ANSI) Z136.1–1997 *The Safe Use of Lasers*. This document provides classification based on maximum permissible exposure (MPE) in detailed chart, graph, and equation form, expressing such limits as a function of wavelength and pulsewidth. It is not regulatory, but rather a user standard. It has been adopted by corporations,

FIGURE 1

Retinal Irradiance for a Variety of Sources
The retinal image area influences the hazard as does the source radiance.



municipalities, and some states in the United States as an official standard for safe use and deployment of laser systems. It is aimed at health and safety professionals charged with providing a clear and well-grounded basis for the use of laser systems as they become more prevalent in our everyday life.

IEC 60825-1 (2000) Safety of Laser Products Part 1–Equipment Classification, Requirements, and User Guide

The International Electrotechnical Commission (IEC) IEC 60825-1 (2000) *Safety of Laser Products Part 1–Equipment Classification, Requirements, and User Guide* is an internationally drafted and recognized technical standard for users and manufacturers. This standard serves as the basis for a subset of standards targeted toward more specific applications—for example, the IEC 60825-2 *Safety of Optical Fibre Communication Systems*. The IEC standards are often directly adopted by countries around the world—or at least form the basis for national policy and regulation on the subject. For manufacturers of products that are sold internationally, compliance with the IEC standards is requisite. In contrast, the United States has an independent standard under the Code of Federal Regulations (CFR).

21 CFR Ch. 1 (4-1-97 Edition) Part 1040 Performance Standards for Light-Emitting Products

The U.S. Food and Drug Administration (FDA) includes the Center for Device and Radiological Health (CDRH), which administrates the U.S. regulatory laser standard. That standard is the 21 CFR Ch. 1 (4-1-97 Edition) Part 1040 *Performance Standards for Light-Emitting Products* Sections 1040.10 and 1040.11. This standard stipulates a classification system, manufacturing and labeling guidelines, and submission of a report of compliance with the CDRH.

Table 1 provides a summary of laser-safety standards currently in existence.

Classification Systems and Certification

Classification

There are three concepts that are normally included (directly or by reference) in a laser-safety classification system: class definitions, accessible emission limit (AEL), and MPE. The class definitions provide non-technical descriptions understandable to the lay-person; the AELs define the classification breakpoints; and the MPEs are based on biophysical data and indicate actual tissue-damage thresholds.

The classification allows an abbreviated way to readily communicate the hazard level to a user by means of classes 1, 2, 3, and 4, for example. It should be noted that various standards, including those described in the previous section, use confusingly similar yet distinct classifications in the form of Arabic and Roman numerals and upper- and lower-case English letters (e.g., Class 2, II, 2A, 3b). These may appear on a user manual or label, for example. The classes are described in words to indicate the general hazard posed by a laser in a given class. *Table 2* shows the classification system of the IEC 60825-1, with the word description and AELs for an example laser of a doubled CW Nd:YAG laser (μ = 532 nm). This is a simple example. The addition of pulsed modulation, extended sources, multiple wavelengths, and so forth are treated with correction factors. Recently added classifications in the IEC60825-1(2000) include Classes 1M and 2M. These classes take into account that applications exist where aided viewing is not likely. In such cases, the AEL is considered for the unaided viewing case only, and therefore Class 1M (2M) is defined as a less stringent class than Class 1(2).

The AEL refers to the power level at a given wavelength that signifies a laser as belonging to a particular class. Generally, a standard includes tables, graphs, and equations of AELs that allow a person to classify a given laser based on wavelength, power, and pulse duration. The AEL may be related by some safety factor to the MPE values.

The MPE values are based on actual biophysical research of laser-tissue interactions spanning wavelength, power, and pulse duration for a specific tissue. They are defined as the level of laser radiation to which, under normal circumstances, persons may be exposed without suffering adverse effect. The MPE are related to the wavelength, pulse duration, and, in the case of visible and infrared, the size of the retinal image. There is a considerable body of research supporting the MPE. As lasers reach new benchmarks of performance, particularly in pulsewidth and power, research is performed to estimate the hazard presented. It should be noted that the MPE values are generally derated by a safety factor themselves, adding further margin to MPE–based AELs. In summary, it should be understood that class limits in the form of AELs are not tissue-damage thresholds, but rather are significantly reduced below such limits in the interest of safety.

Certification

A Class 1–certified laser is considered eye-safe with no special precautions required for persons who may be exposed

TABLE 1

Summary of Existing Laser Safety Standards

Standard	*Type*	*Target*
ANSI Z136.1	User	Laser users and health and safety professionals
IEC 60825-1	Technical	Manufacturers with global distribution
21 CFR Ch. 1 (4-1-97 Edition) Part 1040	Regulatory	Manufacturers in the United States

TABLE 2

IEC 60825-1 (1998) Classification of Doubled CW Nd: YAG (μ = 532 nm)

Class	*Description*	*AEL*
1	Lasers that are safe under reasonably foreseeable conditions.	0.39 μW
2	Visible lasers (400–700 nm) where aversion response such as the blink reflex affords eye protection	1 mW
3a	Lasers that are safe for viewing with the unaided eye. Direct viewing of the beam with aids (e.g., binoculars) may be hazardous.	5 mW
3b	Lasers that are hazardous when the beam is viewed directly.	500 mW
4	Lasers capable of producing hazardous diffuse reflections and that may pose skin and fire hazards.	> 500 mW

Note: microwatts (μW, 10^{-6}W) and milliwatts (mW, 10^{-3}W) are measurements of power used in the AEL

to the system. Being Class 1 requires that a system comply with all Class 1 requirements in the applicable standard(s). Most generally, this means that the system must limit access to radiation below the Class 1 AEL under any reasonably foreseeable single-fault condition. As previously indicated, AELs for a particular class definition are wavelength-dependent.

The CDRH CFR 1040 and the IEC 60825-1 are self-regulated standards in the sense that the manufacturer has the responsibility to correctly interpret and apply the standards to products. There is no mandatory U.S. federal or international compliance testing. The perils of not fully understanding and complying with applicable standards are manifol, and include product liability and, most importantly, potential hazard to humans.

There are a number of nationally and internationally recognized, independent laboratories that perform laser-product safety testing. Examples include Underwriters Laboratories (UL) and TÜV (Technischer Überwachungs Verein [English translation: Technical Surveillance Organization]). The use of an independent test laboratory is good safety practice to ensure that an unbiased party comes to the same conclusion as the people who designed and plan to sell the product. This is particularly important in light of the relative complexity of the laser standards. Most individuals, upon first interpreting the standards, find them difficult to navigate. Employing a laser safety consultant often will save time and money in the development of new laser products, as fundamental design decisions can determine the ultimate laser class of the product and thus the market that the product can address.

Eye Safety and Wireless Optical Networks

With the rapid increase in demand for broadband access and the relative expense and delay in deploying fiber, WONs are being viewed as an affordable, reliable, and fast method of providing fiber-like bandwidth. Currently, carrier-grade equipment is being built to provide reliable, redundant access networks. Wireless optical technology proposes to break the last-mile barrier—the relatively short distance between a fiber-optic network and a user. In the case of AirFiber's OptiMesh WON, for example, this is accomplished by Class 1 eye-safe optical transceivers strategically mounted in a mesh configuration on the rooftops of commercial buildings in dense urban areas.

As laser beams become prevalent in public spaces, new challenges arise for manufacturers and users. In response, the IEC is currently drafting a standard under the IEC 60825-1 base standard that specifically addresses open-air communication systems.

Eye-Safe System Architecture

Like many other enabling technologies, potential hazards posed by lasers have been mitigated by the application of safety standards. Lasers are now safely operated in open-air environments as exemplified by the widespread use of laser pointers, laser range-finders, and light shows. Safe operation requires that human access be limited to Class 1 radiation. Evaluating such access for WONs includes the laser-system class, the deployment environment, and beampath. For example, WONs deployed in a space where casual passers-by could potentially intercept a beam requires that the system be Class 1 and incapable of delivering radiation in excess of Class 1 (i.e., under single-fault conditions). This may be an unlikely deployment scenario, because a WON subject to frequent beam interrupts would not be reliable. However, consider beams being aimed into receivers behind office building windows. The space between the terminals may be virtually inaccessible, but mispointing or beam-spread into adjacent windows must be addressed with reliable systems engineering that meets the standard of safety. Similarly, consider beams being sent and received between tower-mounted rooftop terminals. Although the terminals and space between them may be inaccessible, effective beam-stopping and mispointing again must be addressed and solved with engineering solutions.

There is great diversity in the WON system architectures being developed today. Effecting safe public deployment of these systems requires top-level design choices to limit the access to harmful laser radiation. For example, design features such as the number and size of transmitted beams, divergence, power, wavelength, pulse duration, physical size of terminals, and installation location (i.e., network planning) all must be considered in determining laser-system classification and human access. Furthermore, active safety systems that control the laser in response to a potential access event are often implemented. An example is a location monitor (LM) system or an automatic power reduction (APR) system.

An example timing diagram for such an APR is shown in *Figure 2*, and important time scales are labeled. The constraints on the timing are determined by all of the aforementioned factors that are unique to the architecture of WON equipment. The shutdown time of the APR (T_{APR}) refers to the time from the instant an exposure event begins to the time the laser is turned off. This response time is determined such that, under appropriate viewing conditions, a person does not collect greater than the Class 1 AEL in the time T_{APR}. If delays can occur in the system, they must be accounted for and included in the safety analysis. An example may include the time between the onset of the event and the time that the system actually senses it. This example includes the use of a "ping" to test if the link is still blocked. The power of the laser during this pulse and the duration (T_{ping}) are chosen such that the Class 1 AEL is not exceeded. It must be assumed that an observer is still intercepting the beam during this time, and the method to test the link must be inherently safe. Depending on the laser power at shutdown time and the power contained in the ping, a delay (T_{delay}) may be required to remain eye-safe. Lastly, the total time from the event start (t = 0) to the time at which the cleared link is restarted ($T_{restart}$) is similarly chosen so that the system is eye-safe to a viewer who (hypothetically) repeatedly interrupts the beam. A similar Class 1 ping could be used for link-acquisition mode, where two transceivers use a stare-scan method to establish the link during installation, for example.

The AirFiber OptiMesh Class 1 WON

An example of a Class 1–compliant optical wireless system is the AirFiber OptiMesh WON. The product uses rooftop transceiver nodes that communicate with neighboring nodes. The system uses 785 nm lasers transmitting from a two-inch aperture, and employs an APR system that monitors beam access and reduces output power to Class 1 levels in the event of a beam blockage. (The IEC Class 1 AEL for 785 nm is 0.56 mW.) If a beam interrupt occurs, the APR shuts the system down such that a potential viewer does not collect greater than the Class 1 limit and traffic is rerouted to a redundant link in the network. The system then enters recovery mode, where the link is tested to determine if the obstruction is cleared by use of a Class 1 ping. Once the path is clear, the link is re-established for full data traffic. A redundant system of hardware and software was designed such that the system remains Class 1 under single-fault conditions. Thus, it is a CDRH Class I and IEC Class 1 laser system under applicable standards. Independent certification has been performed by TÜV testing laboratories in which test methods as prescribed by the standards were performed by TÜV representatives, including selectively "failing" various subsystems to confirm single-fault tolerance.

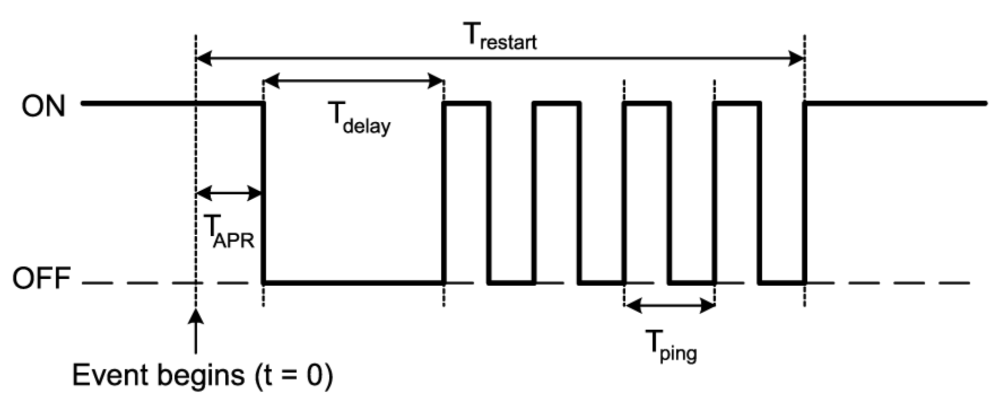
In summary, top-level performance requirements included laser eye safety in the design and prototype stages to realize Class 1 operation. The installation environment spans restricted or inaccessible space. However, in the interest of public safety, the system was designed to be Class 1. Rigorous testing was necessary to achieve proper operation, and independent testing was performed to confirm compliance.

Multiple Factors Impact Eye-Safety Classification

Several other wireless optical systems today use 1550 nm wavelength lasers as an alternative to the shorter wavelengths used by AirFiber. These systems are using lasers and components designed for optimal transmission over optical fiber, because this wavelength is the fiber attenuation minimum. A collateral eye-safety benefit is due to the reduced retinal absorption at 1550 nm compared to shorter wave-

FIGURE 2

Example Timing Diagram for an APR Response



lengths. For example, the IEC Class 1 AEL for 785 nm is 0.56 mW, whereas the Class 1 AEL for 1550 nm is 10 mW—nearly 20 times higher. Does this mean that 1550 nm systems are 20 times more eye-safe? Not necessarily, as the eye-safety and classification of a WON is a function of many system parameters. There are technology trade-offs between long and short wavelengths, such as detector responsivity and active area. In addition, system performance benchmarks such as designed link length, bandwidth, and availability vary. All of the aforementioned determine the amount of laser power required, beam size, and divergence. Thus, to assess the safety hazard of the system, one has to consider the entire system and installation environment.

Safety Standards for WONs

In response to the growth of free-space optical systems for telecommunications, relevant standards bodies such as the IEC and ANSI are developing standards specifically addressing these systems and the unique laser-safety aspects that they present. At the time of this printing, these standards are currently under development by the drafting committees within the standards bodies. It may be possible that they are published in final form in the coming year.

The draft standards at present naturally build from related standards addressing optical fiber systems and outdoor laser light shows, for example. Unique features of WONs, such as LM systems and APRs, are also addressed, as are the environments in which they may be operated and the potential for presenting ocular hazards. For instance, systems beaming lasers near street level, where passers-by may intersect the beam should be rigorously required to be Class 1. On the other hand, systems that send laser beams between towers in restricted environments may be allowed to be in a higher class in recognition of the inaccessibility of the space in which they operate. The committees are composed of laser eye-safety experts, WON manufacturers, optical communication experts, and service providers that will use and deploy such equipment.

Conclusion

With the upcoming deployment of WONs in the public space, laser eye-safety is an important responsibility of the equipment manufacturers and service providers. Laser light poses unique ocular hazards that must be mitigated by inherently eye-safe system architectures, appropriate installation locations, and equipment reliability. The wavelength, power, and aperture of the laser are important, but the entire system and installation must be considered in determination of the relative safety. Current safety standards address laser eye-safety issues and provide guidance to manufacturers and users. However, unique challenges exist in the deployment of these systems in public spaces, and specific standards are being drafted today to address them. The advent of telecommunication-grade WONs and the development of open-air laser-safety standards will enable the delivery of fiber-like bandwidth at a fraction of the cost, while ensuring public safety.

A Class 1–compliant wireless optical network exists today in the AirFiber OptiMesh wireless optical network. Class 1 operation was incorporated into the system by design to meet the most rigorous of eye-safety standards while providing reliable, affordable broadband access technology.

Notes

1. The nanometer (nm) is a unit of measurement used here to describe wavelength (10-9m).
2. The micron (mm) is a unit of measurement used here to describe wavelength (10-6m).
3. The millimeter (mm) is a unit of measurement used here to describe wavelength (10-3m).

Managing Wireless Data Networks in an Era of Change

Gary Barton
Business-Development Manager, OSS Solutions
Agilent Technologies

Eva Thomas
Technical Market Manager, OSS Solutions
Agilent Technologies

Executive Summary

Many service providers see wireless data technology as an opportunity to increase revenue and market-share by providing more valuable services to their customers. But the challenge of adding the core Internet protocol (IP)–based technology necessary to achieve this is much more complex and demanding than many realize. The value proposition has changed from just keeping a physical network up and running, and charging customers for using it, to providing value-added services and content. To succeed, providers will need a unified service and network-management system (NMS)—one flexible and scalable enough to reduce time to market, adapt to managing a more complex environment cost-effectively, and generate a faster and higher return on investment (ROI). Above all, providers must find ways to retain customers with consistently high quality of service (QoS). Optimally, providers should seek flexible operations support system (OSS) solutions that can meet immediate management needs, yet handle the future technologies of the third-generation (3G).

The Outlook for Next-Generation Mobile Networks

Wireless data technology is one of the hottest technologies in the communications industry today. High-speed cable-modem and digital subscriber line (DSL) access have created a hearty appetite for Web-based information, driving business and residential use of the Internet to unprecedented levels. The next logical step is to turn this ubiquitous platform into a vehicle for distributing new kinds of information and services over the airwaves to mobile terminals, such as wireless laptops, cell phones, and other handheld devices.

Cahners In-Stat Group, a market research firm, estimates that 1.3 billion consumers worldwide will have access to wireless Internet service by 2004, with demand for messaging driving this expansion from today's 170 million subscribers. Cahners also predicts that the number of wireless messages sent per month will reach 244 billion by the end of 2004, up more than 800 percent from 3 billion per month in 1999. The study anticipates about 1.5 billion wireless-enabled phones, handheld computers, and other devices in use by 2004.[1]

With consumers' growing desire for access to information anywhere and anytime, we can expect the combination of the Internet and mobile phones to drive up wireless usage significantly throughout the coming years. It is important to note that the business model for such wireless technology is changing to require content as well as access. At the present time, it is unclear what services consumers will value most, and whether these will come from service providers or content providers, which may see mobile devices as just another distribution channel.

Evolving Wireless Data Technologies

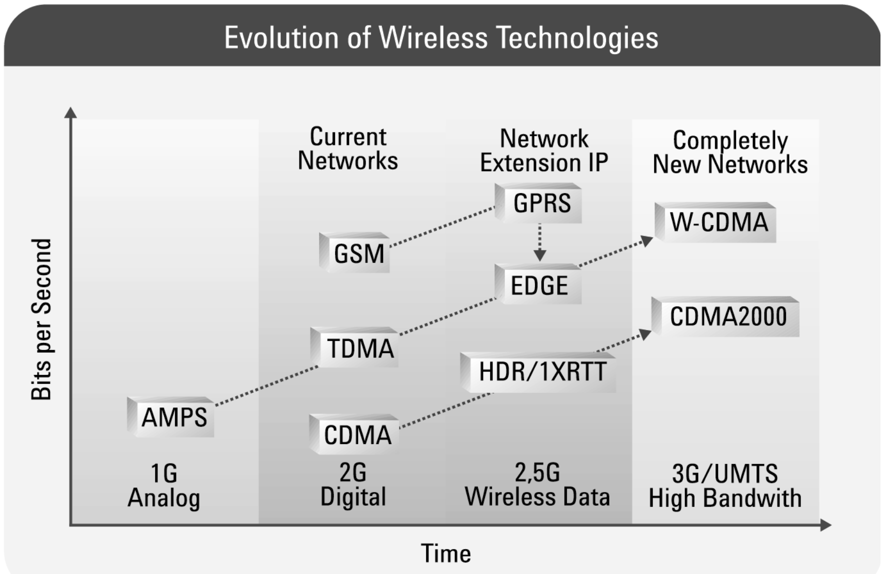
Wireless data technologies are evolving on two levels: transmission type and speed, and content. The current digital air-interface technologies—time division multiple access (TDMA), code division multiple access (CDMA), and Global Systems for Mobile Communications (GSM)—have a planned evolution from second-generation (2G) service through packet-based wireless data and on to 3G, core IP–based networks. *Figure 1* shows how these technologies are migrating. How TDMA will evolve is still uncertain, as is the true value of enhanced data for global evolution (EDGE).

While migration plans for the mobile transmission network may be fairly well established, those for formatting and viewing data are still up in the air. Wireless application protocol (WAP), based on an open standard, is currently the most popular viewing format. But the successful deployment of i-mode, a proprietary standard deployed by Japan's NTT DoCoMo, has also caught service providers' attention by attracting 12 million subscribers with its access to numerous Internet sites and electronic mail. These are critical issues for service providers because access to wireless Internet requires a successful viewing scheme.

As service providers and vendors jockey for position and hedge their bets on standards and technologies, consumers are interested in getting quick, cheap access to content, regardless of the technology that delivers it. For years, Internet service providers (ISPs) have provided inexpensive Internet access for wireline companies. Recently, wireless service providers have begun to see revenue opportunity on the content side as a far more promising revenue

FIGURE 1

Wireless Technologies Are Rapidly Evolving to Handle High-Volume Data Traffic



Source: Agilent Technologies

generator than per-minute connection charges—even to the point of becoming wireless application service providers (WASPs) themselves.

Whichever standards and technologies eventually win, innovative wireless data services are clearly on the horizon. To meet growing demand for high-speed data connections, many providers have acquired wireless providers or paid unprecedented amounts for spectrum licenses. Meanwhile, the high cost of spectra and new infrastructure is creating additional pressure for faster time to market, more cost-effective management, and higher QoS and ROI—all of which requires rapid service deployment and tighter operational control.

Wireless Data Players Today

Not surprisingly, the top contenders are current wireless service providers, including mobile cellular providers whose services are based on voice-only technologies. Today's wireless providers can diversify by expanding the type and size of their customer base and increasing customer usage of new kinds of content, either directly, as ISPs or application service providers (ASPs), or through another provider, such as America Online (AOL).

Mobile service providers not only see wireless data as an opportunity to enlarge their reach and revenues, but some consider it necessary for survival. To gain entry into this market, cellular and other wireless providers in Europe have grabbed up highly prized 3G/Universal Mobile Telecommunications System (UMTS) licenses, in some cases grouping together to dilute the cost. Partnerships have been announced between E-Plus Mobilfunk and Mobilkom and between Telefonica and Deutsche Telekom.

NTT's i-mode network is the first wireless data network available to the general public. As a result, the rest of the world is watching to see how its business and technological models work out. Europe, with many general packet radio service (GPRS) trials currently underway, is ahead of other regions, with large-scale rollouts hampered only by the lack of compatible handsets. In the United States, where Internet access is far more affordable and accessible, wireless data lags, with many wireless providers' Web offerings actually being portals to limited content instead of to the full IP–based public Internet.

Challenges and Solutions for Managing Wireless Data

Providers' eagerness to jump into markets while technologies and standards are still evolving is just one indication that they will need great flexibility to evolve their management systems from one technology to the next. For each time a company adds new technology to its mix of services, it must also update its network-management infrastructure, ideally integrating the new with the old. The current challenge is to find a way to transition management systems from voice-centric to packet-based technology.

Wireless service providers' business model is changing profoundly and rapidly. Formerly, their entire revenue stream came from providing a conduit for voice service billed according to minutes used, along with some services such as voice-mail and short message services (SMSs) that are usually billed on a flat-rate basis. With the advent of wireless data networks that offer content, as well as access, providers may choose to give access away and just charge users for content provided.

Those entering the uncertain market for wireless data face some daunting business challenges. To adapt as markets and technologies change—and profit from as yet unspecified opportunities—providers must achieve several key objectives:

- Reduce the time required to get new services to market
- Adapt to managing a more complex environment cost-effectively
- Generate a speedier and higher ROI
- Retain customers with consistently high QoS

It is a tall order, and not everyone is destined to succeed. But the likely winners are those providers that take a more comprehensive, coordinated approach to managing network infrastructure, using their more efficient NMS for competitive advantage.

Objective 1: Bring Services to Market Faster
Providers always stand the best chance of winning customers by being the first to market with new services. Yet as they add network data capabilities and new services based on IP, they must support them with many more network elements (NEs) and element-management systems (EMSs), slowing time to market.

To help mitigate these effects, providers must have the ability to accurately predict future network capacities and perform true end-to-end data and air interface testing.

Implementing a packet data overlay on a cellular network also requires adding widely different vendors and protocols. For example, regardless of which vendor supplies the cellular voice equipment, a GPRS network may involve additional vendors, as in Motorola's solution, which uses both Motorola and Cisco Systems elements.

Adding packet data to cellular networks imposes the additional burden of managing new standards and protocols and OSS software, risking further delays. These, too, require additional expertise, adaptation to installed infrastructure, and extra time and cost for personnel training. The need to integrate and accommodate different elements, vendors, standards, and protocols can cost providers precious time in deploying new services. Wireless data providers must find ways to manage a growing number of diverse network resources more efficiently by simplifying and streamlining their NMSs and reducing the time and cost of training operators to use them.

Solution: A Streamlined, More Efficient Management System
A single, comprehensive management system based on a flexible, OSS framework can provide a number of economies. It allows providers to extend their services and installed networks, integrate various applications to provide a common view of data and operator functions, and automate tasks and processes.

Such an approach enables providers to implement short innovation cycles and add new elements or services without having to upgrade their NMSs or purchase new ones. For example, automating control of the service-delivery process enables the speedy identification and reallocation of available network equipment.

In 3G networks, routers and asynchronous transfer mode (ATM) switches will play a key role in distributing wireless data. The autodiscovery component of an integrated system can search for new simple network management protocol (SNMP) elements and add them automatically to the NMS. Autodiscovery can identify an element's vendor and type, as well as assign default management policies based on that type. Such automation is critical as networks expand rapidly to include many smaller elements, such as routers, which may be added on a daily basis.

A comprehensive management system also provides a single point of control for managing service activation across multiple technologies—a valuable advantage for integrated communications providers (ICPs) and wireless providers with multiple networks. For example, when migrating from one wireless technology to another, a provider may have to support 2.5G and 3G networks simultaneously.

For 3G networks, a broad and robust management system offers the ability to simulate network traffic, measure network capacity and service quality, and have an architecture that is scalable for future networks. The ability to quickly and accurately identify and resolve sources of radio frequency (RF) problems is crucial to compete in today's rapidly evolving wireless market.

Such unified control enables providers to replace multiple system monitors with a common operator interface, reducing the need to train operators on new systems and improving productivity and efficiency by providing visual and operational consistency.

Once such a foundation is established, the provider can use a combination of process automation and workflow to automate the interaction of integrated OSSs efficiently, saving valuable time and reducing errors and costs by capturing, controlling, and automating complex processes (see *Figure 2*).

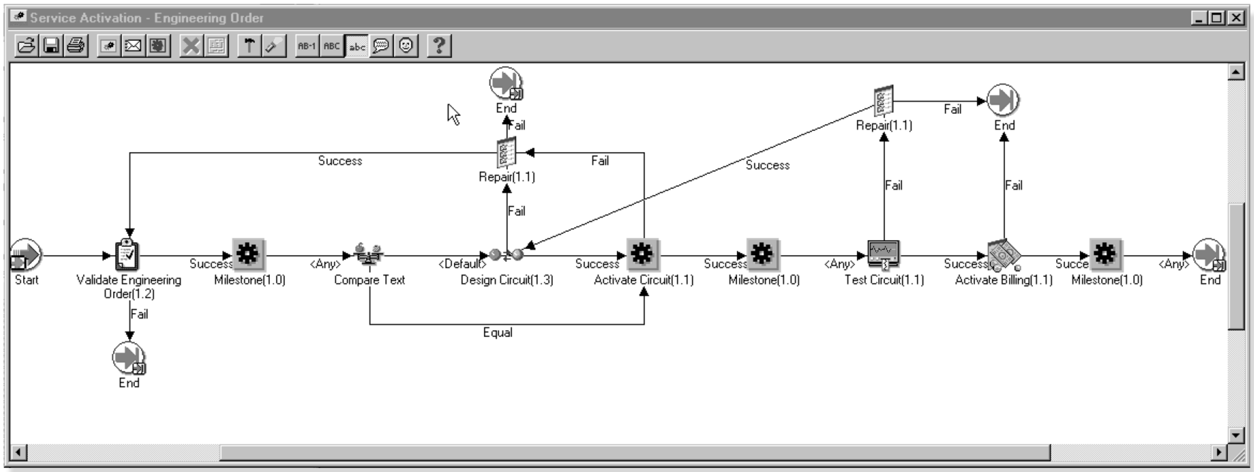
Objective 2: Cost-Effective Management in a Complex, Rapidly Evolving Wireless Environment
Providing packet data and browser-based content requires wireless companies to manage IP–based equipment—a whole new skill set. They must somehow shift their services and customer base from today's circuit-switched cellular technology to a core IP–based, packet-switched environment. To do this, they need a management system capable of supporting constantly changing networks and of determining proactively when certain NEs or services can be shifted to support new types of customers and their wireless data needs.

Providers need to control costs in spite of manual processes, a substantial increase in the number of resources and separate systems that they must manage, and the need to deliver many different kinds of service. For example, the number of incoming events to the NMS increases exponentially in the IP environment. This produces a similar increase in the number of alerts displayed, threatening to overwhelm network operations center (NOC) staff.

Providers also find that they must incorporate newer standards into their management systems to improve efficiency. Initially, based on American Standard Code for Information Exchange (ASCII) or common management information protocol (CMIP) standards, wireless network interfaces are evolving toward the use of SNMP and common object request broker architecture (CORBA), both of which can help reduce costs. For example, SNMP–based equipment, which predominates in packet networks, can

FIGURE 2

Workflow and Process Automation Can Be Used to Manage Complex Processes from End to End, with Minimal Human Intervention



Source: Agilent Technologies

be adjusted to monitor for signs of network overload and thus prevent outages. The CORBA standard is now being used to assure compatibility between EMSs and NMSs and to link OSSs.

Solution: A Highly Flexible, Open and Interactive Management System

To keep pace with rapid change and growth, wireless data providers will need an open management platform with integrated applications that enable not just passive monitoring, but also interaction with the network—even to the point of anticipating and resolving problems before customers are aware of them.

Policy-based management of network data, thresholding of performance data, and process automation all have a useful role here. When combined as packaged fault management policies—sets of reusable rules that can be applied to different groups of elements—such techniques can help providers to get their management systems up and running rapidly. The additional option to design and implement their own management policies lets providers customize the way their management system responds to various problems.

Automated techniques—such as thresholding, correlation, suppression, and escalation—can dramatically reduce the number of alerts shown and point to the most important events, or root causes, saving valuable staff time and effort.

For example, performance thresholding inhibits the generation of an event until a specified number of alerts has occurred within a certain time interval. NOC staff need only respond when the assigned severity exceeds a predetermined level within that interval. Fault correlation enables the system to look for a pattern of alerts and generate a new alert based on their actual cause. Alert suppression limits the display of alerts to just the highest level of alert and suppresses sympathetic alerts. Incoming alerts can also generate trouble tickets automatically and trigger other automated test routines and related processes.

Network operations also become more cost-effective when a provider can normalize network alerts and performance data from all network resources and view them from a common alert display. This requires the tight integration of essential applications for managing network configuration, faults, performance, and accounting, making such data centrally available and visually easy to interpret.

In addition, because the infrastructure of a 3G network is spread over a wide area, operators can benefit from geographical displays that provide an instant, accurate view of network problems and adversely affected areas (see *Figure 3*). This provides operators with a picture of how traffic is flowing to see where loads are high, an important benefit because the virtual—and as a result, largely self—healing nature of a 3G network makes it difficult to locate network problems.

Once key management applications are integrated, a process-management system that combines workflow and process automation can be used to control the end-to-end management of tasks, whether automated or manual. This increases the management system's scalability to handle ever-larger volumes of traffic and data.

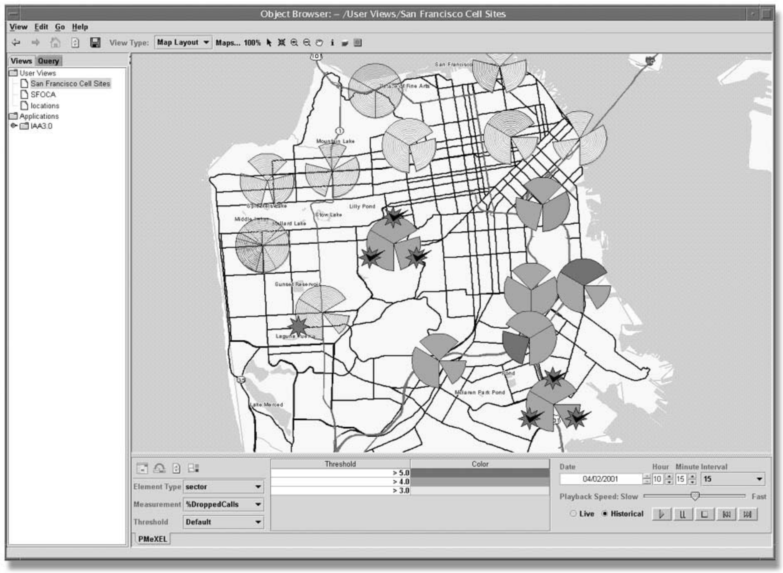
For example, the entire service activation process can be managed from end to end, including validating work orders, provisioning NEs, testing services, setting up service-level agreement (SLA) monitoring, and activating the billing system.

Objective 3: Achieve a Better ROI

Given the high costs of wireless spectrum licenses, additional NEs, and managing increasingly complex processes, service providers are looking for ways to get a faster return on their investment. Because providers must use their spectrum licenses within government-established time frames or lose them, many providers are under pressure to meet very tight deadlines for getting 3G networks up and running. Others need to do so just to recoup their expenditures. The financial market is unforgiving, and any provider that does not implement services rapidly, with good prospects

FIGURE 3

Map-Like Displays Indicate the Location of Network Problems



Source: Agilent Technologies

for satisfied customers and high returns, will find it difficult to finance additional expansion.

To attain higher ROI, providers must increase network availability and find ways to charge for the value of content, as well as for connection time. The problem with network buildout is that no one can actually predict demand for wireless data. For example, no one knows how much bandwidth will be used for data, how the use of voice and data may shift during the day, or what the overall traffic pattern will look like. Given such uncertainties, providers may suddenly need to expand their network or face bandwidth shortages.

Another revenue stream for service providers is in the ability to bill other service providers for the use of the signaling system 7 (SS7 network), trunk network, or service database. Equally as important is the ability to verify the charges billed by other service providers for the use of their networks and services.

One chief obstacle to expanding the mobile voice revenue model to include packet-based content is providers' inability to capture—or even recognize—the limitless possibilities, let alone bill for them. For example, a smart handset equipped with a global positioning system (GPS) chipset can already alert a subscriber to an offer of interest at a nearby store. Providers will eventually want a way to track such instant messaging and bill the merchant involved.

Switching from flat-fee and time-based billing to charging customers for the value of content requires more sophisticated systems than currently available. Providers need more direct ways of tracking data usage than current systems allow, to enable advanced billing based on content value, as well as call duration. For while subscribers may be willing to pay premiums for the transmission of critical wireless data during peak usage hours, providers need the ability to distinguish such use from less expensive service, as well as to determine peak usage by traffic volume and time of day.

Solution: Advanced Management Software for Performance and Billing

Advanced management software that ensures higher network availability and optimizes the value of existing equipment can help providers to achieve a higher rate of return on their investment in network infrastructure and spectrum licenses. Using such an approach, wireless data providers can implement new pricing policies based on content, as well as time, and reduce or at least postpone additional capital asset expenditures, allowing them to keep more revenues and generate higher levels of revenue per subscriber.

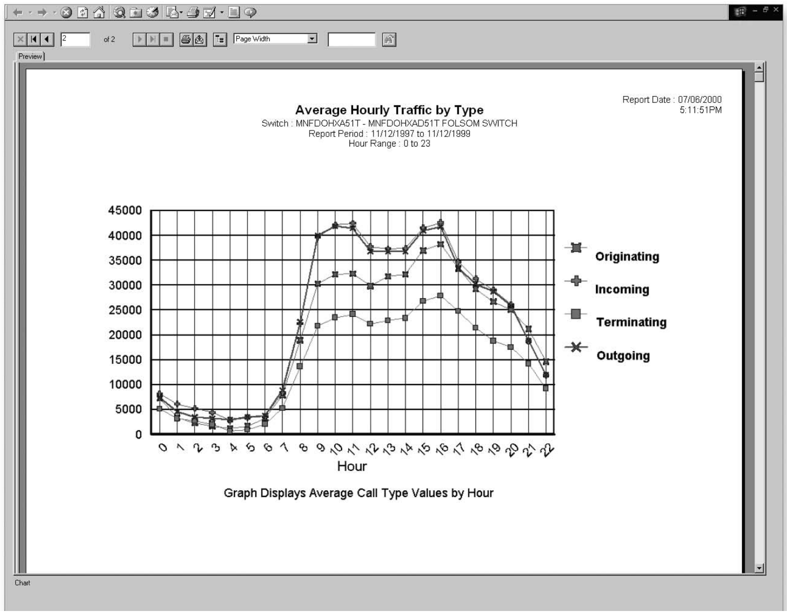
Congestion in the radio access and IP transport network, due to capacity constraints and equipment problems, reduce not only subscriber access to network time and content, but also revenue for service and content providers.

In fast-changing wireless environments, providers will need to monitor system capacity and utilization continuously, analyzing usage trends and forecasting network buildout requirements. An easy-to-use performance-management system can dynamically manage large volumes of performance and traffic data and be used to forecast performance trends to avoid disappointing customers with poor QoS (see *Figure 4*).

In this way, advanced performance management can help providers to keep more of their revenues by assuring network availability, avoiding service degradations and maintaining high call- or connection-completion rates, preventing slowdowns in data throughput and excessive dropped calls and busy signals.

FIGURE 4

Graph-Like Displays Track Network Performance



Source: Agilent Technologies

The accurate collection and analysis of performance data—along with the ability to share the results in reports—is critical to responding immediately to network problems that may affect customers and to understanding where resources can be redeployed or adjusted for optimum benefit and the highest ROI.

Real-time performance management enables providers to minimize expensive performance problems by establishing network resource threshold values that, when surpassed, reveal problems that require immediate attention. It also enables strategic network planning based on the use of performance data feedback and analysis to ensure the correct sizing of network buildout, avoiding excess costs.

The promise of a wide range of new services gives providers the opportunity to implement new pricing policies based on content rather than just time. But to recognize this new revenue stream, providers' accounting mediation and management systems must be able to make billing records from multivendor sources compatible with an upstream billing system.

Billing records for 3G services will contain more call attributes than ever, including details of service priority and quality and of content provided. Useful for more than just billing, these call detail records (CDRs) also help to reduce churn and capture more revenue through their use in QoS analysis, SLA management, and applications that perform secondary functions, such as fraud analysis.

CDRs—a direct record of a customer's experience—currently provide a limited amount of information. In response, some infrastructure vendors are adding charging gateways to their products, making it easier for providers to collect detailed usage records. Many are also working to create the IP data record (IPDR), a new standard for formatting records from IP elements that includes information relevant to billing, such as packet count, time of day, delivery options, service-quality level, and so on.[2]

Objective 4: Retain Customers by Preserving QoS

In an era of tough competition, customer satisfaction has become wireless providers' top priority. Heavy increases in IP traffic threaten to degrade both network capacity and performance, affecting perceived service quality. By taking on wireless data services, providers face even larger challenges with customer churn, because services carried over the data stream will be more sensitive to errors than voice.

For while a dropped voice call is annoying, a broken wireless data connection in the midst of a stock trade is a threat to a customer's revenue stream. Once wireless networks are based on IP, individual packets of wireless data may follow different paths to their destinations, and service providers may not realize there is a problem until a customer calls to complain.

In 3G systems, some services will be far more vulnerable to QoS problems than others. For example, short-term fluctuations such as latency and jitter will not affect Internet access but will definitely degrade the quality of voice (e.g., voice over IP [VoIP]) and streaming applications (e.g., videoconferencing and teleconferencing).[3]

Measuring these fluctuations will be especially critical to assuring QoS in services that involve streaming packets. For while an IP network is by nature self-healing and can retransmit packets that are lost or have errors, such delays can significantly decrease total network throughput.

Monitoring and controlling a wireless data network for QoS will be much more difficult. For instance, while GPRS networks are actually two separate networks—voice and data—they must be managed as one. Each network's performance affects the other because they share capacity constraints and common elements such as cell sites and home location registers (HLRs) (see *Figure 5*).

Failure in the core GSM network could cripple the data network's ability to route packets. To support higher QoS at the network level, providers will need management systems that can pinpoint the location of specific problems and automatically take action to correct them.

To maintain QoS at the business level, service providers will have to satisfy both content providers and their customers, who expect high-quality, uninterrupted service. They need the ability to monitor and manage QoS from the customer's perspective. To maintain customer loyalty and reduce customer churn, service providers must monitor not only the customer experience as it pertains to coverage and penetration, but also measure and monitor the response times and quality of the services that run across the NEs.

Wireless customers already expect the same quality with wireless data that they get with tethered Internet access. To compound the problem, many providers anxious to build market-share for 3G and beyond have set unrealistic expectations for QoS that may later cost them both market-share and revenue. When 3G becomes a reality, providers will have to deliver on their promises of untethered, anytime, anywhere high-speed wireless access to the public Internet—or suffer the consequences.

For reasons like these, SLAs, once unknown in the wireless industry, are increasingly popular with content providers and business users that want guarantees of both access to customers and a specified QoS—with rebates to compensate them for receiving anything less. For if a service provider's data network goes down, the content provider stands to lose both revenues and customers.

Solution: A Robust Management System to Maintain High QoS

QoS is a relative measurement of the service a customer experiences—a combination of many different factors that contribute to customer satisfaction or dissatisfaction. To monitor QoS means monitoring faults, performance, and accounting (CDRs). For an adequate understanding of the service being supplied through the network, providers must even perform simulated test calls. They need a management system that can collect, correlate, and analyze this information for an accurate picture of QoS.

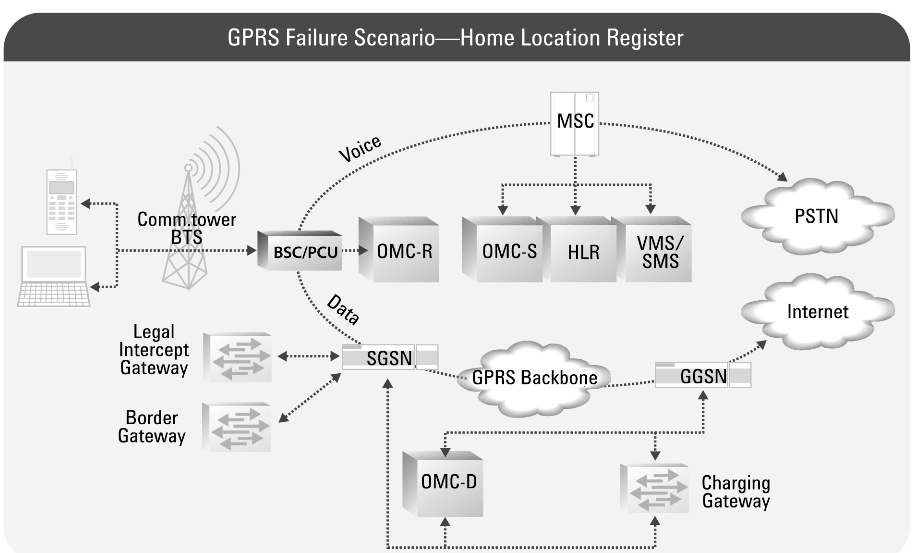
To continue to attract and retain customers and guarantee service levels, wireless data providers need a robust management system that can provide tight end-to-end monitoring of connections and services to assure that customer service levels are met. Unified fault and performance management can play a large role in assuring the QoS across the entire network. A fault-management system can quickly alert operators to problems without overwhelming them with unnecessary alerts, which slow down analysis and response times. Real-time thresholding in performance management can warn of impending problems, including capacity overload.

Service providers must have the ability to verify the quality of network coverage. A management system that provides both in-building and outdoor signal strength measurement allows for proactive measures when addressing current customer need and assessing future customer demand.

Such a system can also provide the automation of systems and processes needed to support high QoS in such a complex, changing environment. The more reliably a provider can keep the network up and running, the less the company's reputation for service will suffer and the less it will have to pay customers in SLA credits. An automated reprovisioning response to an equipment outage can support an SLA far better than a slower, error-prone manual dispatch.

FIGURE 5

GPRS Voice and Data Networks Are Vulnerable to Failure Because They Share Common Elements and Capacity Constraints



Source: Agilent Technologies

Sophisticated forecasting and analysis, using data available from many different management processes, can also play an important part in enabling a provider to identify new opportunities and plan for future services—a necessity in continuing to attract and retain customers. Forecasting can indicate wireless network usage trends and reveal where and when additional capacity will be needed.

Appendix: The Evolution of Wireless Technology

As cellular technology advances, the concept of transmitting high-speed, multimedia wireless data is approaching reality. Over time, wireless technology has evolved from first-generation analog voice networks with limited capacity to more powerful second-generation (2G) digital cellular voice networks based on TDMA, CDMA, and GSM technologies. As demand for wireless data has risen, 2.5G technology was developed to supplement 2G networks with separate GPRS or 1XRTT (wireless data for CDMA) networks—typically packet-based, but not full IP.

TDMA provides a higher density of calls, better sound quality, and improved security. CDMA makes better use of the frequency spectrum and handles even more calls. Some organizations have used high-speed circuit-switched and cellular digital packet data (CDPD) technologies to allow mobile units of police, fire, and utility personnel to send and receive critical information. Recently, several carriers began using CDPD to provide access to business information and applications on a Web-like proprietary wireless network as an intermediate step to full wireless access to the Internet.

For example, Sprint's Wireless Web for Business service boosted transmission speed from 14.4 kilobits per second (kbps) to 56 kbps and gave users access to e-mail, as well as Microsoft Exchange and Lotus Development's Notes. However, such services cannot match the speed and rich graphics of full-screen color Internet displays, so customer demand will continue to build for the real thing.

2.5G Technologies

GPRS, 1XRTT, and EDGE represent higher-speed transitions to 3G. GPRS is a packet-based technology designed to add data to GSM technology for high-speed wireless data service. Currently used for wireless Internet browsing, e-mail, and various push technologies, GPRS can reach speeds of 115 kbps. Mostly in the trial stage today, GPRS has limited implementation by companies such as BT Cellnet.

EDGE technology marks the convergence of TDMA technology with GSM networks to enable wireless data services. GSM networks will initially deploy networks based on GPRS, then may migrate to EDGE if it becomes widely available. TDMA will skip the GPRS phase and go straight to EDGE or Enhanced GPRS (EGPRS-136). Because the transition from GPRS to EDGE only involves changing the air interface technology, it will mainly require making software changes.

GPRS and EDGE will require a new subsystem for carrying packetized data. A packet control unit at the base-station controller (BSC) will split off the packetized data and send it down to the GPRS network, where it can connect to an Internet portal. The GPRS subnetwork will add elements that are new to cellular systems but standard for IP–based networks. Most of the new equipment will consist of ATM switches and routers, with additional standard UNIX workstations for specialized software and SNMP interfaces.

CDMA Wireless Data

CDMA technology is taking a separate path from TDMA and GSM. Whereas TDMA and GSM add a separate network for handling data calls, the CDMA network is more integrated. 1XRTT, the first version of high-bandwidth data for CDMA systems, will convert voice transmissions to data packets within the network to make more efficient use of the spectra than GSM can provide. As the CDMA data standard develops, it will move to 3XRTT for even higher data transmission. Whereas current GPRS networks must establish a set amount of capacity for voice and data, 3XRTT can dynamically allocate capacity depending on need.

3G

Known in Europe as UMTS, 3G networks are designed to accommodate high-speed multimedia data applications in fixed broadband and mobile wireless environments. The original idea was to establish a single air interface on a single frequency for worldwide roaming, using a standard handset, but the abundance of frequency and use of multiple technologies in the United States won out.

The selection of CDMA for its higher bandwidth than other technologies did not prevent the proposal of competing variations of wideband CDMA (WCDMA) technology. Consequently, three different air interfaces—WCDMA, CDMA2000, and UMTS terrestrial radio access–time duplex division (UTRA–TDD)—were approved for the final edition of the IMT–2000 standard. Countries vary in the frequency spectrum available to them, leading to the approval of several frequency ranges, as well.

The core 3G network will evolve from the equivalent of 2.5G core network systems. A new component of network infrastructure for 3G networks is the media gateway, which resides at the boundary of different networks to process end-user data, such as voice coding and decoding, to convert protocols and to map the QoS.

In addition to requiring a new base-station system, 3G networks will require more base stations than comparable 2G networks. 3G networks that combine cellular voice and packet data technologies will also require new radio and core NEs.

Notes

1. Cahners In-Stat Group, "Wireless Data/Internet Market Gains Momentum: Five-Year Subscriber Forecast," No. MD0003MD, August 2000, p. 41.
2. The goal of the IPDR initiative is to define the essential elements and format for data exchange among network devices, OSSs, and business support systems (BSSs) to enable next-generation IP networks to operate efficiently and cost-effectively.
3. Latency refers to the delay of packets traveling through the network, while jitter refers to packets that are out of sequence.

Quality of Service for Wireless Networks

SOTAS, Inc.

Introduction

The purpose of this paper is to address the increasing need to monitor quality of service (QoS) over wireless networks driven by the high penetration of voice portals.

This paper will cover four main topics:

- Current wireless market situation
- A case study of one company's application note and test results
- Benchmarking versus continuous monitoring methods
- A cost-effective monitoring strategy

Current Wireless Market Situation

A current lack in reliable wireless communications is impeding wireless technologies from becoming widely accepted, especially for business-critical applications. Declining prices in wireless services do not present a sufficient incentive for customers to substitute their current wireline communication with wireless communication. Delays in adoption of 2.5G and 3G technologies are also stalling the penetration of data applications. Furthermore, voice-driven menu portals are stepping up as an alternative solution in today's competitive marketplace, requiring higher levels of voice quality and network availability.

Benchmarking QoS twice a year is an extremely costly procedure for wireless providers today and does not provide a true representation of the QoS the customer receives on a day-by-day basis. In fact, it seems that QoS dynamically changes over time based on location and time of day. Continuous monitoring from an end-to-end perspective, then, is needed. Such continuous monitoring will allow carriers to address and troubleshoot quality issues on a proactive basis, thereby enhancing their abilities to reduce churn, to increase the amount of billable time their subscribers incur, and to differentiate their services in the marketplace based on quality and not price alone.

Background

Wireless
Wireless communications, with the right focus on quality, could become a predominant means of communication in a developed society, provided that quality improves to near–toll level for both availability and reliability. Indeed, estimates, such as those provided by ResearchPortal.com (see *Figure 1*), project substantial increases in the number of both data-centric as well as voice-centric small form-factor (SFF) devices.

Nearly half the U.S. population owns a wireless phone, but only 3 percent of those users are relying solely on that medium for their day-to-day communication needs. This is indicative of the perceived quality and reliability of wireless networks by the customer. Though prices keep dropping, approaching toll-level structures, wireless QoS has not been able to improve at the same rate.

According to Consumer Reports, more than half of customer complaints are related to dropped calls. JD Power and Associates' wireless customer satisfaction index 2000 indicates that call quality (30 percent) has the highest impact on consumer satisfaction, followed by pricing (22 percent), customer service (20 percent), cost of roaming (3 percent), handset (2 percent), billing (2 percent), and others (21 percent).

Voice Portals
Voice portals are emerging as a suitable alternative to slow wireless data-transmission rates. The Kelsey Group estimates that 18 million consumers will use a speech recognition portal by 2005. By then, revenues for these portals will top $12 billion.

These portals serve as a stepping stone to high-speed data services that 2.5G and third generation (3G) technologies are promising by 2003. High levels of voice quality, however, are essential for these portals to become widely utilized in a wireless environment.

Case Study: Introduction

As carriers start to focus more keenly on delivering seamless wireless service to the marketplace, the sheer number of vendors and the technologies they use to construct their networks begs the question, "Is the customer is getting the best service in terms of quality and availability?" It is the premise behind this simple question that can spell the difference between capturing a large portion of the market—becoming the leader—or capturing the remaining portion of the market—becoming a follower.

In light of the aforementioned facts, one company, call it Company X, has attempted to apply its knowledge in the end-to-end QoS arena to the wireless marketplace, proposing to implement a cost-effective continuous-monitoring strategy.

Company X began its project by looking at the various factors that would have an effect on the quality and availability of wireless service in major metropolitan areas. The initial stage of this project focused more on the applicability of the conventional QoS metrics within the wireless world. Since this was uncharted territory, it was interesting to note the effects certain factors, such as location and time of day, had on quality and availability metrics.

The next section provides a brief overview of Company X's system setup. It is important to keep in mind here that the sample size of this test campaign was limited and that the main idea was to look at the various relations between QoS metrics and environmental and temporal factors.

Following the system setup information, some key findings, which may provide valuable insights to end-users and carriers alike, are presented. It must be noted, however, that these results are not conclusive and should not be viewed as a general rule in the wireless communications world.

Case Study: System Setup

To conduct a successful wireless test, it is critical to interface to the wireless network in the most seamless method possible, simulating the day-to-day usage scenario of a regular customer. While this may seem like a trivial task, dedicated research in this area led to the selection of several wireless phone interface vendors that would deliver the required functionality.

Two CallWave™ units were used in conducting the tests—one of them connected to the wireless network using a proprietary interface from Vox2 for a digital Nokia 5160 phone, and the other connected to the public switched telephone network (PSTN). Both connections were made over the two-wire registered jack–11 (RJ–11) ports on the CallWave units.

Case Study: Test Setup 1

The main objective in the design of the wireless application was to keep one unit fixed at Company X's headquarters in Gaithersburg, Maryland, and perform tests from the mobile CallWave unit to the stationary unit. Using this setup, a controlled experiment environment was created, which in turn ensured a more reliable and scientific test scenario.

On the mobile-unit side, three locations were chosen for this test. The first location was company headquarters in Gaithersburg, which simulated a professional on the road from work to home. The second location was in the well-populated Georgetown area of Washington, D.C., and was supposed to simulate an end-user accessing the wireless network from a typical metropolitan location. The third location was Arlington, Virginia, which simulated a boundary metropolitan-area subscriber.

Time was the other dimension in this test campaign. The testers wanted to determine whether placing calls at different times of the day had any significant effect on the quality of the calls and the availability of the network. Calls were placed during both busy hours and non–busy hours, covering a 24-hour period with 30-minute intervals between each test call.

Initial tests included a limited number of measurements in order to keep the test setup simple and easy to interpret.

FIGURE 1

Worldwide SFF Device Forecast

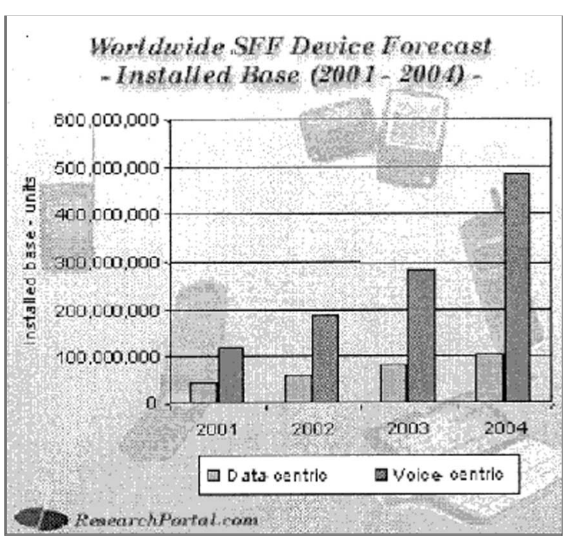

FIGURE 2

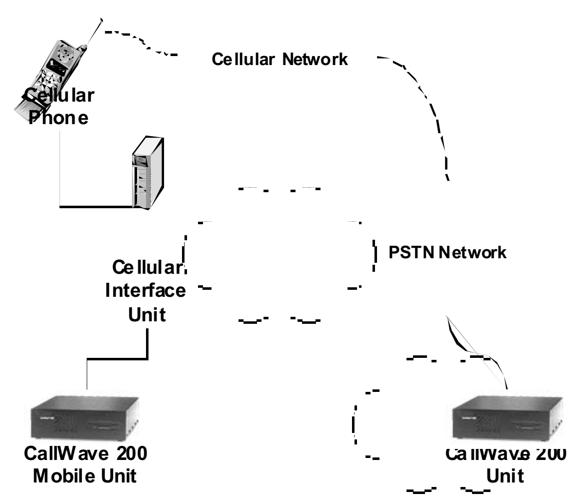
System Setup—Interfacing to the Wireless Network



The following key performance indicators were used in the test setup:

- Call-completion rate (CCR)
- Post-dial delay (PDD)
- Perceptual analysis measurement system (PAMS)

Case Study: Test 1 Results

This section discusses key results in the following three areas:

- Network availability
- PDD
- PAMS—listening effort/listening quality

For each area, two perspectives are given: results by location and results by time of day.

Availability

The main measure of network performance is availability. To measure availability, the completed calls and dropped calls were analyzed.

Figures 3–6 illustrate a clear difference between how calls are handled in Gaithersburg and how they are handled in Arlington and D.C. Call completion was significantly higher in Arlington (where CCR was at 80.48 percent) and D.C. (78.65 percent) than it was in Gaithersburg (58.66 percent). The difference in call completion between Arlington and D.C. was not significant.

Both Arlington and D.C. show declines in CCR between the hours of 1:00 pm and 9:00 pm. Gaithersburg shows a similar decline, but it is not sustained due to the variability of the results.

FIGURE 3

Call Disposition—Gaithersberg

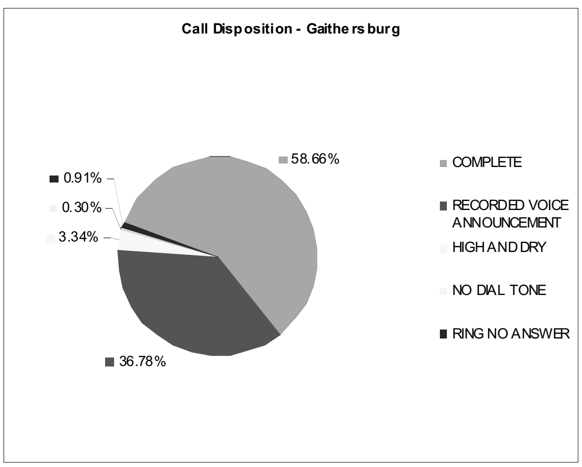


FIGURE 4

Call Disposition—Arlington

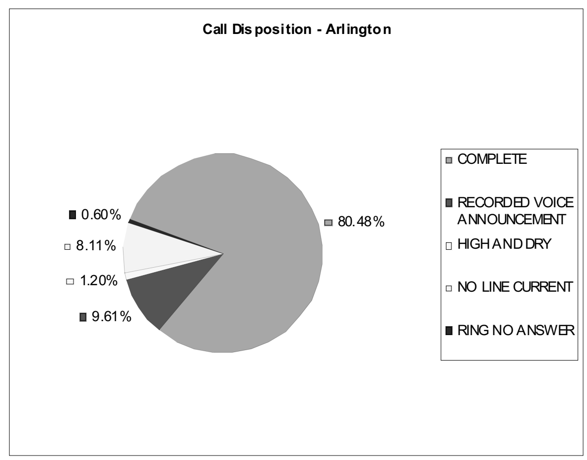

FIGURE 5

Call Disposition—D.C.

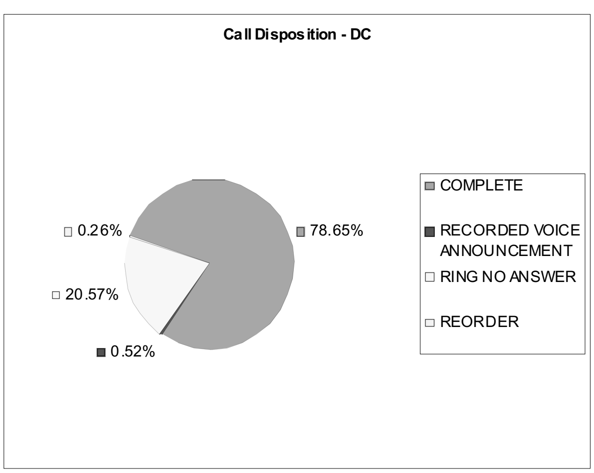

FIGURE 6

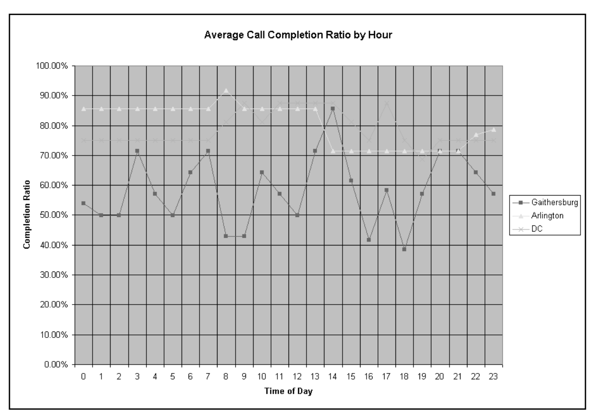
Average Call—Completion Ratio by Hour



PDD

Another important performance indicator that was taken into consideration in this test setup was PDD (see *Figures 7–8*). PDD indicates how responsive a network is in handling call requests by end users.

Looking at test calls that were placed over a 24-hour period covering seven consecutive days, the conclusions can be drawn from *Figure 8*:

- The highest PDD was observed in Gaithersburg (10.54 seconds).
- Arlington and D.C. had the lower PDD observations (7.74 seconds and 8.31 seconds respectively).
- On an hourly basis, there is severe variability in the results; but Arlington experienced the highest PDD measurements at 2:00 p.m., which coincides with its lowest performance in completion rates.

PAMS

The last measure of QoS here was PAMS. Listening effort and listening quality were evaluated using scores ranging from a low of 1 to a high of 5 on a linear scale. The purpose of using PAMS scores is to understand how perceived quality of voice changes by location and over a period of hours. *Figure 9* illustrates a comparison by location:

Figure 10 shows that calls placed from Arlington and D.C. received slightly higher scores on both the listening-quality and the listening-effort measurements than those calls placed from Gaithersburg.

The higher results for Gaithersburg's observations make the measurement on par with those of both Arlington and D.C.

On an hourly analysis, we find that the listening-quality results from Arlington and D.C. are very consistent, while results perceived from Gaithersburg are lowest between the hours of 3:00 pm and 7:00 pm.

Time-of-day analysis does not reveal any significant results on data collected from any of the locations.

Case Study: Test Setup 2

For this test, a credit-card voice-recognition portal was chosen to perform test calls from a CallWave unit. A recording file that would spell out the credit card number was played

FIGURE 7

Average PDD Comparison

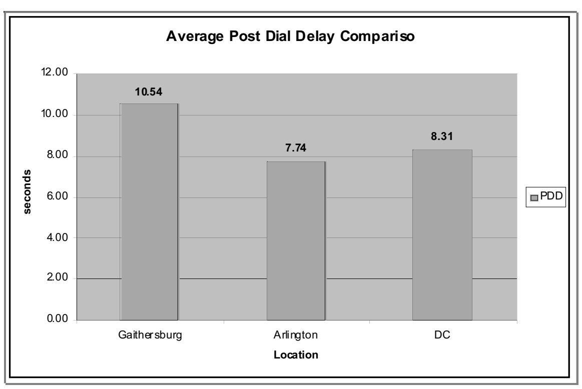


FIGURE 8

Average PDD by Hour

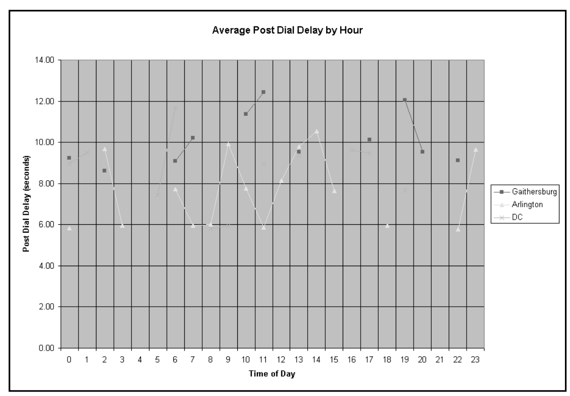

FIGURE 9

PAMS Scores

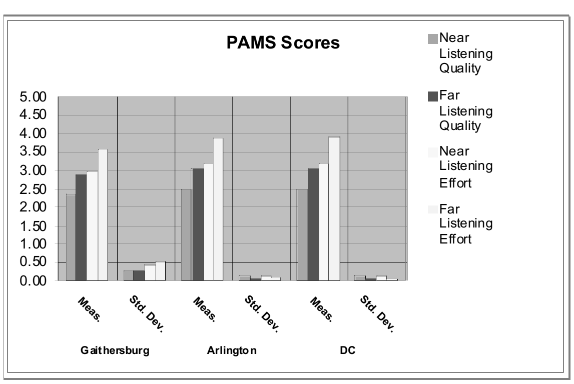

FIGURE 10

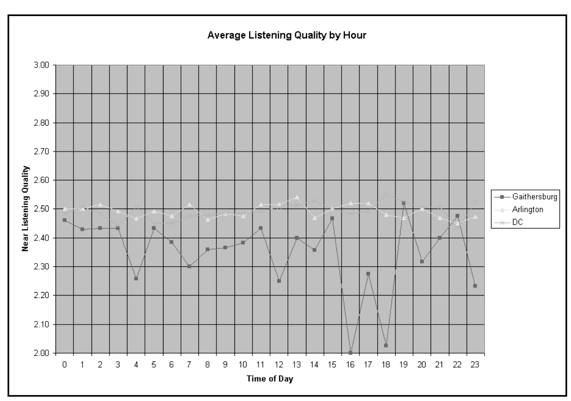
Average Listening Quality by Hour



from the CallWave unit. If the portal recognized the number, it would provide the current credit balance. If not, it would ask the user to "say" the number again.

Twenty calls were placed through the cellular interface, and twenty calls through a landline. The calls were placed every two minutes.

The following results, which are graphed in *Figure 11*, were obtained:

Cellular

Attempts: 20
Completed to the platform: 14
Dropped: 6
Completion ratio: 70%
Recognized by platform: 3
Recognition ratio: 21%

Landline

Attempts : 20
Completed to the platform: 19
High and Dry: 1
Completion ratio: 95%
Recognized by platform:13
Recognition ratio: 68%

Next Steps

1. Gather a significant sample size.
2. Correlate recognition ratio with listening-quality (PAMS) results to arrive at acceptable levels.
3. Incorporate similar setup over IP to determine PAMS acceptable levels, and evaluate dual-tone mutlifrequency (DTMF) recognition.

Benchmarking once or twice a year only covers the first two steps required in effective monitoring strategies. Network conditions are constantly changing with the implementation of new services, carriers, and technologies. Prices keep dropping, and QoS expectations keep increasing. Carriers need to compete and be able to differentiate their services using something other than price.

Through continuous monitoring, carriers can always understand the current QoS that they are offering as perceived by the end users and understand how it compares to their competitors' QoS. They can, therefore, be proactive in addressing QoS issues before their customers even know they exist, which can, in turn, help to reduce churn. Isolation and troubleshooting of QoS problems can only be done in a proactive way with continuous QoS monitoring and network element correlation. Benchmarking alone will not provide adequate measurement. Current benchmarking methodologies—conducted only annually or semi-annually—are price prohibitive and make it impossible for carriers to engage in continuous monitoring.

Another major issue in wireless communications today has been the relative shortness of call duration when compared to landline calls. This has been due to both price and QoS. Thus, improving QoS will allow carriers to increase CCRs and average conversation time—two desirable goals from a carrier's perspective since more completed calls mean more calls a carrier can bill, and since longer conversations mean higher bills.

Proposed Cost-Effective Monitoring Strategy

This section describes a cost-effective methodology that carriers can implement in a short period of time.

Establish Baseline Network Characteristics

These will allow wireless service providers to identify and understand the current QoS that they are providing as perceived by their customers. This baseline can be used later as a reference when comparing and differentiating their services with their competitors' services.

Set Benchmarking and Alerting Thresholds Based on End-To-End Subjective Measurements

"Subjective measurements" here refers to mean opinion scores (MOS), call clarity indexes (CCI), PAMS, etc. that provide a perceptual measure of what is acceptable to the customer and what is not.

These thresholds can be static—standards, design, competitive information, service-level agreements (SLA), customer expectations, regulations, and financial targets—or

FIGURE 11

Percentage of Calls Recognized by the Voice Portal

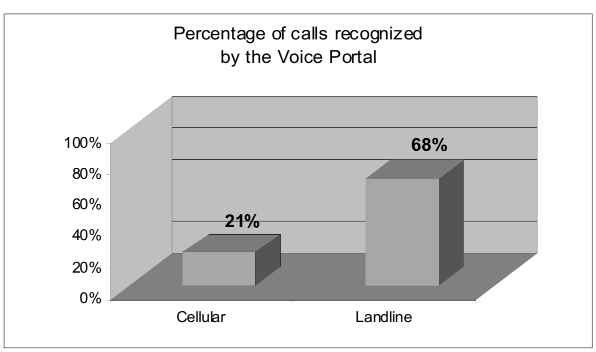


FIGURE 12

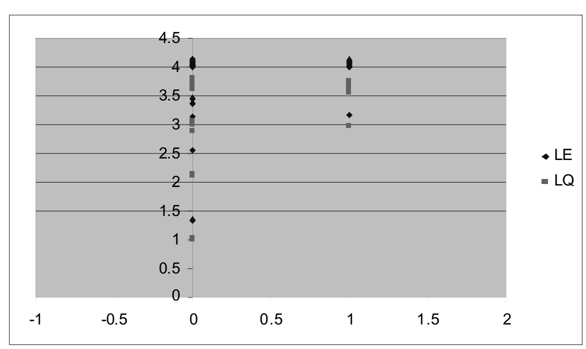
Benchmarking versus Continuous-Monitoring Methods



dynamic—profiling systems that determine what is normal behavior and what is not based on "learned" QoS from specific locations, carriers, customers, and destinations).

Prioritize Alerts Based on Financial Penalties and Response Times

These alerts are usually specified in SLAs, although they can be specified based on the importance of services, region, customer, etc.

Subjective measurements need to be correlated with objective measurements and network elements (NE) for problem isolation and troubleshooting

Once thresholds are exceeded, a monitoring system needs powerful correlation in order to determine what the cause (root-cause analysis). In this case, subjective impairment information needs to be correlated with detailed objective impairment information, global positioning system (GPS) information, radio frequency (RF) information, call detail record (CDR) information, and physical-layer–availability information in order to get a full picture of what caused the threshold to be exceeded.

Continuously Monitor To Address Ever-Changing Conditions

The process needs to be constantly active. This is the only way that carriers are really going to be proactive and detect and address any deterioration in QoS before their customers become aware that such deterioration exists. Important business decisions are made constantly, not once or twice a year. Such constancy should similarly apply in maintaining levels of quality with network conditions that are constantly changing.

Provide Reliable and Timely Information Customized for Each Functional Area of the Organization

An effective monitoring system is capable of not only measuring the above characteristics but also disseminating the data, converting it into the right information at the right time to the right decision makers.

Conclusion

Several conclusions can be drawn from this test scenario:

1. Location and time of day *did* have an effect on network availability (CCR).
2. Location *did* have an effect on PDD and PAMS.
3. After a period of time, one will know if results change over time.
4. IIsolating and troubleshooting problems now require more significant sample size; mobile solution to evaluate dropped calls due to handoffs; and correlation with RF levels, geographical location, and switch CDRs.
5. Continuous monitoring, especially in such a high-churn environment, should be implemented to allow provider to become proactive instead of reactive and to increase the amount of billable minutes.
6. Calls over the wireless network *did* have a considerable impact on voice-driven applications that rely on speech-recognition technologies.

7. It is difficult to set acceptable levels, especially in an environment where customer's QoS expectations are believed to be lower.
8. Impairments with the highest correlation-to-recognition ratio must be found; if not PAMS, others (SG12—58 PSQM Noise, PSQM+ clipping and distortion PESQ) should be found.

The next steps are to conduct more geographically dispersed tests. These will involve more locations as well as moving targets to analyze the effects that cell handoffs have on availability, reliability, and suitability of the wireless network. This approach will also provide a closer approximation to a true customer experience. The above test results already indicate poor quality performance of a wireless network, even though the conditions of the controlled environment test were almost ideal. A more dramatic impact can be expected when the suggested true-customer-experience testing scenarios are entered.

Mobile Operators: The Sky Isn't Falling

Getting Back to Business Basics Will Get the Industry Past the Current Cash Crunch

Brian D. Bolliger

Director of Global Mobility Marketing and Strategy, Mobility Solutions Group

Lucent Technologies

There's been much hand-wringing of late over the costs incurred by service providers around the globe in securing spectrum for new-fangled high-speed mobile Internet services. So much so, that in the latter half of 2001, many deployments had been postponed or scaled back. Among reasons cited were technical hurdles, doubts about the business model for next-generation services, skittishness about further capital investment, and the availability of next-generation devices.

We have been here before. Anyone with the benefit of longevity will recall similar conditions when the concept of commercializing cellular communications was first broached in the 1970s. Regulators were initially fearful about having fixed-line ratepayers subsidize what appeared to be a luxury for rich business people. Then, when analog mobile services became wildly successful, similar doubts were raised in the 1980s about the cost and viability of second-generation digital personal communications services (PCS) to be offered in new spectrum by both incumbents and new operators.

To anyone who has been around the industry for the past three decades, the current concerns being raised today about third-generation (3G) networks ring familiar:

- The rates that operators have to charge to recoup their investment will be prohibitive, and so the services promised by mobile providers will appeal only to a select group of rich people or "road warriors."
- You can't surf the Net from a mobile phone like you can on a desktop computer (updated version of the argument that cellular can't match the voice quality and reliability of landline telephones, so why bother?).
- New upstart operators will be unable to compete against embedded incumbents who have a head start and already have broad-based coverage.
- Wideband code division multiple access (CDMA) technology is radically different from second generation (2G), hence it is best to continue to invest in 2G and 2.5G until 3G is perfected (an updated version of the 1980s argument that spread spectrum CDMA is unstable, so it is best to stick with the far more widely deployed and popular time division multiplexing (TDM)–based technologies, such as Global System for Mobile Communications [GSM]).

Each of these can easily be addressed with counter-arguments. The first point is that while new services are always first marketed to early adopters at a premium, there is a natural spillover to a broader segment. Enterprise workers are accustomed to easily accessing information, such as e-mail messages and graphic intensive multimedia files, while they're in the office. Corporate information officers clearly see the productivity gains and benefits that extending these functions to their mobile workforce would have and are willing to pay for it. Proof that, if you build it, stay close to the market trends, and meet a critical need, customers will come to this field of dreams.

True, mobile high-speed data services are not yet available to mimic the on-line personal computer (PC) experience on mobile phones. But operators can sow the seeds *now* by exploring with device manufacturers new content and applications that take advantage of ever-faster transmission rates. Until there is ubiquitous coverage, they can provide "hot spot" high-speed data access with strategically deployed wireless local-area network (WLAN) technology. The trick is to match the device appropriately to the application and network capability and not to sell the 3G idea as an untethered PC experience.

Some new operators have abandoned the pursuit of 3G licenses or delayed buildout because they see no way of recouping their license and infrastructure investments. Others, thanks to regulatory relaxation, have devised network-sharing schemes or network hosting arrangements, commonly known as mobile virtual network operator

(MVNO) scenarios, to gain a fast entry. The U.S. market is a real-world example how new players have overcome the challenge of competition against incumbents through national branding and consolidation.

Lastly, the technical challenges faced in some quarters by 2G operators unfamiliar with spread-spectrum technologies can and will be overcome—sooner rather than later. To accelerate the return on investment (ROI) on 3G costs, operators need to focus on the immediate market opportunity: high-speed, mobile data services. That means weaning off current technology and getting to 3G *sooner* rather than later.

What's Different Today Is the Internet

The last decade has witnessed a phenomenon that offers the best counterpoint to the 3G naysayers: the advent of the Internet and the New Economy.

One might argue that the burst of the dot-com bubble weighs heavily against the prospects for the mobile Internet, but all signs point to the contrary. In fact, a global independent market study (August 2001) commissioned by Lucent Technologies demonstrated how the need for enterprise data communications is not being sufficiently met for the New Economy. To achieve cost-efficiencies, many enterprises are relying on an increasingly mobile workforce; yet, without the appropriate access to corporate data and communications resources, these workers feel increasingly isolated, frustrated, and out of touch with both their employer and customers.

The number of Internet subscribers worldwide is destined to continue its steady growth, reaching some 650 million by 2005, or nearly twice the number of 2000. Also, consider that over the next three years, the *average* global penetration of wireless communications will grow to 20 percent and that penetration will exceed 70 percent in key markets where wired Internet access is lagging. These trends are strong indicators that pent-up demand for always-on mobile Internet access won't remain just an enterprise-focused service for long (see *Figure 1*).

It is increasingly clear that 2001 was yet another of the historical cyclical technology transition years, when network service providers (NSPs) and the financial institutions that back them hedge their bets on next-generation services as they weigh multiple options for capital expenditures. The events of September 11, 2001, further complicated the decision process, because it clouded the prospects for economic recovery in 2002 and beyond.

The Murky Picture Is Now Clearer

The combined effect of a technology transition year in 2001 and the general economic slowdown, spawned by what's been referred to as "exuberant" market expectations gone sour, has created the current correction that is now manifesting itself in slower telecommunications capital expenditures (CAPEX). The global CAPEX pie for telecom is forecast to shrink by as much as $60 billion to $231 billion globally this year. To rid their core telecom business balance sheets of debt-laden mobile operations, some service providers have created separate, self-standing mobile enterprises or have spun them off completely. While committed to a still sizeable capital expense program ranging from $70–$80 billion globally, the mobile service providers are taking a far more sober approach to their business. In some cases, they have seized an opportunity to bulk up around converged standards to achieve economies of scale, yielding consolidation to the point where the top 20 mobile operators now control 80 percent of the CAPEX.

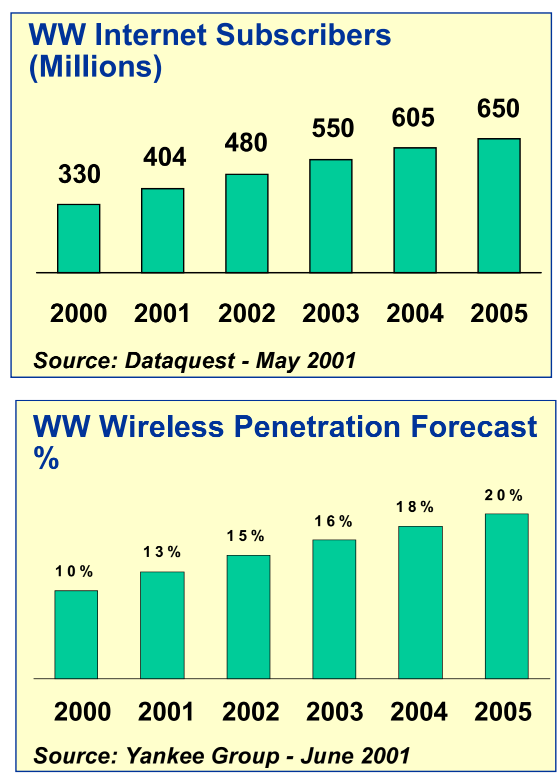
Most importantly, however, in light of the bursting of the dot-com bubble, the largest incumbent service providers have now changed their assumptions about what the future holds and must now plan accordingly. Unlike the two previous years, business decisions today can no longer be based on the assumption that equity is limitless and can be traded as cash to fund current operations. The large incumbent mobile operators have spotted the inevitable rise in Internet usage and are looking for *real-world* models for tapping into the underserved or unserved market segment for new services.

In approaching the opportunity, carriers are now very methodical. Specifically, their objective is to do the following:

1. ***Expand their most profitable customer base.*** By inference, this means putting a priority on business users and business applications that can be marketed to corporate management information system (MIS) decision-makers as a means for *increasing productivity* and *enhancing customer-relationship management (CRM).*

FIGURE 1

Mobile Internet Growth Prospects



2. ***Create high-value, high-margin services.*** One-size-fits-all calling plans can only go so far in attracting customers, because with each additional customer, there is a diminishing rate of return. Carriers recognize that data-based services—including secure, virtual private mobile networks for extending enterprise communications and business functions—present the best opportunity for incremental revenues from enhanced services

3. ***Provide more capacity cost-effectively.*** The never-ending cycle of an expanded user base and need for more capacity to handle the increased traffic is a constant juggle for service providers. The latest intelligent antenna technology and network optimization tools offer the most cost-effective way to manage growth in capacity and coverage—without incurring the cost of new base-station cell sites and equipment.

4. ***Accelerate the implementation of mobile high-speed data technology.*** Operators and handset vendors that have marketed text-based short message services (SMSs) and clumsy text information retrieval on small mobile phone screens as a "mobile Internet" experience have left many early adopters less than satisfied. Rather than prolong this experience with interim solutions, carriers should look to *fast track the promise of mobile high-speed data*, provided vendors can deliver the solution cost-effectively.

5. ***Preserve embedded assets.*** With investment bankers, venture capitalists, and government regulators looking over their shoulders, mobile operators must opt for a solution that best meets their needs for maximum longevity, through multiple standards evolutions. Forklift upgrades can no longer be tolerated in today's tight credits market.

6. ***Turn in solid economic performance to drive up market capitalization.*** When all other criteria are combined, carriers need to execute their plans and create a business with intrinsic value. Higher valuation based on *real*, rather than *potential* performance, creates the capital needed to fuel subsequent incremental and measured growth and a solid economic foundation.

No doubt the challenges facing operators today are formidable, but with the right technology partner, they are surmountable. The key is to develop a market-driven, cost-sensitive business plan and implement a service intelligent architecture, which takes the latest hardware and software for the end-to-end network and makes sure that advanced services can be easily provisioned, maintained, and billed through a highly integrated software management platform.

Key Considerations for Success

Where does the operator start on the road to success? The best point of departure to a solid business scenario is the selection of a strategic partner who understands and can best help execute the following:

1. ***Fast-track to mobile high-speed data services.*** The world has converged on spread-spectrum radios as the common technology for 3G. By extension, the lowest risk path for any operator is to partner with someone with the most extensive global experience in designing and building commercially successful spread-spectrum–based network infrastructure. The most proven and commercially successful spread-spectrum networks today are based on CDMA.

2. ***Maximize the power of the network.*** Unlike other access providers whose roles are relegated to a "dumb pipe," mobile operators have the advantage of seizing the power of network intelligence to extract value that can be packaged for premium, value-added services. A systems integrator well versed in service provisioning can help any operator leverage network intelligence to extract value from this asset.

3. ***Pick the lowest-hanging revenue fruit.*** A Yankee Group study published in December 2001 quantifies the Lucent-commissioned research, which indicated the pent-up demand for extending corporate intranet and e-mail communications seamlessly to mobile workers. The Yankee Group predicts that in the United States alone there will be about 43 million wireless enterprise data users by 2005. It is safe to say that the number of potential users worldwide will be even greater. That's a ready-made, real-world market and a huge revenue-generating opportunity for any service provider.

4. ***Turnkey, out-of-the-box solutions.*** In addition to tightly integrated and easily managed network elements, network operators need to rely on strategic suppliers that have ready-made, out-of-the-box solutions that they can market to the premium enterprise customer. This encompasses a range of standards-based enterprise business solutions that support corporate functions and processes. In the New Economy, businesses must enable mobile workers to be as productive and responsive to customers as if tethered to their office resources. Additionally, deploying these capabilities will create the environment in which services for other market segments can arise and flourish. Moreover, providing always-on, always-accessible CRM systems are critical to remaining competitive in the New Economy. The right strategic partner will have packaged solutions ready for deployment—from back-office support systems, applications software support, and compatible wireless handheld devices optimized for the appropriate function.

5. ***Speed to market.*** The faster the deployment, the faster revenues are realized to shrink the ROI interval for the operator's CAPEX. This calls for rigorous professional business and engineering services that encompass all planning aspects through deployment, launch, and beyond. By relying on this disciplined support, the carrier can build a credible, real-world business plan that establishes accountabilities and financial performance levels that are sure to lead to a successful track record to warrant higher valuations and economic health.

Conclusion

The sky did not fall down on the mobile sector in 2001. It was, in retrospect, part of the normal cyclical downturns that are typically initiated by generational changes in technology. Unfortunately, this trend was exacerbated by the burst of the dot-com bubble in the credit markets and the economic uncertainty following the events of September 11. However, by focusing on business fundamentals and a disciplined methodology for value creation, mobile operators can indeed anticipate sunny skies ahead. The right strategic relationship with a reliable and experienced partner can make all the difference.

The Impact of Intelligent "Push" Services on Wireless Carriers

Jeff Condon

Vice President, Marketing

Otelnet

I. Executive Summary

The world of mobile phones is changing rapidly and dramatically, with global utilization approaching a billion subscribers. Until recently, mobile phones' primary use was for "phone calls"—person-to-person voice communications. With the unprecedented success of person-to-person short messaging service (SMS) in Europe and the iMode phenomena in Japan, the use of the mobile phone is shifting from a rather basic voice communications tool to a true "mobile terminal" whereby the user may have access to the plethora of data otherwise accessible only by those with personal computers (PCs) connected to the Internet. The thirst for information, as well as other data-oriented services, while mobile, has not been quenched by the use of the micro browser—"pull only" services—on the mobile phone. The market has learned that bringing Internet services directly from the PC to the mobile phone has not worked, but valuable information and services can be brought to the mobile phone. Pull services alone are not sufficient. This has created a major opportunity for wireless carriers to better serve their subscribers and to gain a significant new source of revenue by intelligently pushing desirable, valuable information and services to their subscribers.

II. Wireless Data, Content, and the Mobile Subscriber

A. Success of SMS in Europe As a Precursor to Push Services

The success of SMS in Europe, a bit of a surprise since it grew "organically" with little or no marketing of the service by the wireless network operators, has set the stage for consumer uptake of new information or content-oriented services. The ease with which subscribers, most notably younger subscribers, send many millions of short text messages each month to one another has created a very receptive audience for receiving text messages from other sources. Today, something on the order of 90 percent of all SMS messages sent and received in Europe are person-to-person, or phone-to-phone. This is due in part to the ability of conversing with another person while avoiding the ringing phone and by avoiding the cost of making a phone call.

The net result is a huge consumer market already accustomed to receiving (and sending) text messages. A natural progression, then, is to "feed" this hungry market with more of what it wants. Thus, sports scores, for example, are readily available to be sent (pushed) to enthusiasts, often within minutes of a score change, for example, in a football game. Standard content services, such as these sports scores, daily horoscopes, generic news items, and local weather reports, have become "checkbox" items. Since these phones, and the supporting networks, allow the consumer to send messages as well as receive them, new services are becoming available to take advantage of this well-primed market: interactive voting, lifestyle and entertainment services such as gambling, purchasing and downloading of ring tones that have been created from popular music, and so on are leading the charge. This hungry market is willing to pay a bit more to get interesting information, or content, pushed to them if the content is perceived to have high interest or high value.

SMS is an estimated $1 billion a month industry in Europe, although it has lagged significantly elsewhere due to the lack of inter-carrier solutions. In the United Kingdom, for example, SMS message traffic increased more than 700 percent in the nine months after an inter-carrier solution was deployed, according to the GSM Association.[1]

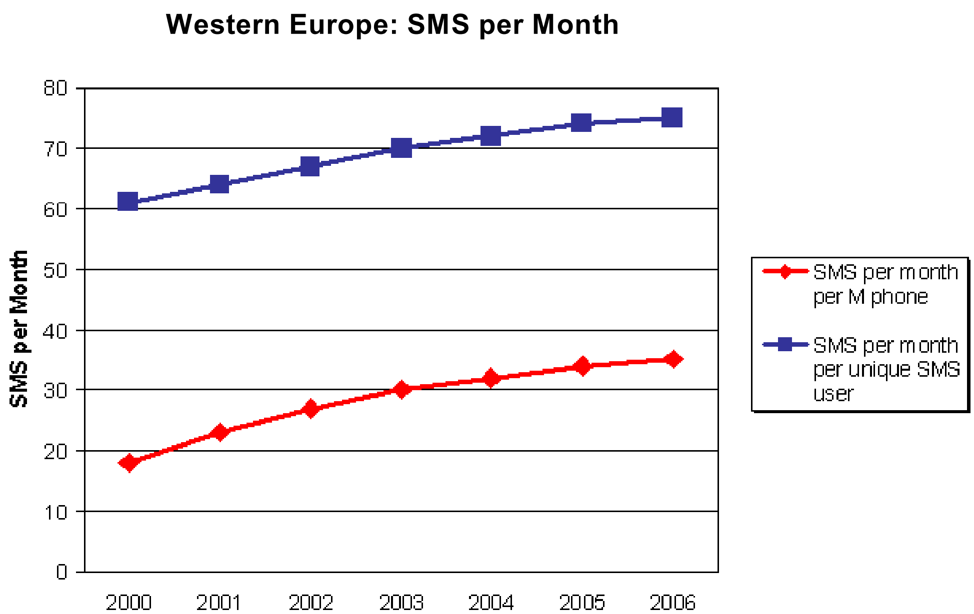
As shown in *Figure 1*, SMS traffic in Western Europe shows just how hungry this market is. For example, in 2001 the average mobile phone user sent or received about 64 individual short text messages each month, and that number is projected to continue to grow through 2005 (upper line). Meanwhile, the number of SMS messages per mobile phone indicates that these users actually have more than one mobile!

This data is based on a mobile phone penetration rate of about 70 percent in the top 15 European counties, meaning that of every 100 people in these countries, 70 of them use a mobile phone.

B. How the European Market Is Different from North America

There are some key differences between the wireless phone markets of Europe and of North America. These differences account for the strong uptake of SMS and SMS–based information services in Europe, whereas this is just beginning in North America.

FIGURE 1



Source: Research Centre of Bornholm (Denmark) + OTELNET estimates

European wireless networks are nearly all Global System for Mobile Communications (GSM), due to a conscious decision by network operators and governments in the mid-1980s to implement a common network protocol for digital (second generation, or 2G) mobile phone networks. One reason this decision was made and agreed to was to make it easy to add new, high-value services, as well as to facilitate the migration to general packet radio service (GPRS) (2.5G) and to Universal Mobile Telecommunications System (UMTS) (3G) packet-switched networks. This resulted in 2G networks being implemented throughout Western, Northern, and Central Europe based on the GSM standard. Having multiple network operators (usually three or four) in each country building GSM networks greatly facilitated voice call roaming, since all that is needed are service and billing agreements among the operators. Thus, a subscriber from Helsinki can travel to virtually any European city and be assured of service availability. This holds true with SMS as well. One can easily send text messages to a subscriber in another country without worrying about incompatible networks. This ease of communications throughout Europe has had a major influence on the high penetration rate of mobile phones in these countries.

In North America, by contrast, the migration from first-generation analog mobile phone networks to 2G occurred in a much different way, and much more slowly. The philosophy shared by European operators to build homogeneous networks to ensure good service and easy roaming was not used in North America, where competition drove the technology choice, not government regulation; North American network operators built 2G networks in the least expensive way they could. The result was a much slower build out of 2G digital services and heterogeneous networks. These networks were based mostly on time division multiple access (TDMA) and code division multiple access (CDMA), with only a few operators choosing to build a GSM network. As a result, when one subscribes to a digital mobile phone service in North America, the handset is capable of working only on that type of network—CDMA for example (these handsets usually can also be used on 1G analog, or advanced mobile phone service [AMPS], systems)—due to the length of time it has taken to build out the digital networks. This has had a dramatic effect on roaming, since a CDMA handset can only roam on a CDMA (or AMPS) network. Of course, these heterogeneous networks have made it difficult to implement cross-network SMS services.

The difference in network evolution has lead to a much slower uptake of mobile services in North America. Key factors driving mobile phone penetration are network homogeneity, life styles, service availability, and price. Only now is the U.S. market approaching 50 percent penetration, meaning that about half the population has a mobile phone. Interestingly, the percentage of American homes that have a PC with an Internet connection has passed 70 percent. Thus, a large majority of American consumers have easy access to information—content—via a "fixed" Internet connection. European countries, by contrast, have a much higher penetration of mobile phone users, and they are all using the same type of device (GSM). This means that mobile network operators, or carriers, in North America still have half the population to sell basic services to and have strongly concentrated new revenue-generation activities on acquiring new subscribers. European network operators, in contrast, do not have this "green field" of population to sell to—most of the available European market (those older than about 9 years of age!) already have a mobile phone, so European operators must find other ways to generate new revenue.

C. The Wild Card: Japan

NTT DoCoMo's success with its iMode service is an interesting and unique phenomenon. Although NTT is not the only wireless provider in Japan, it is the best known.

There are interesting circumstances surrounding iMode and the Japanese market. The service offerings include both push and pull services, are graphical in nature, and are "always on." In addition, the mobile phone penetration is approaching 65 precent; there is a low PC penetration rate; the culture is strongly entertainment-oriented; and the DoCoMo business model of revenue sharing provides strong incentives for content and applications providers. The Japanese consumer desires entertainment-oriented services, often taking the form of small, animated graphic characters. This same consumer most likely does not have a PC in the home and very limited or no Internet access.

The iMode service fulfills the demand for content that is currently satisfied by Internet access via the PC in the Western cultures of Europe and North America. In addition, NTT has created a business model that provides strong incentives for third-party application and content providers to deliver offerings through the DoCoMo iMode service: A significant majority of the fees paid to DoCoMo by the consumer (more than 90 percent) are passed along to the third parties. The result is a plethora of high-quality service offerings for the Japanese mobile consumer to choose from. This has created an interesting competitive situation with other Japanese mobile network operators whose network and service offerings are more like those in Europe.

DoCoMo now has investments in both Europe and North America, and both markets will learn and benefit from the DoCoMo experience. Since lifestyle, cultural, and service-availability factors are very different for Japan, it remains to be seen how well the iMode model will be accepted outside of Japan.

III. Why "Pull" Services Have, So Far, Not Done Well

A. What Is a "Pull" Service?

"Pull" services, in this context, refer primarily to the paradigm of implementation of the "fixed" PC, with a browser and wired Internet connection. The consumer (subscriber) uses the browser and other "on-line" tools, such as search engines and portals, to seek out and "pull" content to the PC.

The first attempts to make Internet content available to mobile "terminals" (e.g., mobile phones and, to a lesser degree, personal digital assistants [PDAs] such as the Palm VII) was, and still is, intended to implement this same paradigm on the mobile phone through a browser—actually, a "micro-browser" on the handset, with which one attempts to "surf the Web" as if it were a PC–based browser.

B. WAP and iMode

Wireless application protocol (WAP) and iMode are two competing network "transport" technologies that provide a mechanism for data to move between the mobile phone and the network. WAP has been most widely implemented in the West (Europe, North America); iMode is the technology used by NTT DoCoMo in Japan, as was discussed. There are some key differences between the two technologies. The current implementation of WAP is on 2G, circuit-switched networks. This requires the user to make a phone call (i.e., dial a phone number) to create the "circuit," or connection, to the network before the micro -browser, often called a "WAP browser," can be used to search for, or "pull," information and content. These micro-browsers are text-only implementations and are forced to communicate over the very slow data circuits of a 2G network. Furthermore, the user pays the same per-minute charges as for a voice call.

iMode, by comparison, is implemented on a packet-switched, "always-on" network. Although slow by broadband Internet standards, iMode is faster than circuit-switched WAP and does not require the user to make a phone call to set up the connection to the network. The iMode browser has been optimized for its network, so the user experience is more satisfactory than for WAP implementations. Billing is different as well. Where the WAP user currently is billed per minute of connect time, the iMode user is billed per data packet received or sent by the handset, regardless of connect time. In fact, the concept of connect time does not apply, since the handset is "connected" to the network whenever it is turned on, much like a PC connected to the Internet via a digital subscriber line (DSL) or cable modem.

Keeping in mind the differences in cultural drivers between Japan and the West, plus the organic success of SMS in Europe, one can easily see why micro-browser–based, pull–based services have failed in Western markets and that iMode services have seen a resounding success in Japan. It is the user experience that will determine success or failure, and the user experience with WAP–based browsing has been very poor. A combination of factors has caused this, including that the user interface—a text browser on the very small screen of a mobile phone—is awkward and difficult to use. The very slow connection to the network significantly exacerbates this awkwardness, since each time the user sends, for example, a menu choice for a new screen of information, the latency, or waiting time, for the new information is agonizingly slow. For a time, wireless network operators tried to mitigate this by creating the "walled garden," which essentially restricts the user to the browsing menu choices provided by the operator. Unfortunately, this worsened the situation by preventing the user from getting at information or content that is readily available on the Internet-connected PC, so this approach has mostly been abandoned. The result is that most mobile subscribers who have tried to use WAP and micro-browsers rapidly abandon it in frustration.

In Japan, the iMode browser is more intuitive to use, and the mixed graphics and text appeal to the Japanese consumer. Also, the typical Japanese mobile subscriber does not have ready access to the Internet via a PC, and so has no preconceived notions about the user experience of browsing.

IV. The Evolution of SMS

Infrastructure refers to the mobile network and how the mobile phone user actually can use the network for something other than making phone calls. This is not an attempt at a dissertation on 2G, 2.5G, and 3G networks, but some discussion is needed to understand why "push" services are so important to wireless network operators and subscribers alike.

The majority of wireless networks have been migrated to digital service using the three aforementioned technologies: GSM, CDMA, and TDMA. Each of these has unique characteristics, with advantages and drawbacks, and it appears that TDMA systems are nearing the end of their life, such that any new 2G networks are either GSM or CDMA. In any event, all three have the common characteristic of being circuit-switched, meaning that for the user to connect to the network, a phone call must be made to create the connection, or circuit, to the network. This is fine for the most part for making simple voice calls but is not fine for data.

As mentioned, this connection (regardless of whether its GSM, CDMA, or TDMA) is so slow as to have very limited usability. One reason that SMS has become so successful in Europe is that it does not use the "circuit" and does not require a phone number to be dialed. Rather, is uses a different part of the network, called signaling sstem 7, commonly called SS7. This is the part of the network that, among other things, causes your phone to ring when someone places a call to you. This is true for today's wireline phone networks as well as wireless networks. This process of making your handset ring is accomplished before creating the circuit from your handset to the network and to the calling phone.

Without this SS7 mechanism, the process of initiating a call—dialing a number and making a handset ring—would completely fill and overwhelm today's networks. SMS uses the SS7 network to send short messages to (and from) the mobile handset. As it happens, most network operators have also implemented e-mail gateways between their wireless networks and the Internet; the result is that one may send an e-mail to most (SMS–capable) mobile phones, and some phones can originate an e-mail message as well.

As described, about 90 percent of the SMS traffic in Europe is handset to handset—all done without making a single phone call and without using up voice call minutes, and all via homogeneous GSM networks that have roaming agreements not only for voice calls, but also for SMS traffic. This is one of the reasons why SMS has been so successful and has created a major opportunity for wireless network operators to create new revenue-generating services that leverage this capability.

V. Content Sources, Wireless Portals, and the Value of Intelligent "Push" Services

This opportunity for wireless network operators revolves around creating new content-oriented services. If the operators can capitalize on this now, they become well positioned to take advantage of the increased bandwidth (with more than just greater voice call capacity) to be made available with the migration to packet networks: 2.5 G and 3G. Pull will get better, and push will still be needed for many services. This means getting access to sources of content—content that the network operators cannot create on their own. Virtually all wireless network operators now offer some sort of portal, mostly accessed via PC–based web browsers, and offer mobile phone micro-browser access to some of the portal content, which has been specially formatted and often replicated for the micro-browser. The larger multinational operators have created separate lines of business in support of their portals, using this increased buying power to create relationships with a variety of content partners, including content aggregators and large original content sources such as international news services.

Smaller operators have outsourced their portal to wireless application service providers (WASPs). This content is made available to the operators' subscribers, either branded by the content provider or by the operator's portal. This model is very similar to, for example, the Yahoo! portal. Also like Yahoo!, the operator's customers can subscribe to have a limited amount of content "pushed" to their wireless phones as SMS messages. For the most part, the kinds of content currently offered to be pushed to the mobile handset are regularly scheduled standard content types, such as the aforementioned horoscopes, general weather conditions, and news "snapshots." This kind of content is useful but has not taken on the cachet of "valuable" to the extent that the wireless consumer will pay a premium for it.

Intelligent push services become important to the subscriber for key reasons: convenience, more personalization than via a browser, and event-driven delivery. As wireless subscribers, especially in Europe, become accustomed to these kinds of content services, usually on a subscription basis either at no extra charge or for a small monthly fee, and receive information on a regular basis rather than having to poke around with a wireless browser to find it, a significant revenue opportunity comes into play: Offer content, or information, often on an event or "triggered" basis, for which subscribers are willing to pay a premium price because the information is perceived to be valuable.

VI. The Nascent Opportunity for High-Value, Premium "Push" Services

With the uptake of SMS–based push services beginning, following close on the heels of the person-to-person SMS phenomena in Europe, wireless carriers—and other players in the wireless services value chain—are beginning to explore "premium services" or "premium alerts."

Since, as described, the European (and Japanese) markets provide a fertile, receptive audience for information to be pushed to the mobile device, "premium" alerts are relevant, personalized, and perhaps location-sensitive–compared to "standard" alerts, which are more general and generic in nature. *Table 1* shows some examples of each.

A. What Makes a True Premium "Push" Service Offering?
Intelligence for push services means being relevant, personalized, and timely. If an alert (a message, some information, some content, etc.) is to be pushed to a subscriber such that the subscriber is willing to pay extra—perhaps a lot extra—for it, then the decision to send the alert must be based on a number of attributes of the subscriber and the content. The subscriber should not have to engage in a tedious search process for information; rather, a set of criteria needs to be pre-established to make it extremely easy to use. This is a key reason why "push" is such an important content-delivery model. The service provider must provide an easy to use interface for the user to create subscriptions to all sorts of alerts (self-provisioning), as well as to create and modify a profile of characteristics that is used to decide when a given alert is to be sent (pushed) to the mobile phone.

TABLE 1

"Standard" Alerts	*"Premium" Alerts*
Sports scores	Real-time, event-driven alerts
Stock-market data	Opt-in advertising,
Ski reports	M-Coupons
Weather	Location- and presence-sensitive alerts
Where the fish are biting	Actionable alerts (e.g., making a purchase)
Headline news	One-2-one marketing
Horoscopes	Profile-based services

Subscriber attributes: For "scheduled," standard alerts, this is fairly easy to implement and has been done so by most network operators, usually within their portal, and often outsourced to a WASP. Significantly more difficult is being able to offer event-based alerts that must be sent only when all the elements of the user's profile have been satisfied: time of day, day of week, time zone, presence on the network (i.e., whether the mobile phone actually turned on), physical location or proximity, and others.

Content attributes: The alert must be *intelligently pushed* based on all of the scheduled alert criteria that the user chooses plus the variables of event-based content (a stock hits a high or low, and the user needs to react quickly; a traffic crash just happened one kilometer ahead, and the next highway exit is 500 meters ahead; a poisonous gas just escaped from the chemical factory, and the cloud is moving to the user's position; the user has just passed near a Macy's and is sent a coupon she "opted in" for to get a special price on a new pair of jeans, but only on Thursday evenings, etc.). Clearly, the user cannot be interactively actively searching (pulling) for these events; these kinds of services are highly valuable to the user when *intelligently pushed* to their mobile phones under just the right conditions.

B. What Does the Carrier Need to Effectively Offer Premium Services?

Although the potential for significant new revenue is great, intelligently pushed content, messages, and alerts put a lot of requirements on the wireless carrier. The necessary software is complex and sophisticated: It needs to constantly perform matchmaking between myriad content sources and millions of subscribers, each with a set of very specific attributes. A robust and flexible rules engine would allow subscribers to specify the information delivered to them such that it is highly personalized and timely and delivered only under the conditions dictated by the subscriber. They also need access to standard, easy-to-use Web interfaces to set up and modify their user profile, notification services, and delivery preferences.

An additional requirement is that the software environment must make it easy for the carrier to implement new content services quickly and to easily add (or remove) and manage new content sources and types. The software must be able to track and account for every message sent and update the carrier's billing systems. It needs to be easily scalable as more users and more services are added. And, it must easily integrate with the systems in which the carrier has already invested. In short, this must be "carrier-grade" software. It is unlikely the carrier has the resources to build this in house (beyond perhaps building a prototype) and will need one or more vendors and systems integrators to do the job properly.

VII. How Carriers Can Make Significant New Revenues—and Why They Must

With all of this background, what does the revenue opportunity look like for the carriers and for other participants in this value chain? Is it significant enough to justify a substantial investment in this intelligent "push" technology and to create the partnerships needed to make it work? Are the carriers satisfied with their current means of generating new revenue?

As described, existing opportunities for new revenue are different in each of the major geographies. Dramatic uptake of intelligently pushed services is occurring new in Europe and will continue to grow. Since the European wireless market is becoming saturated, carriers serving this market are desperately seeking new and innovative revenue sources, since they can no longer depend so heavily on gaining new subscribers. Obviously, they have experienced the SMS phenomenon and want to somehow capitalize on it. They tried the "Web browsing" paradigm, using microbrowsers and WAP, and it has not yet worked well. As described, the next logical step is to ride the SMS wave by offering creative new services delivered via SMS. This is particularly attractive as the migration to packet networks (GPRS) is under way. Both the network operators and the wireless portals are now developing and launching new services, many focused on entertainment as well as affinity and permission-based "m-marketing," with premium price tags—and subscribers are biting.

The Japanese market, with its successful iMode service model, continues to grow at a rapid pace, and new push-and-pull services are rapidly being introduced that take further advantage of this receptive market and the technology base.

The North American market, especially the United States, will have the unique advantage of learning from both

Japan and Europe and applying this learning to the rapidly growing youth market that has migrated from carrying pagers to carrying mobile phones and are rapidly embracing person-to-person "texting." Similar to the European SMS phenomenon, this is creating a large receptive market for push services.

VIII. Conclusions

The SMS phenomenon in Europe, the success of iMode in Japan, and the convergence on 2.5G and 3G networks in all markets have created a hungry and receptive market for content, or alerts, to be intelligently pushed to mobile subscribers' handsets. To capitalize on this huge opportunity for badly needed new revenues, the carriers must take clear action to implement technology and operational practices that will provide them with the means to deliver valuable, desirable content to their subscribers in a way that takes advantage of existing investments in networks, software, and human resources.

A key element is to find vendors the sophisticated software and services that are needed and to implement them in a way that maximizes revenue to the carrier. In most cases, this means the carrier must implement in the carrier network rather than outsourcing and giving up a large portion of the new revenue to the outsourced service provider. Fortunately, this new genre of carrier-grade software is beginning to appear on the market. One important point is that the user experience for pull services will likely improve as higher-bandwidth packet networks—2.5G and 3G—become available and as pull services created uniquely for the small "footprint" of the mobile handset are brought to market. The most likely forward-looking scenarios are services that are implemented according to how they work best: some pull, many push, and many a mix of both.

Wireless Data in the Coming Decade

Jay English
Consultant, Network and RF Systems Engineering
inCode Telecom

Introduction

"Is that all there is?" Astronaut Al Bean's musing to Mission Commander Pete Conrad upon departing the moon during the Apollo 12 mission seems to fit the mood surrounding wireless data in the latter part of the 20th century. For all the tremendous technological advances the industry and the world saw during the previous decade, we were left feeling like there should have been something more. The promise of 3G with "always-on" high-speed wireless connections, fixed wireless broadband to home and office, and wireless local-area networks (LANs) removing the leash of cable from our laptops and personal computers (PCs) led to high expectations and an almost palpable anticipation. In spite of all the promise, excitement, and investment made, the century turned without those services making an appearance on a wide scale, and, despite tremendous technological advances and subscriber growth, so did the market.

2001 saw the beginning of man's permanent habitation of space, a concept that was only a dream when Bean and Conrad stepped foot on the moon a scant 30 years ago. It also saw what could only be described as one of the most horrific events in human history on September 11. No small wonder that somewhere in between the two our economy tumbled with technology companies, and telecommunications in particular, being hardest hit.

While the growth and promise of high-tech opportunities teetered on the brink of disaster, the determination and resolve of the wireless data industry refused to be quelled. In spite of the odds, lack of capital, and a sagging economy, bold steps were planned to forge ahead. 3G1xRTT was launched in overseas markets, wideband code division multiple access (WCDMA) and Universal Mobile Telecommunications System (UMTS) groups continued development plans, U.S. carriers announced their intent to implement a variety of data services in the coming decade, and market forecasts showed data overtaking voice and consuming an ever-increasing portion of the wireless market by 2010.

This paper is an examination of the possibilities and applications that await us in the coming decade in the world of wireless data. We will examine 2.5 and 3G services; discuss the differences between high-speed circuit-switched data (HSCSD), short message service (SMS), and packet data; and study the offerings available. Those offerings range from relatively inexpensive overlays like cellular digital packet data (CDPD) to next-generation services such as WCDMA and UMTS and include a few other increasingly popular options like SMS, enhanced data rates for GSM evolution (EDGE), and general packet radio service (GPRS). We will discuss what this means for carriers and consumers and make a few "educated guesses" as to what the wireless landscape might look like as we move forward into this first decade of the 21st century.

Current industry predictions show a strong trend toward dynamic growth in the wireless data sector. Currently, wireless data occupies approximately 2 percent of the marketplace. However, it is projected that more than 60 percent of all wireless subscribers will utilize some form of wireless data by 2007 (see *Figure 1*).

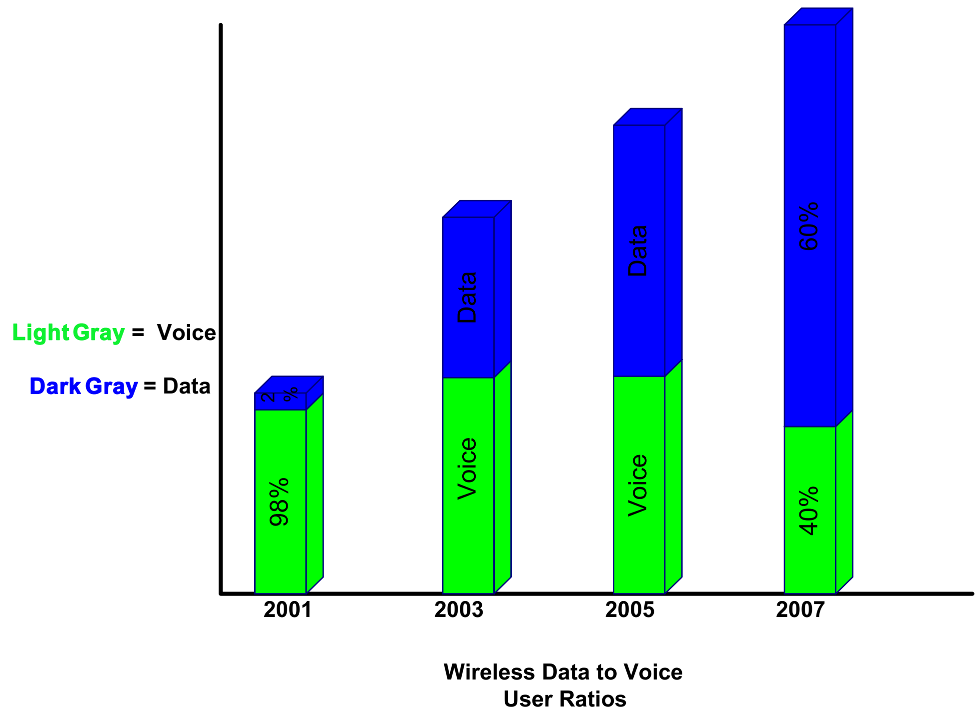
The technologies that will be implemented to enable this growth include current HSCSD, CDPD, GPRS, EDGE, and third-generation (3G) services such as 1xRTT/3xRTT, WCDMA, and CDMA2000. Each of these technologies offers unique services and benefits to both users and carriers and will be discussed in the course of this paper.

High-Speed Circuit-Switched Data

Initial efforts to provide data services to the consumer included HSCSD, which utilizes existing carrier infrastructure, with minimal modification and equipment addition, to provide the customer data connectivity over the traditional circuit-switched path. The addition of an interworking function (IWF) to the circuit-switched path allows for validation and routing of dedicated data traffic such as fax, file transfer, and Internet services over existing wireless networks. The maximum data-rate predictions for this service are 14.4 kilobits per second (kbps). Compression technology allows the user to experience speeds equivalent to approximately 28.8 kbps. Implementation of working networks was accomplished successfully by all major U.S. carriers by late 1999/early 2000. HSCSD call flow mirrors a traditional wireless call in its origination from the wireless device, connection over the air to a base station, transition to landline, and connection to the base-station controller (BSC) and mobile switching center (MSC). Where a traditional voice call would continue via the MSC to the public switched telephone network (PSTN), the data call will route to the IWF for further processing and routing to the end user or application. End users can include fax machines connected via

FIGURE 1

Wireless Data Projected Growth Relative to Voice



the PSTN, file transfers, and "Web surfing" via Internet connectivity along with virtual private network (VPN) connections via internal and external routers. An example of current HSCSD network configuration is illustrated in *Figure 2*.

The advantages offered by this service are the ability of the consumer to access services previously unavailable over wireless networks, such as e-mail and Web access. The major drawbacks include the impact on the total capacity of the carriers network, the low speed limitations, a result of the air interface, and the fact that users are charged for minutes of use as they must connect, conduct their transactions, and disconnect from the network, just as they do with voice calls. These limitations were noted from the onset of HSCSD, and new technologies evolved rapidly to overcome them.

Short Message Service

In addition to HSCSD services, carriers implemented another effective data transfer mechanism during virtually the same timeframe as HSCSD. SMS is a wireless service that enables the transmission of text-only messages between mobile subscribers and external systems, such as electronic mail, paging, and voice-mail systems. SMS provides a mechanism (via signaling system 7 [SS7]) for transmitting short messages to and from wireless handsets. The service makes use of a SMS center (SMSC), which acts as a store-and-forward system for short messages. The wireless network provides for the transport of short messages between the SMSCs and wireless handsets. In contrast to existing text message transmission services, such as alphanumeric paging, the service elements are designed to provide guaranteed delivery of text messages to the destination. A distinguishing characteristic of the service is that an active mobile handset is able to receive or submit a short message at any time, independent of whether or not a voice or data call is in progress. SMS is characterized by out-of-band packet delivery and low-bandwidth message transfer.

Initial applications of SMS focused on eliminating alphanumeric pagers by permitting two-way general-purpose messaging and notification services. As technology and networks matured, a variety of services were introduced, including electronic mail and fax integration, paging integration, interactive banking, and information services such as stock quotes. Wireless data applications include downloading of subscriber identity module (SIM) cards for activation, debit, and profile-editing purposes.

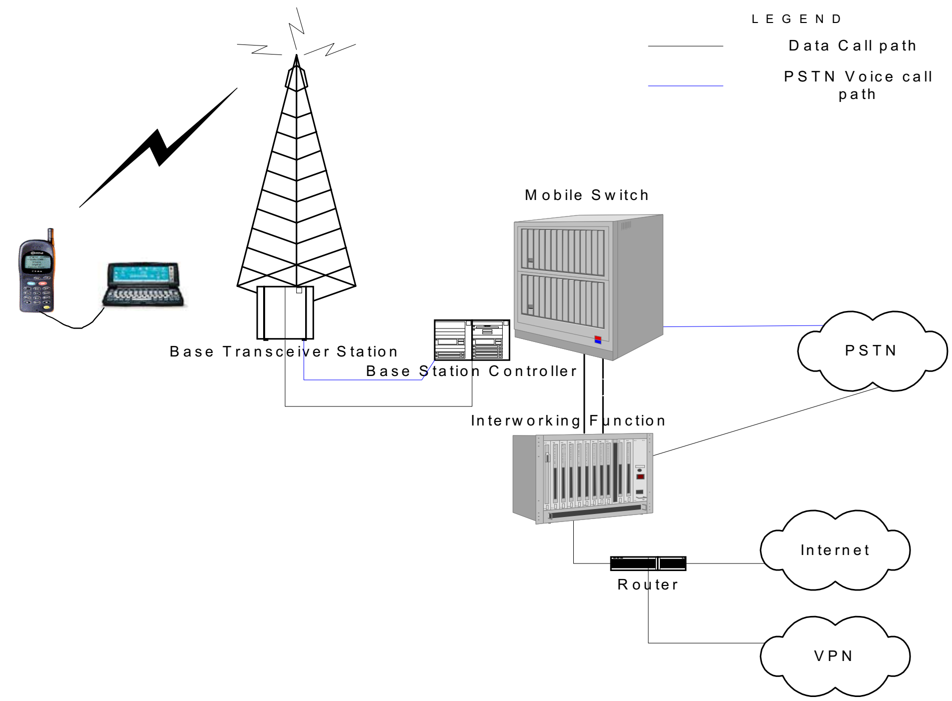
The benefits of SMS to the service provider include the following:

- Increased call completion on wireless and wireline networks by leveraging the notification capabilities of SMS
- An alternative to alphanumeric paging services
- Enabling wireless data access for corporate users
- Provisioning of value-added services such as e-mail, voice-mail, and fax/mail integration; reminder service; stock and currency quotes; and airline schedules
- Provisioning of key administrative services such as advice of charge, over the air downloading, and service provisioning.

SMS comprises two basic point-to-point services: mobile originate (MO) and mobile terminate (MT). Mobile-origi-

FIGURE 2

Example of Typical HSCSD Network



nated short messages (MO–SMs) are transported from the handset to the SMSC and can be destined to other mobile subscribers or for subscribers on fixed networks such as paging networks or electronic mail networks. Mobile-terminated short messages (MT–SMs) are transported from the SMSC to the handset and can be submitted to the SMSC by other mobile subscribers via MO–SM or other sources such as voice-mail systems, paging networks, or operators.
Depending on the access method and the encoding of the bearer data, the point-to-point SMS conveys up to 190 characters. Many service applications can be implemented by combining these service elements. Besides notification services, SMS can be used in one-way or interactive services providing wireless access to any type of information anywhere. Leveraging emerging technologies that combine browsers, servers, and new markup languages designed for mobile terminals, SMS can enable wireless devices to securely access and send information from the Internet or intranets quickly and cost-efficiently.

Intercarrier interoperability is often considered the "holy grail" of SMS. In Europe, where all carriers operate the same technology, interoperability has not been a problem. Usage of SMS in Europe has seen tremendous growth, especially within the teenage market.

In the United States, due to the dissimilarity of technologies in use, interoperability for SMS traffic has not been achieved. Current solutions, not yet deployed, include a "clearinghouse" approach in which all carriers "subscribe" to the clearinghouse routing services and "interoperability gateway" solutions. Gateway solutions convert the SS7 traffic to an Internet protocol (IP) backbone and transfer to the partner networks gateway, which then converts traffic back to SS7–compatible traffic for transfer back to a receiving SMSC. Numerous problems exist with both solutions, mostly that the carriers in the United States will not agree to a common solution.

In addition to the interoperability issue, compatibility with next-generation services is essential. GPRS and EDGE compatibility is a "*must*," as two major carriers in the Unites States—AT&T and Cingular—will be completing Global System for Mobile Communications (GSM) overlays to their time division multiple access (TDMA) networks. The intent of both carriers is to evolve to packet data solutions, either GPRS or EDGE, in the near future. Both carriers will seek SMS compatibility with their next-generation networks.

Plans for 3G1xRTT, 3xRTT, CDMA2000, and UMTS (WCDMA) also include compatibility for SMS traffic over the packet data architecture.

Cellular Digital Packet Data

The next evolution of wireless data technology is the transition from circuit-switched to packet-switched data services. In a packet-switched network, a data stream is broken into packets that are wrapped with information such as destination, length, and order (usually specified in a packet header). Each packet is transmitted separately and can take different routes from the sender to the recipient. The recipient receives these packets and uses packet header information to verify successful packet transmission and reassemble the packets into the original data. Packet-switched networks enable billing schemes based on the amount of data transmitted, not minutes used. Among the early entrants to packet data is CDPD.

The CDPD concept was originally conceived by IBM researchers in the early 1990s. In 1992, leading cellular carriers formed a standards group to create CDPD specifications, and shortly thereafter, in 1995, initial deployments of CDPD in North America began. Service availability now exists in the United States, and CDPD deployments also exist internationally in markets such as Mexico, Canada, New Zealand, Israel, and Venezuela.

CDPD is an overlay to existing advanced mobile phone service (AMPS)/TDMA networks and again builds on the existing infrastructure with minor additions and modifications. CDPD is still dependant on the traditional network for radio frequency (RF) coverage and is extremely vulnerable to frequency planning considerations and interference. The initial design of CDPD involved the creation of an overlay network consisting of mobile database stations (MDBS) and intermediate systems (MD–IS) to facilitate the packetization of data, and the utilization of unused voice spectrum. CDPD is designed to take advantage of the fact that much of the spectrum in existing voice networks is unused for a significant portion of time. CDPD utilizes the available spectrum on a per-timeslot basis to send short bursts of packetized data over the network. CDPD utilizes this “frequency hopping” scheme to scan for available slots on each channel and allocates packets for transmission based on the results of the scan. Early CDPD networks relied exclusively on this channel hopping to allocate and transmit/receive traffic. Early results indicated that packet switching became very limited in its usefulness as the capacity on the network increased. As a result, many CDPD carriers chose to utilize a dedicated CDPD channel. In this implementation, CDPD is allocated to a dedicated channel, and multiple users can be placed on the channel. The division of the packets and ability to avoid collisions is based on the complex Reed-Solomon calculations. CDPD’s reverse link is a contention-based system utilizing digital sense multiple access with collision detection (DSMA–CD) to determine if the allocated channel is busy. Two possible events can occur:

1. *Idle Channel:* If an idle channel is encountered, then the CDPD modem immediately begins to transmit data packets. The modem then waits for an acknowledgement from the base station:
   - *Successful Acknowledgement:* Packet has been received correctly by the base station
   - *Decode Failure:* Packet was received by base station but was not decoded correctly (usually because another modem begins transmission at the same time). The CDPD modem assumes a collision has occurred and “backs off.” Transmission is retried after a random delay time.
2. *Busy Channel:* If reverse link is busy, then the CDPD modem “backs off” and delays transmission for a random amount of time.

If a collision is detected, the CDPD specification uses an exponential weighting system to determine when a modem should retransmit. The back-off algorithm is designed to increase the average wait period before retransmission if more and more consecutive collisions are encountered. When the channel experiences heavy traffic from multiple CDPD subscribers, this will result in more collisions, which can cause longer delays in accessing the channel and successfully transmitting data.

DSMA–CD is very similar to Ethernet’s carrier sense multiple access with collision detection (CSMA–CD) approach for transmitting data on a shared channel.

Applications for CDPD include the following:

- Transportation: Dispatch and vehicle routing information to drivers, fleet managers, and customers.
- Mobile Professional: E-mail, Web, corporate application, and database access from anywhere
- Public Safety: Real-time access to critical information for law enforcement officers and fire fighters
- Health Care: Home patient monitoring, remote medical support, and on-site prescription orders
- Field Sales: Customer and sales order database access on the road
- Field Service: Work orders, service order details, customer and equipment histories, and product information to service employees in the field
- Telemetry: Monitor and control remote equipment (e.g., utility meters, vending machines, alarms, office equipment)
- Financial News: Up-to-date financial data, including stock quotes and analysis, bank rates, industry announcements, etc.
- Financial Transactions: Credit-card verification and other point-of-sale applications

CDPD offers many advantages over circuit-switched data, which includeIP–based and open specification (no royalties or licenses), full duplex operation, raw transmission speeds of 19.2 kbps, and an “always-on” connection, since once a CDPD modem is registered with the network, the user is connected indefinitely. In a properly designed and operating network handoffs do not affect this connection. All of this can be accomplished in a fairly cost-effective manner, as the additional infrastructure is minimal in comparison to other data services.

The primary disadvantages of CDPD are that the actual transmission speed is limited to 9.6 kbps due to protocol formatting, and real network speeds are closer to 4 or 5 kbps. In addition, to utilize CDPD in its most effective manner, dedicated channels should be used, eliminating capacity on the voice network. CDPD is also subject to co-channel and adjacent channel interference and remains highly dependant on existing cellular design for proper operation.

General Packet Radio Service

The next step in the evolution of data in the wireless world is the utilization of packet-switched services in what is known as 2.5G offerings. First to be examined is GPRS. GPRS supplements today’s circuit-switched data services and SMSs.

Like CDPD, GPRS involves overlaying a packet-based air interface on the existing circuit-switched network, in this case a GSM network. The GPRS system is implemented in such a way as to allow network operators to add a minimal number of new infrastructure nodes and upgrade software on some existing network elements. GPRS, as other packet networks, splits information into separate "packets," then transmits and reassembles them at the receiving end. The Internet is the most well known example of a packet data network.

Packet switching offers efficient use of the available spectrum, as GPRS radio resources are used only when users are actually sending or receiving data. With GPRS, rather than dedicating a radio channel to a mobile data user for a fixed period of time, the available radio resource can be shared between several users. As a result, a larger numbers of GPRS users can potentially share the same bandwidth and be served from a single cell. The actual number of users that a GPRS network can serve is dependant on the length or size of the packets sent and the constraints of the carrier's infrastructure as it relates to total spectrum made available to the customer.

GPRS facilitates mobile Internet functionality by allowing interworking between the existing Internet and the GPRS network. Any service used over the fixed Internet today, including file transfer protocol (FTP), Web browsing, e-mail, and telnet, will also be available over the mobile network via GPRS. As it uses the same protocols, the GPRS network will actually function as a sub-network of the Internet. It should also be noted that GPRS is not only designed to be deployed on mobile networks that are based on the GSM standard—the IS-136 TDMA standard will also support GPRS.

GPRS theoretical maximum speeds have been rated up to 171.2 kbps, with GPRS using all eight timeslots at the same time. This is significantly faster than the data transmission speeds possible over today's fixed telecommunications networks and current circuit-switched data services.

Also, as with CDPD, GPRS offers the customer an "always-on" connection and facilitates several new applications not previously available over GSM networks. Other new applications for GPRS, profiled later, include file transfer and home automation—the ability to remotely access and control in-house appliances and machines. GPRS allows network operators to maximize the use of their network resources in a dynamic and flexible manner along with user access to resources and revenues.

Enabling GPRS on a GSM network requires the addition of two core modules, the gateway GPRS service node (GGSN) and the serving GPRS service node (SGSN). The GGSN acts as a gateway between the GPRS network and public data networks such as IP. GGSNs also connect to other GPRS networks to facilitate GPRS roaming. The SGSN provides packet routing to and from the SGSN service area for all users in that area. In addition to these nodes, some other technical changes need to be added to a GSM network to implement a GPRS service. These include the addition of packet control units, mobility management to locate the GPRS mobile station, a new air interface for packet traffic, new security features such as ciphering, and new GPRS–specific signaling.

While we can see that GPRS is a valuable new mobile data option, offering major improvements in spectral efficiency, capability, and functionality, it is important to note that there are some limitations with GPRS. GPRS will have an impact on a network's existing capacity. As with any cellular network, there are limited radio resources that can be deployed. The extent of the impact to the network depends upon the number of timeslots, if any, that are reserved for exclusive use of GPRS. One positive aspect of GPRS is that it dynamically manages channel allocation, which facilitates a reduction in peak time signaling channel loading. In addition, achieving the maximum GPRS data transmission speed of 172.2 kbps would require a single user occupying all eight timeslots without any error protection. It is highly improbable that a network operator will allow all timeslots to be used by a single GPRS user, therefore actual customer speeds will be significantly less than the theoretical maximum. Typical single user throughput is likely to be 56 kbps in first-phase GPRS. With the phased implementation of GPRS, higher bit rates will become available on an incremental basis, reaching realistic speeds of up to 112 kbps as GPRS Phase 2/EDGE begins to emerge.

Enhanced Data Rates for GSM Evolution

The beginning of 3G evolution includes EDGE. EDGE is a 3G technology that can be introduced into both GSM and TDMA networks. EDGE will support speeds up to 384 kbps in wide areas and at considerably higher speeds within existing radio spectrum bands. EDGE provides significantly higher capacity and the same "always-on" connectivity that customers enjoy with CDPD and GPRS.

For carriers, EDGE offers a relatively cost-effective means for providing 3G services within existing spectrum. EDGE will provide the ability for carriers to offer single terminal roaming between TDMA and GSM networks in all frequency bands worldwide. EDGE is widely regarded as a key factor in access and service convergence between the GSM and TDMA worlds, leading to seamless global roaming with advanced mobile Internet services.

The first step in the deployment of EDGE will be the overlay of an enhanced core network based on GPRS technology to handle data transport within the network. The GPRS core network is a common standard for use in GSM, TDMA, and UMTS networks. Adding GPRS, an intermediate step in the evolution to 3G services, involves new and updated switching and network nodes in the core network. Further migration to EDGE usually involves a software upgrade to the radio base-station equipment. International standards for EDGE and GPRS require roaming between the two types of networks, therefore users with GPRS terminals will be able to use them on EDGE networks and vice versa.

The benefits of EDGE to the consumer are the higher bandwidths, enabling high-speed access to the Internet, multimedia and data services, and the "always-on" connections. Advantages to the carrier include a cost-effective way to migrate an existing GSM or TDMA wireless network to 3G without requiring the acquisition of new radio spectrum. EDGE also increases the overall network capacity as a result of its spectrum-efficient nature utilizing packet data transmission. EDGE offers as much as three times the capacity of GSM with GPRS and as much as seven times the capacity of TDMA networks.

Universal Mobile Telephone Service/WCDMA

The 3G migration path will also include UMTS, commonly referred to as WCDMA. WCDMA is a 3G technology designed to support high-speed multimedia services such as video, Internet, and videoconferencing.

The UMTS standard will interoperate with EDGE 3G deployments for both TDMA and GSM operators and provide transparent high-speed wireless data services to customers around the world. EDGE and UMTS share the same core network and are supported by the third-generation partnership project (3GPP)

A high-level overview of the upcoming evolution in data rates enabled via 3G WCDMA technology is subsequently quoted and can be found at www.mobilestreams.com.

3G Data Rates
The International Telecommunications Union (ITU) has laid down some indicative minimum requirements for the data speeds that the IMT2000 standards must support. These requirements are defined according to the degree of mobility involved when the 3G call is being made. As such, the data rate that will available over 3G will depend upon the environment in which the call is being made:

- *High Mobility*
  144 kbps for rural outdoor mobile use. This data rate is available for environments in which the 3G user is traveling more than 120 kilometers per hour in outdoor environments. Let us hope that the 3G user is in a train and not driving along and trying to use their 3G terminal at such speeds.
- *Full Mobility*
  384 kbps for pedestrian users traveling less than 120 kilometers per hour in urban outdoor environments
- *Limited Mobility*
  At least 2 Mbps with low mobility (less than 10 kilometers per hour) in stationary indoor and short-range outdoor environments. These kinds of maximum data rates are often talked about when illustrating that the potential for 3G technology will therefore only be available in stationary indoor environments.

In addition to the network equipment and protocols that will be needed to enable WCDMA, new cell planning methods will be required to support the 3G network rollouts. Basically, more 3G base stations will be required to provide coverage comparable to that which exists on current 2G networks.

The following information courtesy of http://www.ericsson.com/wcdma/img/WhitePaper_wcdma_ran.pdf provides additional insight into the workings of WCDMA:

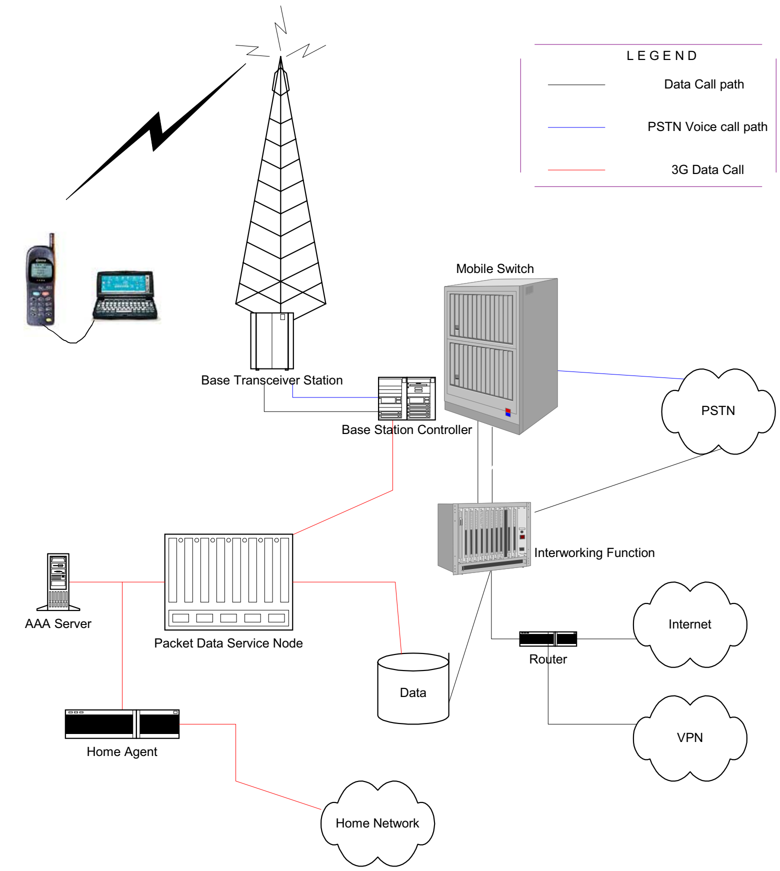
> Code Division Multiple Access (CDMA) is a multiple access technology where the users are separated by unique codes, which means that all users can use the same frequency and transmit at the same time. With the fast development in signal processing, it has become feasible to use the technology for wireless communication, also referred to as WCDMA and CDMA2000. In CDMA, a narrow band signal is multiplied by a spreading signal (which is a pseudo-noise code sequence) with a higher rate than the data rate of the message. The resultant signal appears as seemingly random, but if the intended recipient has the right code, this process is reversed and the original narrow band signal is extracted. Use of unique codes means that the same frequency is repeated in all cells, which is commonly referred to as a frequency re-use of 1. WCDMA is a step further in the CDMA technology. It uses a chip rate of 3.84 Mcps, which is about three times higher than the chip rate of CDMA2000 (1.22 Mcps).
>
> The main benefits of a wideband carrier with a higher chiprate are:
>
> - Support for higher bit rates
> - Higher spectrum efficiency thanks to improved trunking efficiency (i.e. a better statistical averaging)
> - Better coverage as the frequency diversity is improved
>
> Further, experience from second-generation systems like GSM and cdmaOne has enabled improvements to be incorporated in WCDMA. Focus has also been put on ensuring that as much as possible of WCDMA operators' investments in GSM equipment can be re-used. Examples are the re-use and evolution of the core network, the focus on co-siting and the support of GSM handover. In order to use GSM handover the subscribers need dual mode handsets.

3G encompasses many aspects of service to the wireless customer and includes volumes of information and research. A high-level view of 3G includes IP–based data and voice communications over a packet data service node (PDSN) as opposed to the existing PSTN, which is ill equipped to provide the speed and accuracy needed for future wireless applications. Current wireless systems utilize the PSTN for both voice and data services. A typical call path today would include base transceiver stations, located at the tower sites; base-station controllers, located adjacent to mobile switching centers; and common fiber or copper transmission paths to the PSTN. Wireless data integrates the interworking function (IWF) into the path to create circuit-switched data calls for fax, paging, or data transfer and now include network interface and server devices to create a path to the Internet or VPNs.

3G technology will enable the current air interface to increase available bandwidth from 14.4 kbps to 144.4 kbps in its first release, scheduled for a phased implementation beginning in 2002. Speeds of 2 Mbps will be achieved in future applications of 3G. In addition to eliminating the current air-interface restrictions, 3G will incorporate packet switching, as opposed to circuit switching, for more capability in the data arena. PDSNs will be added to the call path for 3G data traffic and will utilize IP–based systems for routing and transfer of voice, data, and video services from a common device. An example of a 3G personal communications service (PCS) network can be found in *Figure 3*.

FIGURE 3

3G Network Configuration



In the very near future, it will be possible for the customer to utilize a single handheld device to view Moving Pictures Experts Group (MPEG) files, make voice calls, receive e-mail and faxes, and surf the Internet simultaneously. In addition to providing expanded services, this IP–based system will allow for better network monitoring and troubleshooting, as well as provide billing and services in a very surgical manner. Another advantage offered by 3G is that bandwidth will be allocated on an "as needed" basis. According to Maria Palamara and Lucia Sellers of Lucent Technologies, "When a user makes a voice call, the system automatically allocates eight kilobytes per second. When the user wants to video conference or surf the Internet, the system automatically allocates more bandwidth" (http://www.lucent.com/wireless/products/solutions/tgwire.html).

3G will incorporate current CDMA, TDMA, and GSM platforms into upgraded, standards-based, worldwide deployable systems that provide the bandwidth needed by both business and home users. Palamara and Sellers sum up the potential of this technology as follows, "The third generation takes wireless communications to new levels, making it even more competitive with wire line communications in terms of cost and services. Just consider how remarkably the wire line communications marketplace has changed in the past few years. With the explosion of the Internet, phone lines now carry more minutes of data traffic than voice traffic. It is only a matter of time and technology before this trend hits the wireless industry and the third generation technology will make it possible to meet the high-speed data demands of any consumer" (http://www.lucent.com/wireless/products/solutions/tgwire.html).

3G will require a number of hardware and software upgrades, and in most cases will involve "forklift" upgrades to existing equipment. In addition, as with most new wireless technologies, the effective footprint of each base station will become smaller, as the reliance on clear, error-free data streams becomes essential. With a voice call, a missed bit or two equates to static or a missed letter or word, easily compensated for and still understandable to the callers. With a data call, that same missing bit or two results in a break in the data stream that can be interpreted by the receiving device as either an end to the message, resulting in a dropped call, or a change in the context of the entire data stream, which could generate spurious information. Either results in a complaint call from the customer. The solution is to provide better, contiguous coverage through more sites and shorter distances between them. This growth potential alone will keep infrastructure providers busy through 2005.

According to Peter Benson, a senior consultant with EMS-Global:

> The truth is that wireless data transfer isn't particularly fast or reliable. It currently runs at just 9.6 kilobits to 14.4 kilobits per second—a whole lot slower than the 56 kilobits per second speed of that modem hooked up to your PC at home that you complain is already too pokey. That's why the wireless companies are virtually giving the service away. Sprint PCS (Personal Communication Service, for example, will let you sign up for its wireless Internet service as a $10 a month add-on to its regular PCS service.
>
> But you know what? The wireless industry also isn't spending anything significant to provide this toy. Nobody's upgrading their network to deliver stock quotes to a few thousand customers. If somebody buys a more expensive Internet phone instead of a basic model from Motorola (MOT) or Nokia (NOK), that's gravy. The $10 a month is a little incremental revenue to pay for some of the marketing campaigns.
>
> ***Getting ready for the big rollout***
> All that the wireless companies are doing right now is getting the market ready for the rollout of the next generation of wireless broadband technology—or maybe it's more accurate to say technologies. In the time-honored tradition of the wireless industry, these companies are backing two competing standards:
>
> CDMA (Code Division Multiple Access) and General Packet Radio Service.
>
> Both CDMA and General Packet Radio Service offer really big increases in speed over the current 9.6 kilobits-per-second rate. According to Michael Murphy, editor of the California Technology Stock Letter, General Packet Radio Service promises 100 kilobits per second—about 10 times faster than the current wireless standard. The new CDMA standard will be even faster at 128 kilobits per second. That's about twice as fast as the current 56-kilobit home PC modem.
>
> That speed probably isn't fast enough, however. You know how long it can take to load an Internet page at home. No one will stand around in the street waiting that long. So these new technologies play tricks to make the Internet faster. For example, Nokia and other companies backing the General Packet Radio Service standard are also pushing a technology called Wireless Access Protocol, or WAP. A WAP server—and Nokia is currently giving these away—automatically rewrites a Web page from the HTML language into the simpler WAP language to speed up delivery.
>
> Wireless data speeds will continue to increase with time, but the development path for this technology is pretty clear. The next generation will be faster than the standard PC modem operating over standard copper wires, and about as fast as ISDN. (Remember that technology?) It will still lag the 640 kilobit speed of DSL, but even at 100 to 128 kilobits, wireless is in the game (www.ems-global.com).

Conclusion

As we can now see, based on the information and technological growth both documented and predicted, the entrepreneurial style that has defined wireless from the onset answers the question asked in the introduction of this paper. The long answer comprised the content of this paper and included an examination of wireless data technology from current HSCSD to early packet data and into advanced, high-speed packet-switched networks. The short answer is that the growth seen in the last decade of the 20th century is most definitely NOT "all there is." In fact, all indications are that the best is yet come and that the world of wireless data will continue to be an exciting, evolving place in which to live and work.

Understanding Multimedia Messaging

Gideon Fostick
Director, Multimedia Messaging
Comverse

Chen Porat
Director, Multimedia Messaging
Comverse

Profitable operation of next-generation cellular networks poses a significant challenge for mobile network operators. Because the deployment of these networks requires substantial financial outlays, one of the greatest concerns for mobile operators is how to recoup their massive investment in network infrastructure. Operators need to offer end users enhanced communications services that will maximize return on investment (ROI) and strengthen market-share in this increasingly competitive marketplace. Designed for both 2.5G and 3G networks, and capitalizing on the Internet protocol (IP) connectivity and increased bandwidth of these advanced networks, multimedia messaging service (MMS) has the potential to meet this need.

Overview

Multimedia messaging introduces considerable enhancements to current mobile person-to-person messaging services—enhancements that promise to enrich the end-user experience. Imagine sending or receiving your stock portfolio summary with daily charts, a birthday card for a faraway friend, a promotional clip for a potential client, and new baby footage for Grandma—all via your mobile phone or personal digital assistant (PDA). MMS augments traditional text- and voice-based messages with any combination of rich-media elements, such as photos, images, and streaming audio, and video. MMS builds upon the short messaging service (SMS) user experience model by adding new capabilities easily understood by consumers. Given the impressive popularity and proven profitability of SMS, MMS is expected to experience rapid end-user adoption and market penetration.

An international in-depth research study, commissioned by Comverse and completed in January 2001, revealed that an overwhelming 80 percent of mobile phone users would enthusiastically embrace MMSs as soon as they become available. The study surveyed three key mobile phone user markets—residential consumers, business consumers, and young (15- to 16-year-old) consumers—in London, Frankfurt, Madrid, Milan, New York, Paris, Seoul, Stockholm, and Tel Aviv.

The results of this study provide compelling evidence for service providers to exploit the opportunity of 2.5G networks and initiate an MMS revenue stream without having to wait for the advent of 3G. Their introduction to launching MMS in 2.5G environments will then enable them to migrate seamlessly to more sophisticated 3G services. Although the basic function of MMS is person-to-person messaging, it should also be viewed as a powerful enabling environment that allows the provision of additional services, such as information and entertainment services, leveraging the capability for mobile multimedia content delivery.

To take advantage of this market opportunity, network operators must fully understand the link between the end user's desired experience and the advanced technology behind MMS. End users, now accustomed to using their mobile phone for non-voice communications, will expect Internet-like multimedia messaging capabilities over mobile networks. If MMS is to leverage the success of SMS, the MMS user experience must replicate the SMS user experience—immediate, fun, and easy to use. Though the market perceives MMS as the natural evolution of SMS, MMS requires far more advanced underlying technologies. MMS breaks from SMS's native "old world" circuit-switched environment, operating instead as an IP–based solution for dealing with multimedia files of varying sizes over multiple devices. To deliver true MMS functionality while preserving the SMS user experience, operators must build MMS systems that meet three critical requirements: the deployment of scalable and open platforms, support of legacy handsets with limited MMS capabilities, and provision of content and media to stimulate MMS service usage.

The Technology

MMS versus SMS

The only similarity between MMS and SMS is in the user experience—the underlying technology is completely different. SMS is based on traditional telephony protocols, such as signaling system 7 (SS7). MMS, on the other hand, is firmly rooted in the realm of IP messaging—a concept as different from SMS technology as the mobile phone is from the traditional fixed line telephone. To mirror the SMS user experience, MMS must utilize a system of rules that take into account user preferences, handset capability, and available network resources.

SMS has gained widespread popularity in recent years, most notably in Europe and parts of Asia, but its technology does not extend to the MMS arena. SMS is strictly text-based and limits messages to 160 characters. SMS uses the signaling channel between the handset and the base station to send and receive messages. This channel was selected because it is the only packet data channel that always remains "open," but its low speed and low capacity create significant constraints on traffic. The transmission of graphic and video data demands massive bandwidth. An updated version of SMS, known as enhanced messaging services (EMSs), uses a string of concatenated SMS messages to send larger multimedia content files. Even EMS, however, would heavily tax limited signaling network resources.

The different system design requirements and conceptual paradigm shift in moving from SMS to MMS are illustrated in *Table 1*.

Because of the technology differences described, major vendors of SMS have had to build a completely new architecture to handle MMS—without reusing proprietary SMSC technology. In MMS, legacy SMSC is retained solely for the notification stage of MMS transfer.

MMS versus Mobile E-Mail

Although MMS has technology roots in the e-mail domain, it has significant and distinctive characteristics that differentiate it from mobile e-mail services and enable it to provide users with a superior mobile messaging experience. The main differentiating factors are as follows:

- ***Push:*** MMS supports push and streaming as delivery methods, using store-and-forward architecture. Push is an important factor for the end-user experience: Users will receive an intriguing notification of new multimedia messaging, followed by an immediate view of the content, because the push mechanism automatically downloads the content before notifying the user. This quick and satisfying experience was a key factor in SMS success.

- ***Client-Server Negotiation Capability:*** The MMSC detects the multimedia capabilities of the recipient's device and performs comprehensive adaptation measures on the message content to ensure optimal display.

- ***Enhanced Multimedia Presentation:*** MMS minimizes the need to use attachments. Text and images can be presented in a synchronized manner as part of the message body while other audio and video elements are incorporated in the message body by using universal resource locator (URL) references. On MMS clients that support synchronized multimedia integration language (SMIL), all media elements can be presented in a synchronized manner.

Building an MMS Solution

In selecting the right technology and architecture to develop a robust MMS system, operators must consider the experience and legacy of the various vendors as well as the inherent technology, architecture, and management support. A system should incorporate the following:

- ***Strict Adherence to MMS Standards:*** The MMSC must be fully compliant with the third-generation partnership program (3GPP) MMS model as specified in the standards specifications TS22.140 (service definition) and TS23.140 (functional description), and with the WAP Forum MMS encapsulation standards (WAP 206 through 209). Adherence to these standards is crucial to ensure interoperability between the MMSCs and MMS handsets provided by all vendors.

- ***IP Store-and-Forward Technology:*** The proven IP store-and-forward structure embodies technology for high-volume real-time multimedia processing for effective content transcoding and streaming.

- ***Flexibility:*** MMSCs must accommodate different message processing flows, defined by operator policy, subscriber preference, client operating system, or message characteristics such as type or size.

- ***Openness:*** In the MMS world, content and technical partnerships will be crucial for creating business models and service platforms. MMSCs must support these models by offering highly open architectures and dedicated interfaces based on open IP protocols. This openness will attract third-party value-added service providers.

- ***Protection of Current Infrastructure Investments:*** A substantial number of operating companies throughout the world are already deeply invested in IP–messaging infrastructure, including equipment for connectivity, storage, security, load balancing, and management. This infrastructure supports existing systems, such as unified messaging. Reuse of existing system components and infrastructure will optimize investments and save footprint, which in turn will translate into a highly competitive user service.

- ***Performance:*** The processing of multimedia traffic will result in dramatic increases in both the volume and the size of the messages. MMS infrastructure must be designed from the outset to deal with these enormous throughput requirements, expected to reach more than 1,000 multimedia messages per second.

- ***System Management:*** Managing a large and functionally rich distributed MMS system requires extensive facilities. Sophisticated management and billing tools—multi-site, Web, or graphical user interface (GUI)–based—must be made available as a part of the MMS solution and must be configurable for distributed MMS networks. Advanced tools for system monitoring and statistics analysis are important for optimizing the MMS service.

- ***Billing:*** MMS must conform to the maxim, "Bill it or kill it." Extremely flexible billing solutions, for both prepaid and postpaid subscribers, are necessary to accommodate evolving billing models, as operators learn how to best charge for MMS services. Billing solutions should handle straightforward models, such as event-driven billing, based on volume, content, or message type, as well as complex billing situations, such as reverse- and reply-charging and revenue collection and sharing for third-party service providers.

- ***Service Flow Flexibility:*** MMS systems will need to adapt dynamic subscriber behavior to service models. For this purpose, leading MMS systems are designed with flexible service behavior definition tools, such as those based on the extensible markup language (XML)

TABLE 1

MMS Functionality

Functionality	Short Message Service Center (SMSC)	Multimedia Message Services Center (MMSC)
Protocol	• Message to handset via SS7, MAP	• IP–based protocols, WAP Encapsulation, SMTP
Message characteristics	• Text messages/icons • Small: 160 bytes • Fixed size • Simple format	• Multimedia messages • Large: Megabyte levels • Varying sizes • Complex MIME format, nested and multipart messages
	This profound disparity in message characteristics dictates that the two platforms require totally different data structures and handling processes.	
Message delivery	• One-stage delivery: message push • Single SMSC handles end-to-end delivery • No adaptation of content	• Two-stage delivery: Notification push followed by content retrieval after an indefinite time period • Two MMSCs (at sender and recipient networks) cooperate for delivery. Raises discovery, routing, and interoperability issues • Content adaptation and transcoding—can require heavy processing
	These different message processes break the MMS delivery mode away from SMS and require processing overhead, which SMS platforms do not support.	
Facilities for external applications	• Requires multiple and specific protocols/solutions: SMPP/CIMD2/UCP	• Easily implemented using standard Internet protocols, e.g., SMTP, XML/HTTP
Capacity planning	• Load balancing is not easily applicable to SS7, thus planning for heavy loads is based on highly specialized proprietary platforms • Closed standards implemented by a few specialized vendors	• Use of Internet SMTP technologies ensures scalability, including load sharing and balancing • SMTP technologies are widely sourced by many vendors and proven scalable by prevalent use in Internet systems
Streaming	• Not possible	• Possible and desirable

service description scheme, which allows the addition of service components and applications as an integral part of the process. In contrast, SMS systems are closed and proprietary by nature and have no need or facilities for such dynamic service forming.

- ***Security:*** MMS is implemented in the open IP world, creating the potential for the sort of malicious acts, spamming, and unsolicited material that plague e-mail and the Internet. Both operators' and users' concerns make this a high-priority issue.

- ***Scalability:*** MMS systems should be designed with an eye to the future, enabling many options rather than being locked in to a single inflexible program. As the market matures, savvy customers will request MMS enhancements, such as increased storage and handling of messages, multi-access, and unified mailbox integration.

Expanding MMS Horizons

Multimedia Album
As subscribers adopt MMS, they will require specialized resources to help them compose fun and expressive multimedia messages. One such resource should be the Multimedia Album. This is an on-line repository of "canned" multimedia elements such as pictures and video clips—similar to the concept of clip-art files—from which a user can select professionally created images to enhance their messages. The Multimedia Album should support a variety of multimedia content types and should be accessible by Web, WAP, and standard MMS handsets. The Multimedia Album should also accept content provided by the subscribers themselves, by the operator, or by third parties. Automatic and periodic content updates should be supported while maintaining the security of the album content and interfaces.

Safe Storage
Subscribers are sure to demand safe and unlimited storage for multimedia content. However, handset memory will always be limited and may lag far behind demand as people start using handsets to view rich media such as pictures and video. As MMS usage becomes common, content-storage security will become a very important issue. As distinct from SMS, multimedia messages are bigger and more precious: "I don't want to lose valuable pictures (of family, friends, or special occasions) if I lose my handset or drop it on the floor." This suggests a new and valuable service for operators to provide network-based storage. By providing this service, operators will become trusted agents for storing users' valuable content, thereby enhancing relationships with subscribers and reducing churn.

Overcoming the Handset Challenge

A key impediment to mass-market acceptance of MMS is the expected delay in the production of MMS handsets that incorporate a dedicated client to support the standard. Such handsets may gradually trickle into the market, too slow to meet the demand of consumers who are intrigued and eager to engage in the MMS experience. However, by the innovative use of existing technology, a taste of MMS will be available to virally stimulate the market far in advance of the mass-market penetration of the devices designed to deliver it.

The lesson drawn from SMS success is that, as with all communication technologies, demand and value of MMS will only increase as the technology becomes more widely used. As an example, if one person has a telephone, he or she has nothing, but one million people with telephones have valuable communication tools. In Europe and Asia, SMS took off because most people had SMS–capable handsets. In the United States, where only a portion of the population had SMS–capable handsets, SMS did not experience the same success.

Operators can overcome the handset challenge by offering MMS systems that support legacy devices. An MMS system must be intelligent enough to determine the capabilities of the target device and adapt the content delivery as necessary. The device can be anything from a legacy 2G phone (e.g., Nokia 6110), a wireless access protocol (WAP) phone using circuit-switched service (e.g., Motorola Timeport), a GPRS WAP device (e.g., Siemens S45), a PDA (e.g., Cassiopeia) or a fully compliant MMS device (e.g., Ericsson T68).

Subscribers with legacy handsets will then be able to receive and enjoy multimedia messages and, to some extent, send them as well. Legacy devices will be able to access MMS messages via adapters to widely accepted clients—mobile and personal computer (PC) Web browsers, WAP browsers, and e-mail clients (IMAP4/POP3). This MMS experience may be more limited than the full-blown service, and sending messages may not be a streamlined process, but the initial experience will be available. It is important to note that full billing capability should be preserved; operators must be able to charge for MMS use by legacy devices, both for prepaid and postpaid subscribers.

The important implication is that those people who have purchased dedicated MMS handsets can immediately start sending multimedia messages to friends and colleagues with legacy devices. Introducing MMS to the market in this way creates the potential for a dynamic viral effect, whereby early adopters start using MMS with each other and toward friends with legacy devices, thereby stimulating and encouraging their friends to join the MMS "party" and purchase their own MMS–capable handsets.

By virally introducing the MMS experience and giving users with legacy handsets their first taste of MMS, it is estimated that uptake of MMS could be accelerated by 18 to 24 months.

Summary

MMS is poised to initiate a totally new form of communication. It may well be as big as, if not bigger than, SMS, and while it is tempting to follow the SMS model, the axioms are profoundly different and require a conceptual quantum leap.

The message characteristics and delivery flow are remarkably different, thus dictating that the MMSC messaging platform requires totally different underlying technology from that of the SMSC. Despite the anticipated delay in MMS–capable handsets reaching full market penetration, MMS can take off right now, allowing early adopters with MMS handsets to send messages to friends with legacy devices, thereby providing a viral dynamic for introducing people to the taste and fun of MMS. This will accelerate the uptake of MMS by up to 24 months, providing early entrant operators with a significant market advantage.

MMS is available here and now, in 2.5G, and operators need to get ready.

Prospects of Secure Real-Time Video Transmission over CDPD Networks

Forouzan Golshani

Abstract

With the current channel limitations of cellular digital packet data (CDPD) networks and also the lack of bilateral authentication, it is difficult to meet the bandwidth needs of secure real-time video. Various error sources make it difficult to meet the quality of service (QoS) requirement within an acceptable bit-error rate and delay. Access point limitations and additional security measures add more traffic overhead. Adaptive control over the network traffic provides extra support for end-to-end QoS. Thus adaptive multimedia applications are at the core of wireless media streaming [12]. In this paper, we first show that CDPD is suitable for real-time video streaming by use of the adaptive mediator system [11]. Then we provide an end-to-end encryption and bilateral authentication technique based on X.509 certificate between the mobile units and base stations. The overhead traffic resulting from the additional encryption and authentication layer is one of the major challenges for secure real-time video transmission over CDPD.

1. Introduction

Wireless and wired networks have similar security requirements, namely authentication of who the other party is, securing the data as it travels from the handheld device to the destination host, and ensuring that the traffic hasn't been altered en route. However, wireless networks present some unique difficulties, including limitations on bandwidth, higher levels of latency, and instability of connections. Several techniques have been proposed to address these issues, more notably, wireless transport-layer security (WTLS), which functions similar to secure sockets layer (SSL), and connection-oriented security communications using traditional protocols such as Internet protocol security (IPSec) and secure shell (SSH).

Following the complete standardization of intelligent transportation systems (ITS) in 1993, full implementation of CDPD is possible. We use the work by Pereira [1] as the basis for our work for video transmission over CDPD. In [1], the performance of a minimal CDPD network is analyzed for different applications. The CDPD network is then deployed in a major metropolitan area (in Pennsylvania in 2002), where the infrastructure is shared by all wireless applications (meaning that no CDPD channel will be reserved exclusively for ITS).

A CDPD forward link channel operates in broadcast mode. Thus there is no contention involved, other than occasional retransmission with the possibility of some queuing. The performance challenge is on the reverse link, where many users compete for a single channel. The CDPD random access protocol conforms to a non-persistent digital sense multiple access with collision detection (DSMA–CD). The forward channel generally operates far below capacity. This allows for reducing the delay in the forward link to queuing delay. For the reverse channel, due to the inherent contention mechanism, only simulation can provide the necessary delay/throughput information.

The observed performance of CDPD networks confirms the adequacy of CDPD for wide-area wireless data service, accommodating even the most demanding and time-critical applications. Sending real-time video data over a CDPD network may require strong encryption of video traffic and authentication of all involved parties in the communication. The current CDPD specifications, R.1.1, have not provisioned a mechanism for bilateral authentication between the mobile end system (M–ES) and serving mobile data intermediate system (MD–IS), i.e., base stations. The available security requirements within CDPD networks address only one-way M–ES authentication by home MD–IS (also known as mobile home function, or MHF). In addition, there is no encryption capability provided between mobile serving function, or MSF (when the user is roaming outside of the home area), and MHF. The current encryption is not enough to prevent active attacks against CDPD traffic. In this paper, a new protocol, which provides bilateral authentication and packet encryption privacy, is proposed. Due to scalability and simplicity for generalization, this proposal may be seen as addressing the security aspects of an infrastructure for wireless environments.

2. Video over CDPD

Although 2.5G and 3G wireless solutions raise high expectations, their full deployment requires some time, and in the meanwhile work on 2G systems continues. According to estimations by GTE research [1], more than 60 percent of the market will belong to public wireless usage and non–ITS applications in 2002.

The GTE research also indicates that non–ITS data load will be 2.5 times the ITS load in the reverse direction and four times higher than that in the forward direction formulas 1 and 2. The reason for different treatment is that reverse direction traffic is mainly due to e-mail alone, while forward traffic is expected to be e-mail plus World Wide Web (WWW) access.

Reverse_Direction CDPD Channel → Non_ITS_Load=2.5 x ITS_Load (1)

Forward_Direction CDPD Channel → Non_ITS_Load=4 x ITS_Load (2)

The bit rate for a typical CIF (352x288) formatted uncompressed 10 fps video is around 12.2 megabits per second (Mbps), and around 36.5 Mbps for 30 fps video. Considering the limited bandwidth provided by CDPD networks, we have to limit the quality of video transmission. A simple multimedia application that requires the transmission of one-way video (SQCIF 128x96) with 10 fps and one-way telephone quality audio can enable a satisfactory visual implementation environment for CDPD networks. As known, an 8-kilohertz (kHz) sampling of telephony quality audio requires around 64 kilobits per second (kbps) of bandwidth. The overall uncompressed bit rate will be (983 kbps plus 64 kbps) around 1 Mbps. With a high-performance compression scheme, bit rate can be reduced to 10 kbps. Considering the maximum end-to-end delay requirement of 150 ms of meaningful video, the results reported in [1] indicate an average delay of 200 ms for more than 50 percent throughput for both ITS and non–ITS traffic, which prove CDPD to be suitable for video transmission.

The near future of video coding will be content based [2, 3, 4, 12], meaning each video stream will consist of several video objects as provisioned by Moving Pictures Experts group (MPEG)-4 [4]. Each video object will have different scalability levels, content information, bit-rate requirements, and QoS parameters. A source may have multiple video objects, each with multiple importance layers. The definition of video objects within a frame will be application-dependent. Each video object will have different characteristics and priorities. The advantage of using priorities and multiple objects is that the transmission system becomes more flexible for losses.

On the other hand, content adaptation and scalability is needed to allow wireless operators to support the increasingly diverse mobile wireless devices (personal digital assistants [PDAs], cell phones, communicators, laptops, etc.) with different video and audio capabilities (operating system [OS], bandwidth, display resolution, etc.) to respond to the fluctuating wireless bandwidth during a stream session, to support the constantly evolving wireless bandwidth (CDPD, IS-95B, CDMA2000 1x, general packet radio service [GPRS], wideband code division multiple access [WCDMA]) and to enable content to be created in a one format and played back in any of a number of formats and characteristics. Adaptive control over the Internet is providing extra support for end-to-end QoS. Thus adaptive multimedia applications are at the core of wireless media streaming [12].

3. Importance of Wireless Security

Some of the most publicly used wireless networks today suffer from architectural security flaws. Wireless (or wireless fidelity, or Wi-Fi) local-area networks (WLAN) based on 802.11b can be compromised with little effort. There are several security flaws in the wired equivalent privacy (WEP) algorithm, which is responsible for establishing a secure tunnel between the mobile user and the base station. Some of the major flaws in WEP are 1) passive attacks based on statistical analysis for decrypting the radio frequency (RF) traffic, 2) active attacks based on known plain text with the purpose of adding new packets to the traffic flow by an invalid mobile unit, or 3) dictionary attacks that help a perpetrator to conduct real-time decryption of traffic. The end result is an insecure network that provides a false sense of security for its users [14].

Another standard that has some security defects is wireless application protocol, or WAP [16]. Although WAP is using WTLS, which is a subset of SSL and transparent LAN service (TLS), it lacks provisions for providing full-scale security to its users. This is due to the changes that had to be made to TLS to make it more prominent for wireless mobile users. Because of these changes, WAP is now more susceptible to some attacks, such as chosen plain-text attack based on predicting the initialization vector, brute force attack against 40 bit key in data encryption standard (DES) algorithms, and the use of unencrypted and unauthenticated "warning messages" in between regular packets. These warning messages are issued by the base station, and they can be altered and resent to a mobile user by a perpetrator with devious purposes [15].

Although CDPD standard is one of the few wireless networks that is designed to operate and utilize several data communication security standards, it fails to meet some others, such as bilateral authentication, end-to-end data confidentiality, nonrepudiation, and traffic-flow confidentiality. The availability of inexpensive and sophisticated RF scanners that can be easily obtained (approximately the size of a credit card) by anyone, adds more emphasis to the importance of providing better security for a typical wireless network.

The most important determining factor for choosing a mobile network over others is how well it can create a real sense of security for its users. Also, the users must be assured that they are the only valid users of the channel.

3.1. Security Loopholes in CDPD Networks

CDPD specs are designed so that a central authentication process, located at the home service provider, known as the mobile home function (MHF), can authenticate all mobile end systems (M–ES). In addition, the wireless traffic on the air is encrypted for privacy of the messages between the M–ES and the MSF (when the user is roaming). However, as can be seen in *Figure 1*, the CDPD network does not provide any bilateral authentication between all parties. For instance, a mobile unit (M–ES) does not authenticate the service provider at the roaming area (MSF), nor vice versa. In other words, there is no bilateral authentication process between the involved parties in the aforementioned scenario. The provided security in CDPD networks blocks all of the static attacks on the radio traffic, but this does not protect the end user from dynamic attacks. A general security rule states that if the worth of information that can be sniffed off the air is much higher than the total cost of the attack, then such an attack is highly possible. It is possible to masquerade a serving MD–IS (service provider in the roaming area) in the CDPD network. As a result of that, a disguised serving MD–IS, after overpowering the real serving MD–IS RF signal strength, can obtain the end-user credentials. In such a case, when a mobile end user observes an acceptable signal strength from a serving MD–IS, it will participate in the handshake and key exchange procedure with the unauthentic serving MD–IS. After receiving the shared secret parameters from the mobile user, the fraudulent entity decrypts the messages and extracts the most important credentials from it, i.e., a unique network entity identification (NEI) number and a special sequence number known as shared historical record, or SHR. By now, not only does the disguised MD–IS have full access to the CDPD network, but the home service provider also will deny the real mobile user during the next authentication phase. This is due to the lack of knowledge of the latest SHR by the mobile end user, which is altered each time by the home MD–IS. The only entity that has the full knowledge about the latest SHR is the fraudulent MD–IS and mobile user who is using someone else's credentials [5,8].

There is another security problem that surfaces in CDPD networks when an attacker eavesdrops on the traffic between the serving and home MD–ISs. As can be seen in *Figure 1*, all of the traffic between the MSF and MHF is exchanged on the terrestrial line. There is no encryption or authentication mechanism between these two entities. The redirect request and redirect confirmed packets (RDR and RDC), which carry mobile end-user credentials, are exchanged in clear text between the MHF and MSF.

In the following section, a security mechanism is proposed that protects all the entities involved in the CDPD network. This mechanism provides a full end-to-end encryption as well as a strong authentication scheme. This is due to providing a bilateral authentication between M–ES and a serving MD–IS and home MD–IS [8].

3.2. Proposed Enhanced CDPD Security Algorithm

The new proposed approach takes advantage of a certificate authority (CA) system based on X.509v3 [9] standard. It provides end system authentication and a secure channel for data exchange through a combination of public key and private key algorithms. All messages between M–ES, MSF, and MHF are encrypted with RSA and RC4 [6,7] after verifying the authenticity of both the sender and the receiver.

Before reviewing the proposed security algorithm, it is essential to know that all involved entities in each session must already be registered with a CA and must own a certificate and also have access to the CA's public key. This provides a trust relationship between all entities. However, in the initial stage of communications between any two parties—e.g., a request for a connection and subsequent handshake process—there is no trust between the involved entities until each M–ES validates the authenticity of other M–ES's certificate.

FIGURE 1

Required Steps for M–ES Authentication and Message Encryption

STEP	M-ES		MSF		MHF
1		TEI REQ. →			
2		← TEI Assigned			
3		← $a, p, a^y \bmod p$ IKE			
4		→ $a^x \bmod p$ EKE			
5	$a^{xy} \bmod p$	Shared Secret Quantity	$a^{xy} \bmod p$		
6		ESH <NEI,SHR> → Encrypted Message	Decrypt	RDR <NEI,SHR> → Clear Text	M-ES Authentication
7		← ISC <NEI,SHR> Encrypted Message	Encrypt	← RDC <NEI,SHR>	

In the initial stage of the connection, the M–ES communicates with the MSF by sending a request protocol data unit (PDU) and its certificate for a new identification number or temporary entity identification (TEI). After authenticating the M–ES, the MSF in return sends the TEI, MSF certificate, and intermediate system challenge number (ICN), which is encrypted with MSF public key, to the M–ES. Upon receiving the reply, the M–ES uses the CA's public key to confirm the CA's digital signature. After confirmation, the M–ES extracts the MSF public key from the certificate and decrypts the ICN with its own private key. Then it generates two random prime numbers known as the master key (MK) and end system challenge number (ECN). Next, M–ES uses the MK to create two secret keys known as read and write keys, which are used in RC4 symmetric cryptography algorithm. In the next step, the M–ES sends a packet to the MSF consisting of the ICN, which is encrypted with the write key, ECN, and MK and encrypts the whole PDU with the MSF's public key. Upon receiving this "tuple," the MSF uses its own private key and decrypts the data and extracts the MK and ECN, and encrypted ICN. MSF uses the same algorithm that the M–ES used and creates two secret keys based on the MK (read and write secret keys). Next, the MSF uses the read key and decrypts the encrypted ICN, and confirms that this is the same ICN that it has created before. This insures that the MK is issued by the authentic M–ES. After confirming the ICN, the MSF uses its write key and encrypts the ECN, and sends it back to the M–ES. Upon receiving this message, the M–ES uses its read key and decrypts the message to confirm the ECN. This insures that the MSF is the one that issued the TEI. At this point the (A) interface (air channel) is secure between the M–ES and MSF, and the M–ES may send the end system hello (ESH) PDU. The same type of security handshake must be used between the MSF and MHF for securing the channel between them.

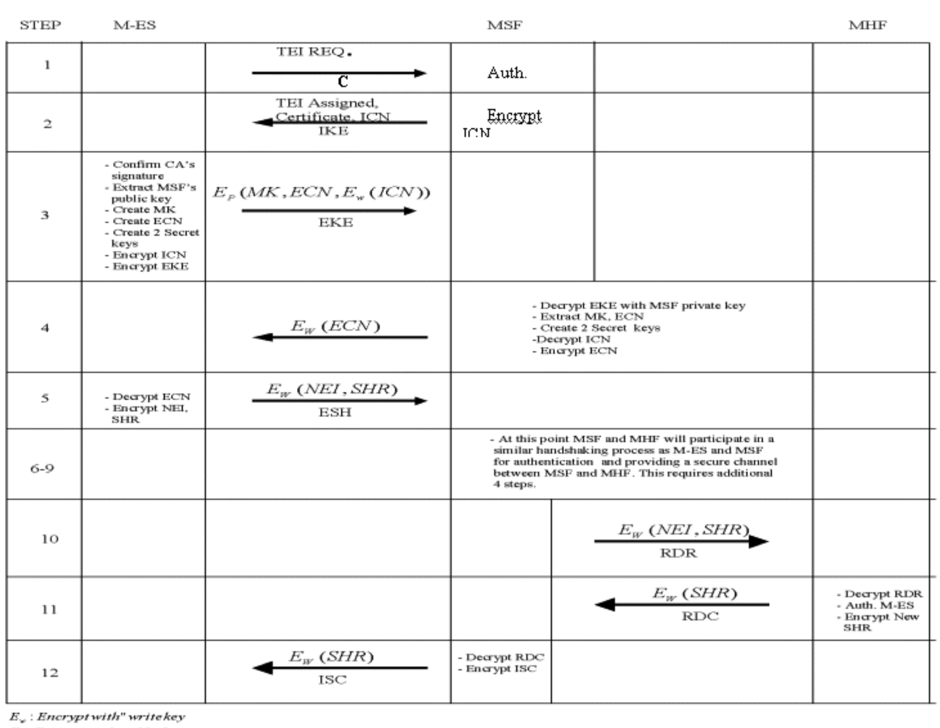
3.3. Analysis of the Algorithm

The enhanced security algorithm protects the visiting M–ES against a masquerading MSF. If a fraudulent MSF tries to masquerade its authenticity by sending a wrong certificate, the M–-ES will realize that as soon as is it reconfirms the CA's digital signature. It is extremely expensive (even impossible) to counterfeit the CA's digital signature, because the digital signature is the CA's encrypted hash value [6] of CA's encrypted hash value [10] of the contents of the certificate. CA uses its own private key to encrypt the hash value. Theoretically, the only entity that knows the CA's private key is the CA itself. Without the knowledge of the CA's private key, the fraudulent MSF must use a different pair of public/private key for encryption. If this happens, the confirmation of the CA's digital signature fails by the M–ES. If the fraudulent MSF captures the previous sessions' packets during the handshake and tries to replay them, the M–ES will accept the digital signature, but the masqueraded MSF wouldn't be able to extract the MK from the M–ES reply message. This causes the fraudulent MSF to not be able to create the read/write session's keys.

The enhanced security algorithm will also protect the MSF and MHF against static attacks during the exchange of RDR and RDC. Once the serving and the home MD–IS are both authenticated, they are the only entities that know the ses-

FIGURE 2

Required Steps for Enhanced Security in CDPD Networks



sion read/write key. This will create a fully secure channel between them. In case an eavesdropper tries to capture the ongoing packet between MSF and MHF, everything would be encrypted and meaningless.

4. Performance Considerations

The proposed additional security layer introduces some overhead, which impacts the performance of the system. In the following section, some measurements and comparisons are made in order to illustrate these impacts. These following measurements are based on the best condition in a CDPD network, which is behaving like a low-bandwidth wired network.

4.1. The Impact of Security on System Performance

Based on the research done in [17], a typical 60-bytes-long message needs additional 24 bytes (16 bytes for MD5, 4 bytes source time stamp, and 4 bytes for destination time stamp) to include data integrity and authentication information in the messages. This increases the original size of the message by 40 percent. Typically, this results in an increase of the service time for that message. If depicts the service rate of the CDPD system without the additional security layer, and is the service rate after adding the security layer, the following equation illustrates the service time increases due to a lower service rate after adding a security layer:

$$s = \frac{\mu}{\mu'}$$

Also, the real throughput of the system is the minimum value of for the different components (e.g., M–ES, MSF, MHF) in a CDPD network:

$$\mu_b = \min_{i \in [1,..n]}(\mu_i)$$

The statistics show [17] that the service rate for 100-bytes packets is about 1,900 packets per second. Packet authentication and authorization drops this service rate to 1,500 packets per second, implying a 20 percent increase in service time. On the other hand, the encryption alone drops the service rate to 630 packets per second (a 300 percent increase in service time).

Taking into account the packet retransmission time and transmission control protocol (TCP) congestion-control mechanism, the harsh wireless environment lowers the service time even more. To remedy some of these side effects, the TCP layer in a CDPD network must be optimized for such an environment.

5. Testing Environment

The initial set of tests for our research includes a feasibility study of video streaming over CDPD. To show that real-time video-streaming quality is acceptable over CDPD, we used Luxxon's adaptive mediator system [7] over a CDPD modem connection.

The mediator system is a real-time transport protocol (RTP)/real-time streaming protocol (RTSP)–based wireless streaming solution that takes in open standards–based MPEG video and audio, provides broadcast service through real-time video and audio transcoding, and can also perform off-line video and audio transcoding to create media-on-demand content for storage on file servers. The mediator system meets the challenges of wireless streaming by performing the adaptation, which is necessary to handle the diversity of devices, formats, and network characteristics. It provides bandwidth adaptability, end-device detection, and transcoding media to various bit rates and formats. Through these adaptability features, the mediator system supports various wireless bandwidths for 2G, 2.5G, and 3G networks, such as CDPD, IS-95B, CDMA2000 1x, general packet radio service (GPRS), and wideband code division multiple access (WCDMA).

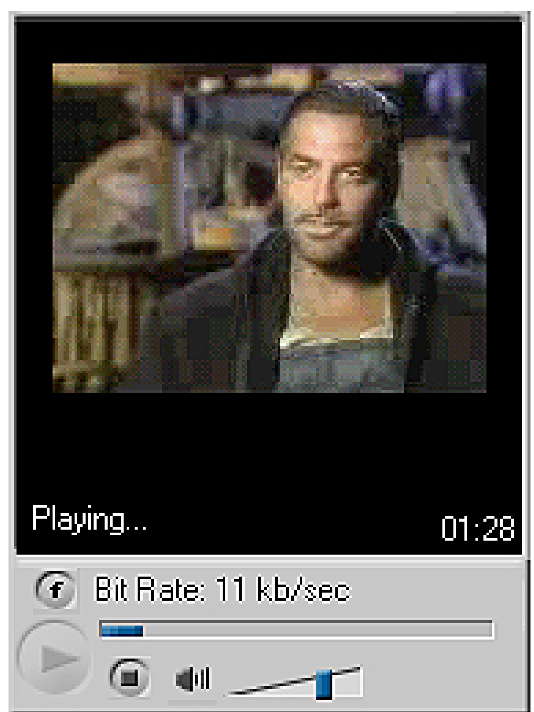
Figure 3 shows a MPEG-4 video and GSMAMR audio clip with a frame rate of 5 fps and bit rate of 11 kbps. The CDPD connection was established through a UNIDEN Data-1000 modem with an average received signal strength indication (RSSI) of –76 dB with 600 mW antenna power output.

6. Conclusion

Any proposal related to an infrastructure for wireless and mobile networks must include an urgent discussion of how the so-called "gap in the WAP" can be plugged. This gap surfaces in a variety of ways in all other frameworks. Clearly, it is the device makers and the service providers that should provide the security protection. However, it is imperative for the consumer to understand the threats, be prepared with the necessary tools to combat them, and show readiness to deal with them should precautionary measures are shortcut.

FIGURE 3

Sample of Luxxon Player Streaming an MPEG-4 Clip at 11 kbps



In this paper, we show that real-time video streaming is possible over CDPD networks. We suggest the usage of adaptive video over CDPD networks for better bandwidth utilization. To enable adaptive video streaming over CDPD, we have used the mediator system of Luxxon Corporation. X.509 v3 certificates and public key/private key encryption are used for further security enhancement of the video traffic. The X.509 certificates provide bilateral authentication for both M–ES and MHF. Also, the performance impact due to additional proposed security layer to the CDPD network also needed to be addressed. One possible solution to this problem would be an optimized indirect TCP (I–TCP) being implemented at the mobile database station (MDBS).

Earning Revenue with Third-Generation Wireless: Killer Applications

Allen Groh
Director, International Trade and Regulatory Compliance
Ericsson

Sources of revenue in telecommunications and media are constantly changing—the result of ever-advancing technology. In the early days of long-distance service, charges for minutes of long distance were very high, due in large part to the cost and inefficiency of carrying analog signals long distances over copper wires. Advances in transmission technology from copper wires to microwave to satellites to fiber-optic cable and now to dense wavelength division multiplexing (DWDM), which dramatically increases the capacity of fibers, have made long-distance phone calls very inexpensive. Bandwidth has become a commodity, much the same way that long-distance service has become a commodity.

For third-generation (3G) wireless systems, financial analysts and service providers are asking, "Where will the revenue come from?" The cost of 3G wireless licenses in Europe has put the pressure on return on investment (ROI) for deploying 3G services. The answer is most likely in services offered via high-speed data networks that include voice traffic. The next question is "What will be the applications that will attract the most users and produce the most revenue?" The traditional source of wireless revenue—air time—is also becoming a commodity. Competitive pressure from as many as five wireless carriers in one metropolitan area helps to drive down the price of air time and thus decrease profitability for voice services. The introduction of data services will increase revenue only if a large number of customers subscribe. So far, wireless application protocol (WAP) offerings have had limited success. What is clear, though, is that significant add-on revenue can be earned by deploying data service along with voice only if enough customers will pay money for it

Killer Applications Defined

In the information age, killer applications have produced broad market appeal for consumer electronics in many forms. One of the first was the electronic calculator, which was one of the first consumer applications for newly invented integrated circuits. The electronic calculator, which was based on an early integrated circuit designed for missile guidance, replaced mechanical calculators and eventually the slide rule.

Advances in semiconductor design produced the first engineering calculator, the HP 35 followed by the HP 45 (both from Hewlett-Packard), which could do the job of the most sophisticated mechanical calculator faster and which cost 10 times less—about $400 versus $4,000 for an equivalent mechanical calculator. Soon, as the price came down and functionality increased, calculators made engineering slide rules obsolete (1975).

Perhaps the most famous killer app that launched the age of personal computers (PCs) was VisiCalc, an electronic spreadsheet program similar to today's Microsoft Excel. It literally saved a forest of trees in the form of paper spreadsheets and tons of rubber used in erasers. VisiCalc played another, much more important role. In the late 1970s, PCs were considered toys for hobbyists. Apple and Sinclair owned the market, but applications, where they existed at all, were more entertaining than useful. One could hardly make a case for PCs as a business tool, let alone for becoming an important economic driver of the 1980s and 1990s. VisiCalc, which was programmed to run on the Apple II computer, made the job of accountants infinitely simpler in preparing budgets and business plans. Just the idea that changing one number anywhere on a spreadsheet would result in automatic recalculation of the entire page revolutionized the financial planning segment of the business world. Sales of Apple computers took off like a rocket. The desktop PC as a business tool was born (Source: Texas Instruments, 1981).

In 1981, Texas Instruments, at its Corporate Research Laboratory in Dallas, was developing a word processor program for the TI 99-4 PC that would soon be sold at a street price of $399. Business word processors from Xerox, IBM, Philips, and Wang were replacing the typewriter at a significant premium—costing $6,000 to $15,000 per workstation. The prospect of a less-than-$1,000 word processor (including the computer, necessary peripherals, and software) was perceived by marketing folks as the next "killer app" for PCs. Alas, the project was not completed (the 99-4 had some fatal flaws that caused it to crash in the middle of various tasks). Word processing on PCs did later became the killer app of the IBM PC and its clones. Why spend $10,000 for a word processor when you could achieve the same goal with a $3,000 IBM PC or clone running Word Star (an early disk operating system [DOS] version of word-processing software). Small, medium, and large businesses by the thousands bought IBM PCs and clones (most notably Compaq) because they could run Word Star and Lotus 123 (the next-generation spreadsheet program that replaced VisiCalc).

Killer applications put technology to work. The Internet became a crucial business tool with e-mail. Other important applications, such as the ability to do on-line research and e-commerce, have propelled the Internet revolution. *Figure 1* shows a few of the important milestones that have propelled the Internet to where it is today. The creation of the Mosaic browser followed by Netscape certainly qualifies as a killer application. Mobility may provide the next great boost to the growth of the Internet.

The promise of high-speed mobile Internet connectivity with 2.5 and 3G wireless applications provides some interesting food for thought as to how the Internet, liberated by wireless mobility, can change the way we communicate, do business, are entertained, or become educated. Before these sweeping changes can take place, various regulatory and security problems remain to be solved.

Restraints to E-Commerce Transactions

Governments and the private sector in countries around the world are grappling with issues that could slow down or even kill the growth of the wired and wireless Internet. Issues such as e-commerce taxation, privacy, and transactional security are at the heart of most of the trade-related discussions domestically and internationally.

Taxation

Taxation is a sticky problem. Nations, states, cities, and local communities are very concerned that their funding, which is based, at least in part, on sales tax revenue, will be eroded by e-commerce, which is protected under a Congressional moratorium on taxation in the United States. European Union member states, which rely on value-added tax for a large proportion of their budgets, have proposed that value-added tax (VAT) be imposed upon companies that conduct business over the Internet in their country. Such an imposition could cause a U.S. e-business to simply refuse to sell products to anyone residing in any of the 15 E.U. member states. This would clearly be a consequence that would disrupt the rapid growth of e-commerce and the growth of the Internet in general.

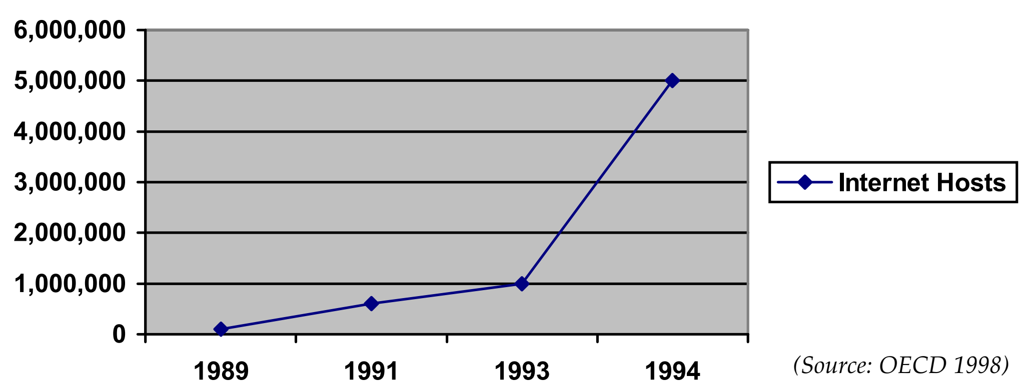
In *The Economics of Electronic Commerce*, Choi et al states that "to at least maintain the current level of tax revenues, state and local governments need to figure out how to apply existing rules of taxation to electronic transactions…similar situations are found globally." The Texas Sales and Use Tax Definition Sec. 151.005 defines tangible personal property (subject to taxation) as "personal property that can be seen, weighed, measured, felt, or touched or that is perceptible to the senses in any other manner." From this definition it appears that packet data is tax exempt. In another example, a purchase made out of one's state of residence is normally tax-exempt. What then is to prevent an Internet retailer from locating in two or more states and always doing "out-of-state" business? Clearly, tax laws will have to be changed and e-commerce defined before it can effectively be taxed.

Privacy and the Safe-Harbor Agreement

Privacy has become a hot issue, particularly in trans-Atlantic trade. European privacy rules allow individual member states to set their own levels of privacy protection for their citizens. This is a significant potential problem for U.S. e-business companies doing business with European customers. If a U.S. e-business company does not protect consumer data according to the laws of the member state in which their customer resides, they could be in violation of the law.

FIGURE 1

1989 HTML Invented; 1991 NFS Allows Commercial Use; 1993 Mosaic Browser; 1994 Netscape Browser Released



(Source: OECD 1998)

The U.S. Department of Commerce and the U.S. Trade Representative have successfully negotiated the issue with the European Commission and the member states to establish a "Safe Harbor" agreement. U.S. companies wanting to do e-business in Europe can sign on to the Safe Harbor agreement and then follow one uniform set of privacy requirements.

Network Security

Choi et al states that "unsecured transmission on the Internet is often sited as the main deterrent (to) rapid growth of electronic commerce." Add mobility to the equation, and the problem grows. The government tends to get involved at both ends of the security spectrum. On one hand, in the name of law enforcement and national security, there have been restrictions in place on the export of products with advanced encryption (a necessary element of security). Fortunately, the U.S. Department of Commerce and other agencies involved have realized the link between restricting encryption algorithms and the disadvantage it places on U.S. industry, not to mention the potentially harmful effects on the economy caused by inadequate levels of security.

At the other end of the security spectrum, the Department of Commerce's National Institute of Standards and Technology (NIST) and the National Security Agency (NSA) are participating, along with other governments and industry, to develop a "Common Criteria" for network security. The Common Criteria document states that "the Common Criteria represents the outcome of efforts to develop criteria for evaluation of IT security that are widely useful within the international community...and opens the way to mutual recognition of evaluation results." One of the goals of industry is to develop the Common Criteria as a consensus standard accepted by all parties and not regulated by national governments.

The Evolution of New Applications

As with the early computers, wireless applications will evolve together with enabling technology. An article in *TelOSSource* dated March 2001, Susan Weese said that "the wireless industry is standing astride another technology migration chasm. The market drivers for faster, content-enriched wireless services require a leap from existing networks and services to an entirely new business model. This transition is far more complex than the jump from analog to digital services just a few years ago. Delivering new services and enabling this wireless convergence between telecommunications, information technology, media and content will be a difficult and potentially rewarding task for enterprises…along with (managing) ordering and billing of new services, content providers must develop high quality, multimedia content to feed those new services "

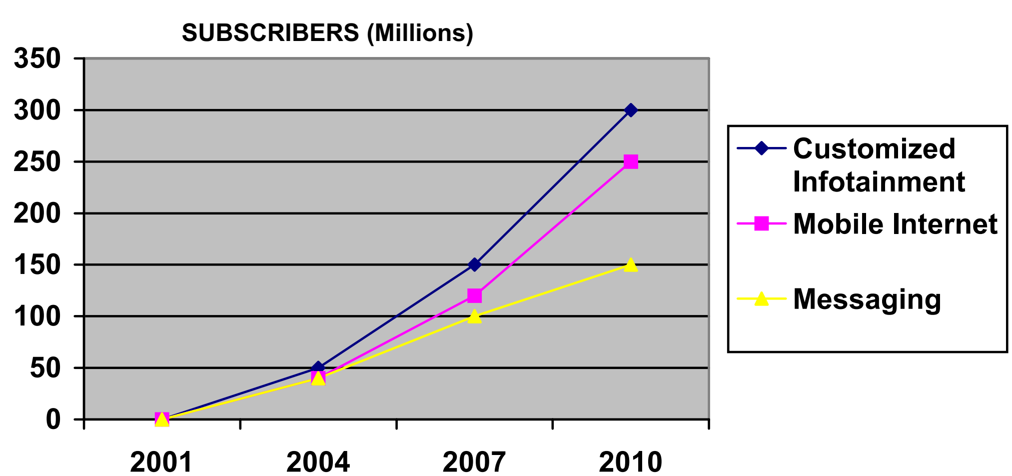
Steven Hayes of Ericsson, who chairs a subcommittee in the Third Generation Partnership Project (3GPP), which is made up of wireless manufacturers and carriers, said, "I think one of the key issues with transition to the wireless Web will be the shift from a telco model to an Internet model of services. In the past, telecommunications services have been referred to as a 'walled garden,' and within that garden, the subscriber has good services available, but only services a specific telecommunications company provides. With the transition to the mobile Internet, there will be greater opportunity for third party service providers." *Figure 2* shows forecasted numbers of subscribers for three different 3G services (Source: *TelOSSource*, March 2001).

Japan's i-Mode Business Model

Some of the multimedia applications developed for 2G systems that will likely transfer to 3G systems can be found today in NTT DoCoMo's i-Mode service. The always-on Internet service over cell phones has grown from 6 million subscribers to 20 million in one year. Applications have developed rapidly, providing a good look at what people will pay for. One of the surprises has been a service that provides a "Pokemon" screen saver to cell phones. Literally millions of subscribers pay a little more than U.S.$2.00 per month to download updated Pokemon characters.

Wireless Week's Brad Smith (March 12, 2001) said, "To understand i-Mode's acceptance it is necessary to look at the serv-

FIGURE 2



ice both as a technology and a business model. i-Mode is packet-based unlike the circuit-switched solutions that most Wireless Applications Protocol (WAP) carriers traditionally offer….What i-Mode offers to end users is rich content. DoCoMo has applications partnerships with more than 795 companies and 39,150 Web sites." There is no charge for Internet access, instead Web sites can charge for access. Some sites are free, but those providing value-rich content—such as news services, maps, and games—charge as much as U.S.$3.00 per month.

DoCoMo is taking i-Mode around the world with investments in AT&T Wireless (U.S.$9.8 million), KPN Mobile in the Netherlands, and Telecom Italia Mobile. DoCoMo is also leading everyone in the deployment of 3G services. They are building a wideband code division multiple access (WCDMA) network in Japan that will begin trials in May and be ready for commercial service in October this year—well ahead of any other carrier.

In a *Wall Street Journal* article (December 11, 2000), David Pringle said, "i-Mode is a huge hit in Japan, now the big question: will it travel well?…translating i-Mode into other languages is probably the least of DoCoMo's worries. Analysts believe that a lack of compatible handsets and suitable networks will make it difficult for DoCoMo to replicate the service in Europe…(But) The company has a gold mine of information about i-Mode that could be used to design a more compelling wireless Internet experience in Europe."

Killer Apps

So, what will make 3G phones become, in the words of the International Telecommunication Union [ITU], "an indispensable life tool carried by everyone, everywhere, just like a wallet or purse"? For starters, what if you didn't need a wallet—or purse, or cash, or credit cards, for that matter—to pay for things? The electronic wallet is available today in, of all places, Estonia. Drivers there can use their Global System for Mobile Communications (GSM) phones to pay for things such as parking fees.

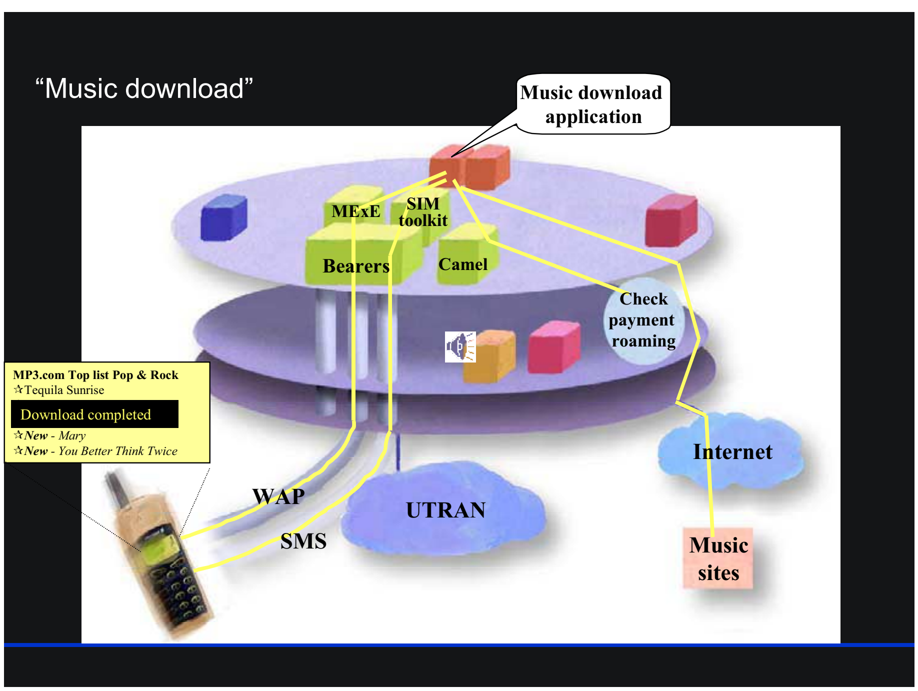
The success of the electronic wallet depends heavily on network security. It also will require re-thinking of how payment transactions are handled. Once these issues are worked out, electronic payment on 3G phones, perhaps by communicating with cash registers through a Bluetooth connection, may well be the first "killer app".

Christopher Wu of Yahoo!, in a December 11, 2000 *Wall Street Journal* article, said, "The best way to get consumers on the mobile Web is to help them use it for old-fashioned shopping, in-person, at stores…..E-wallets are a necessity for any type of m-commerce. There's no way you're typing in all that (credit-card information) every time you want to buy something." With a sufficient level of security protection, the e-wallet will certainly become the basic tool for m-commerce.

Music via Wireless

Shawn Young, in a *Wall Street Journal* article (December 11, 2000), said, "Music is a strong candidate to become a killer app, analysts say. Mobile devices could combine the enormously popular success of online music with the portability of a Sony Walkman." Ericsson currently makes a Moving Pictures Experts Group (MPEG) Layer-3 (MP3) music module for GSM phones. The added bandwidth of 3G networks (384 kilobits per second [kbps] to 2 megabits per second

FIGURE 3



[Mbps]) could indeed make mobile music a killer app. *Figure 3* shows how a music purchase would be transacted over a mobile network.

Location-Based Services

The Federal communications Commission (FCC) has ruled that wireless carriers must provide location information for 911 calls. The ruling calls for ultimately locating a mobile phone within 50 to 150 meters. Today, carriers can identify which cell site the call is coming from, but that guarantees only that the call is within one to several miles from the base station. That information would not help an ambulance driver find someone in need of emergency medical treatment. There are essentially three technologies being proposed to provide pinpoint location information. The first is network-based and uses triangulation based on the time it takes for a signal to travel to two or three base stations or the time to reflect from known objects near a base station. The second technology is handset-based, using the Global Positioning System (GPS) in the handset. The third is a hybrid technology that requires modifications of both the handsets and base stations. The cost of installing any of these technologies is estimated be in excess of U.S.$1 billion.

Leave it to entrepreneurs to find a commercial opportunity in an FCC mandate. Young, in the *Wall Street Journal*, said, "Analysts expect a proliferation of location-based services that tailor the content to a user's location, providing directions to the nearest theater, say, or the neighborhood Italian restaurant or service station. For such convenience, the theory goes, tightfisted Web browsers might finally be willing to fork over some money."

Games and Other Revenue-Generating Applications

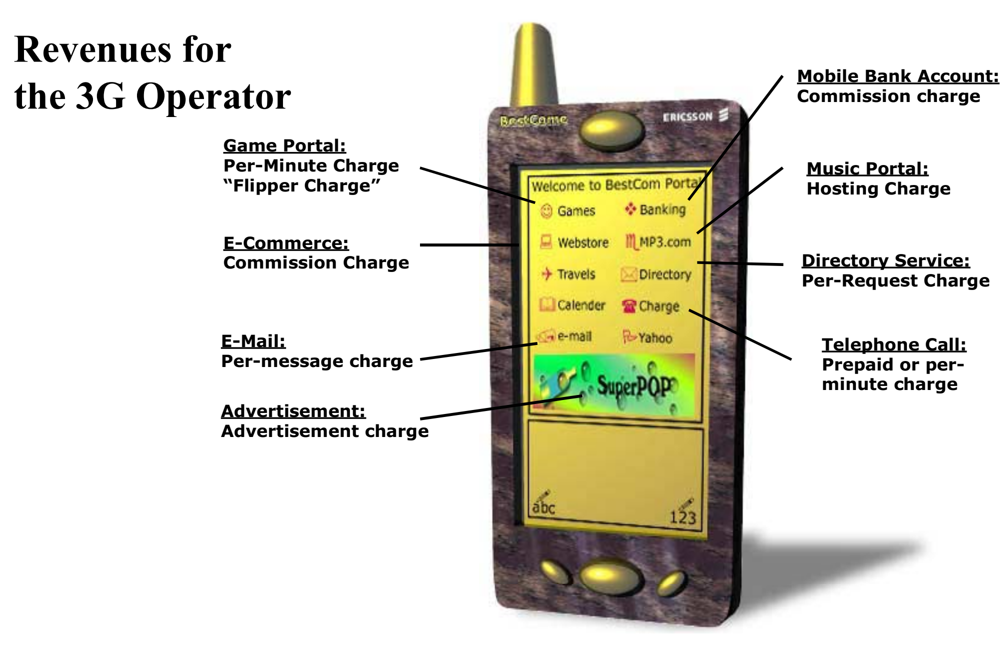
NTT DoCoMo reports that more than half of the i-Mode pages accessed by users are cartoons, games, horoscopes, and other entertainment services. Considering that many young people use computers for playing games, it is easy to imagine that entertainment, including games, is likely to contribute to more than a few killer apps.

In his *Wall Street Journal* article, Young identifies several potential killer apps, such as messaging, which would provide a natural extension of wired e-mail. In Europe today, there are 15 billion messages sent per month on GSM short messaging services (SMS).

Young mentions other applications, such as comparison shopping, movies (downloaded video), and a very important area of "Business Missions." He says, "Many experts believe the real money lies in business use of the mobile Web. CreSenda Inc., a closely held Los Angeles company is beaming real-estate listings, maps and images to real-estate agents….More broadly, industry experts say, giving people mobile access to corporate networks—so they can handle normal business transactions from lightweight, easy-to-use devices—could be a real killer application on the wireless Web."

Revenue generation for the carriers and the content providers will probably look much like the i-Mode model of micro-payments. DoCoMo adds charges for Web site access to the user's monthly bill, takes a nine percent commission and sends the rest to the content providers. *Figure 4* shows how 3G revenue may be earned by carriers and service providers.

FIGURE 4



Conclusion

That 3G wireless services will change the way we live, do business, and are entertained is easy to imagine. The mobile Internet will also change the way we are taxed and will pose vexing problems for regulatory authorities. Getting there is full of obstacles that must be overcome. Operators, equipment manufacturers, and content providers will need to manage new challenges such as the cost of 3G licensing (U.S.$230 billion in Europe), the anticipated cost of network build-out, and the cost of developing content that will eventually produce the revenue to reach profitability. The transition from first-generation analog networks to second-generation (2G) digital services offers a model, but the transition to 3G and the mobile Internet is much more complex. Instead of simply introducing a better system for voice calls and later SMSs, as was the case with 2G, we are adding the Internet and mobile commerce. There will be mistakes and failures along the road to 3G, but as Columbia University Professor Eli Noam said, "a lot of people tried to fly before the Wright brothers came along."

The Evolution of Mobile Network Backhaul Architectures

High-Capacity Multiservice Networking for Mobile Backhaul Applications

Larry Keith
General Manager
Millimetrix Broadband Networks, Inc.

Introduction

The demand for new data services combined with the growth of mobile networks requires mobile operators to begin planning the evolution of their backhaul networks to support new network requirements. Additionally, the public's increasing reliance on mobile networks creates the need to improve network reliability and availability, while economic realities drive the need for lower-cost network solutions. These often-conflicting demands make it necessary for the operator to rethink the backhaul architecture and begin the implementation of scaleable, reliable, cost-effective backhaul network architectures.

This white paper examines the current state of mobile network backhaul architecture in both access and core networks, then looks at factors driving the network evolution toward higher capacities, new protocols, and improved reliability.

Current Mobile Network Architectures

Mobile network backhaul architectures are usually categorized into two segments, each with different network requirements. The *access network* segment includes the subscriber-to-base transceiver station (BTS) connections (the mobile wireless connections) as well as the connections between BTSs and the base-station controller (BSC). This part of the network is characterized by low bandwidth requirements, many distributed locations, and varying traffic demands.

The *core network* segment includes BSC–to–mobile switching center (MSC) connections and MSC–to–MSC connections. This portion may also include connections from BTS hubbing locations (subsequently defined) to the BSC and connections from MSCs to the wired telephone network. This network portion is characterized by high bandwidth requirements and fairly predictable traffic demands due to the concentration of traffic, and by the need for high reliability because so many BTSs are aggregated into a BSC.

Figure 1 shows the architecture for typical, second-generation (2G) mobile backhaul networks. Each of these network segments has unique requirements that drive the current mobile network architecture.

Access Network

The access part of the network includes subscriber-to–BTS (mobile wireless) connections as well as BTS–to–BSC connections; only the BTS–to–BSC connection is considered part of the backhaul network architecture. For 2G mobile networks, each BTS typically has one to four T1 or E1 circuits to the BSC; the exact number depends on the expected peak load of that BTS and the number of sectors. The communication in the access network is strictly hierarchical; the BTSs communicate only with the BSC, not with other BTSs. Each BSC may serve from a few to several dozen BTSs.

The current backhaul architecture in the access network uses either fixed wireless T1/E1 systems or copper-based T1/E1 circuits in either a point-to-point configuration between each BTS and its BSC (the "star topology") or a ring of T1/E1 radios or circuits connecting the BTSs to the BSC. Fixed wireless is used when line-of-sight is available, and the distance provides sufficient availability (typically 99.95%) for the service. Otherwise, copper facilities from the incumbent operator are used.

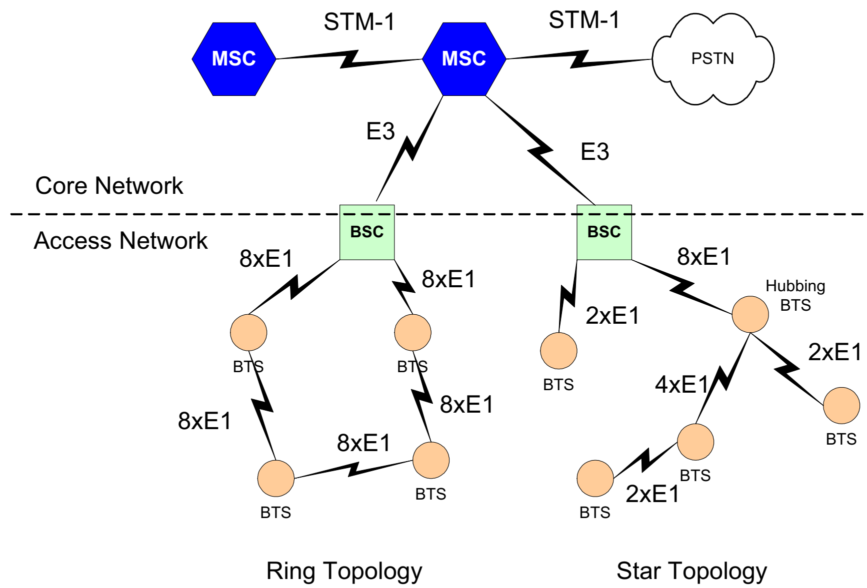
Core Network

The core part of the network includes BSC–to–MSC and MSC–to–MSC connections. In some networks, where it makes economical sense to aggregate traffic from several BTSs before connecting to the BSC, the connections from this "hubbing" BTS to its BSC may be considered part of the core network as well. In 2G networks, each BTS typically requires a digital signal (DS)–3/E3 connection to the MSC, and hub BTSs typically have eight to 16 T1/E1s or a DS–3/E3 connection to their BSC.

In the core network, communications is strictly hierarchical from hub BTSs to BSCs to MSCs. If the network has multiple MSCs, these operate in a peer-to-peer fashion, with each MSC switching traffic locally and sending traffic to the other MSC if required based on call destination. MSC–to–MSC connections are typically optical carrier (OC)–3/synchro-

FIGURE 1

Current Network Architecture



nous transfer mode (STM)–1. A mobile network may have anywhere from two to dozens of BSCs, and one to four or more MSCs.

The current backhaul architecture for the core network again uses a combination of fixed wireless and wired facilities. Due to the higher capacities required, wired facilities must be fiber-based, which may not be available outside of the urban core. Outside of urban core areas, fixed wireless is the best solution for the backhaul network. Because of the reliability needed for aggregated traffic, protected (fault tolerant) configurations are typically used for these facilities, either synchronous optical network/synchronous digital hierarchy (SONET/SDH) rings for fiber-based facilities or protected (hot-standby) configurations for fixed wireless facilities.

It should be noted that in both access and core networks for 2G systems, the traffic is strictly time division multiplexed (TDM); no packet-based protocols are used.

Evolution of Mobile Networks

Like much of the telecommunications industry, mobile communications technologies are constantly evolving. The increasing penetration of and dependence on mobile wireless communication necessitates better network planning. The advanced data services made possible through 2.5G and third-generation (3G) offerings will provide users with high-speed access to Internet and intranet applications from their mobile devices. Furthermore, operators and regulators are investigating how they can share infrastructure to reduce 2.5G/3G network deployment costs. These trends are described in the following section.

Continued Growth

The worldwide wireless subscriber base continues to grow, as shown in *Figure 2*. In the United States, which is behind much of Europe in mobile subscriber penetration, the September 11, 2001 terrorist attacks have accelerated subscriber growth, since individuals have realized the value of cell phones for security and personal use.

Studies have shown that the saturation point for mobile subscriber penetration is 70 to 80 percent in developed countries, primarily due to age and poverty. If this is true, there is still room for significant growth in many countries. This incremental growth will only increase the amount of traffic carried on the mobile backhaul networks.

Improved Reliability

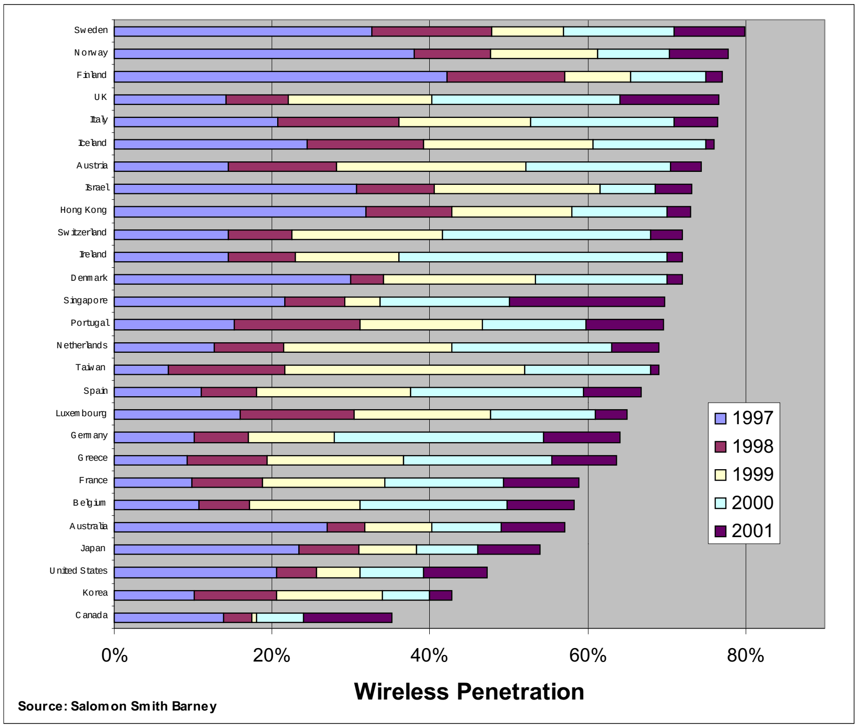
As the mobile subscriber base continues to grow, consumers and businesses that become more dependent on wireless service will also become less tolerant of dropped calls, outages, and busy signals. Consequently, operators must incorporate network redundancy in planning future networks.

2.5/3G Data Traffic

The principal driver now under way in mobile wireless penetration is the introduction of high-speed mobile data services. Known collectively as 2.5G and 3G technologies, these services include general packet radio service (GPRS), enhanced data rates for global evolution (EDGE), 1xRTT (Radio Telecommunications Technology), wideband code division multiple access (WCDMA), and CDMA2000. 2.5G systems are generally characterized as having peak data throughputs of 64 kilobits per second (kbps) to 384 kbps, while 3G systems can support data rates of up to 2 megabits per second (Mbps). Compared to voice traffic that ranges from 16 kbps to 64 kbps, data traffic could require a tremendous increase in the capacity of the backhaul infrastructure. In addition, data traffic is "bursty," meaning that the average throughput is much less than the peak throughput, while voice traffic is constant throughout the conversation. Therefore, migration from the current copper-based access

FIGURE 2

Mobile Subscriber Growth by Country



network infrastructure to 2.5G and 3G network will be a tremendous challenge.

To achieve the highest rates, users of 3G networks will need to be closer to the BTS than they need to be with 2G systems. This means that eventually the density of base stations must increase, creating a larger concentration of BTSs for each BSC (called a radio network controller [RNC] in WCDMA). This higher density will increase the traffic in the core network from each BSC/RNC.

Furthermore, while the current mobile network is built around TDM technologies, 2.5G/3G will introduce packet-switched communications into the backhaul network. Packet switching is a more effective method of supporting bursty traffic, as statistical multiplexing takes advantage of the "lulls" in data conversations to support other users, allowing more users to be supported with the same bandwidth. Asynchronous transfer mode (ATM) is the packet switching protocol currently used in 2.5G and 3G systems, although Internet protocol (IP) is widely expected to replace ATM in future systems, gradually moving from the core network into the access network.

The plesiosynchronous digital hierarchy (PDH) and SDH transport architectures currently in use are optimized for TDM traffic and do not efficiently support packet-switched communications. Any future network architecture must include efficient support for packet switching to realize the economic benefits of a shared (voice and data) transport network architecture.

Though 2.5G/3G networks will become the infrastructure of the future, they will be built on top of today's 2G networks. The migration will give subscribers ample time to upgrade their handsets, which will increase the demand for backhaul from each BTS site.

Infrastructure Sharing

Return on invested capital is of great concern for mobile network operators as they plan the rollout of 3G networks. Having paid so much for licenses, many operators cannot ever hope to earn enough return on their investment without some regulatory relief. While such relief may take the form of reduced license fees or tax reductions, many countries are considering "infrastructure sharing" to be the best form of relief, since it also reduces the impact that new networks would have on the environment. Infrastructure sharing would let operators share towers, antennas, base stations, sites, and access, reducing the cost of deploying new networks.

To the extent that regulators and carriers adopt infrastructure sharing, the need for higher-capacity backhaul will be amplified. With infrastructure sharing, two to as many as five or six operators could potentially co-locate on the same tower, creating the need for two to six times more bandwidth in the shared backhaul infrastructure.

Primarily in the United States, mobile operators have been selling their tower portfolios to specialized tower companies. This trend may expand to Europe and Asia as operators focus on their core business. Tower companies act as tower landlords, leasing space to multiple mobile operators.

Leasing tower space, such as the 3G regulatory relief previously described, serves to effectively amplify the backhaul bandwidth requirements at each tower.

Future Network Architecture Requirements

Given the evolution just described, it is clear that the next-generation backhaul network architecture must offer several improvements over today's network, while maintaining current aspects such as fast deployment, cost-effectiveness, and low delay for voice traffic. These required improvements are described in the following sections.

High Capacity
The future mobile network architecture must support higher capacities. BTS backhaul will require additional T1s, but capacities must increase dramatically in the core network. Whereas today DS–3/E3, and in some cases OC–3/STM–1, is sufficient, OC–12/STM–4 will become the base transport capacity. In the dense urban core, OC–48/STM–16 will be used.

Multiservice
The future mobile network architecture must provide efficient support for multiple services, including TDM as well as packet-based services. TDM will remain in the network to support current 2G networks, while 3G deployments will initially require ATM and, later, IP. While packet over TDM is an option, many operators will want the economies of native packet support in their transport network.

Multiple Transport Media Options
The move away from copper-speed to fiber-speed networking creates enormous challenges for operators. Fiber does not exist in the metro area outside of the urban core, so other alternatives must be considered. Broadband wireless has been and will continue to be an excellent alternative, and emerging free space optics solutions can also have a role for short distances. The challenge for the operator will be to integrate these multiple transport media options into a seamless network architecture.

High Availability
To provide the highly reliable network that customers expect, operators will need to plan around the inherent limitations of the transport media. For fiber, this means alternate routing—where this is not feasible, fiber combined with broadband wireless or free space optics. For broadband wireless links, protection switching must be considered, and outages due to rain fade must also be planned for. Advanced radios use adaptive modulation to reduce the data rate while still maintaining the connection during the worst rainstorms. For free space optics links, fog and snow fade issues can be solved with adaptive coding, again to reduce the data rate while maintaining a reliable connection.

Flexible Configurations
A high-availability network ensures that each link is almost always available by providing multiple paths for each connection. Ring or mesh architectures provide multiple routes for customer traffic, ensuring that the network stays up even when entire sites may be lost due to accidents, power outages, or natural disasters. Mesh architectures are especially flexible, allowing the operator to grow the network based on traffic demand rather than attempting to pre-plan the entire network, which can be the case with ring architectures.

Fast Deployment
The frenetic pace of network deployment will only intensify as mobile wireless networking continues to evolve. The slow pace of fiber deployment will not support the market demand. The future network architecture must use innovative solutions such as broadband wireless and free space optics to quickly deploy and make new sites operational.

Quality of Service (QoS)
With all of the changes required of the mobile backhaul network, delay requirements must not be forgotten. The future mobile network architecture must provide the strict QoS required for voice conversations, whether carried as TDM or as packets. Data is more tolerant of delay and packet loss, but the operator must still be able to provide service-level agreements (SLAs) for data to support corporate applications.

Low Cost
Finally, all of this new functionality must be economical. Going forward, operators must be even more cautious with their money for at least two reasons: operators already spent a tremendous amount on licenses, and operators don't know how much consumers will be willing to pay for mobile data. Balancing capital expenditure (CAPEX) with revenue potential has become more critical. A reasonable objective in the core network would be to upgrade from OC–3/STM–1 to OC–12/STM–4, a four-times bandwidth increase, with no more than a two-times increase in CAPEX and recurring costs.

Future Mobile Network Architecture

One concept of a future mobile network architecture is shown in *Figure 3*.

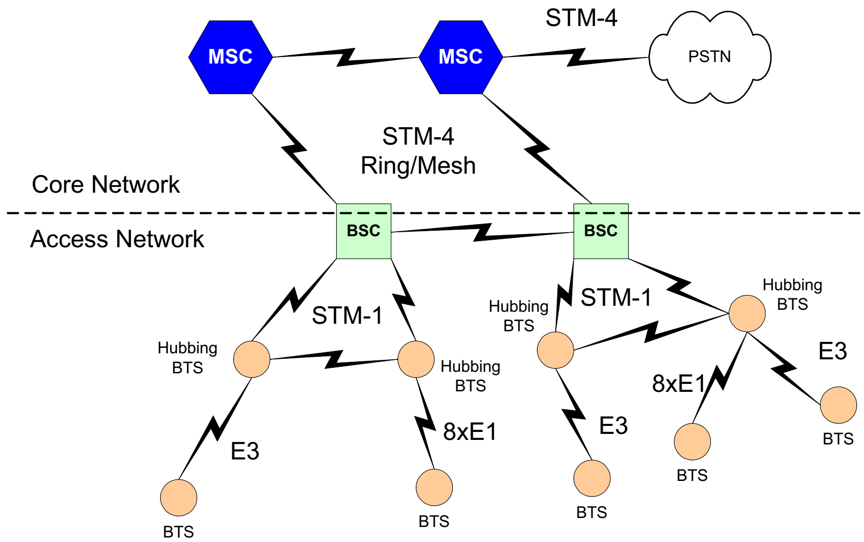
This architecture contrasts with the current architecture shown in *Figure 1* in several important ways. The future network architecture uses a variety of transport media at STM–4 (622 Mbps) rates in the core network, as opposed to the STM–1 and E3 rates of the current architecture. The access network uses hubbing BTSs to a greater extent and uses STM–1 links in a ring topology to connect hubbing BTSs to the BSCs for higher capacity and higher reliability.

Unity‘ for Mobile Network Backhaul

One solution that meets all of these requirements is the Unity‘ system from Millimetrix Broadband Networks. Unity is a multiservice, multimedium transport system that is ideal for mobile network backhaul. It facilitates the buildout of hybrid, high-capacity, optical-rate networks that combine fiber or "fiberless" links, such as licensed radio channels and unlicensed free space optics links, to create a unified transport network. The Millimetrix transport layer incorporates proprietary Optilinx‘ technology that maximizes the reliability, dynamic nature, availability, and constrained capacities of nonfiber media. Millimetrix's Optilinx technology provides a multiservice, multimedium platform that supports both legacy and emerging services and creates the modularity and network scalability that give the carrier the competitive advantage needed in a dynamic market.

FIGURE 3

Future Network Architecture



The Unity architecture is comprised of two network elements: an indoor unit (IDU) and an outdoor unit (ODU). The IDU includes service interfaces, service provisioning and monitoring, service bandwidth management, multiplexing and switching, and the Unity network-management interfaces. The IDU has a modular architecture and supports OC–3, OC–12, Fast Ethernet, and Gigabit Ethernet. The multiplexed and switched traffic is then transmitted to other Unity sites using existing fiber or a “fiberless” alternative, provided by Unity ODUs. Millimetrix offers two types of ODUs: a radio frequency (RF) ODU using a single licensed radio channel (50/55/56 MHz), and an optical ODU using an unlicensed free space optics channel. Each Unity ODU type supports a maximum capacity higher than 622 Mbps.

A service provider deploying a next-generation network with Unity will benefit from being able to exploit available fiber along with the other alternatives provided by Unity and from being able to scale the network as customers are acquired. Unity enables the immediate generation of service revenue while giving the carrier reduced CAPEX per bit of traffic.

Conclusion

The mobile network backhaul architecture of the future will be very different from today’s network. In addition to supporting more voice traffic and efficiently supporting new high-speed data services, the network will need to offer improved reliability at a lower relative cost. This network will take advantage of fiber but not be limited by it, using broadband wireless and free space optics wherever it benefits the operator. This new mobile backhaul network will be a key enabler of profitable services for the forward-thinking operator.

Content Revenue Solution for Mobile Internet Services

André Kopostynski
Director of Marketing, Customer-Management Solutions Services Unit
Ericsson

Overview

The market for wireless Internet applications is set for explosive growth both in the United States and around the world. The Yankee Group predicts that by 2005, 56 million people or 20 percent of the U.S. population will be regular users of the wireless Internet over a voice-enabled device representing 15 percent of carriers' revenue[1]. Moreover, Merrill Lynch estimates by the end of 2003, there will be approximately 47 million mobile Internet subscribers representing 25 percent penetration of U.S. wireless subscribers[2]. Service providers wanting to capitalize on the demand for wireless Internet will need to invest large amounts of capital in network expansion and licenses as new technologies such as third generation (3G) requires massive replacement in infrastructure as well as new radio spectrum.

This white paper discusses some of the major challenges that wireless operators and service providers are facing as they transition themselves from mobile telephony providers to next-generation carriers with service offerings that combine voice and data, content, and other value-added applications to an increasingly sophisticated and demanding user base. New network technologies spell new business opportunities. This paper will scrutinize how these opportunities are challenging the existing operations and business support systems (BSSs) in which carriers have invested. Additionally, the carrier support system features that are required to support the emerging value chain, where new revenue streams will be made up of several types of pricing schemes, such as airtime or data transfer fees, content fees, transaction fees for m-commerce and advertising, and other sponsored revenues, will be featured.

To justify the significant capital investments that 3G requires, operators must seek ways to maximize the revenue potential of their data offerings. After remarkable growth of the traditional voice subscriber base, where some countries have reached penetration rates in excess of 75 percent, wireless carriers now are witnessing declining average revenue per user (ARPU), increasingly saturated markets and segments, intense competition, and very few means, if any, to differentiate their offerings from rival carriers.

As virtually every competitive communications service provider is struggling to justify their network investments, it has become apparent that flat-rate, all-you-can-eat pricing schemes for accessing data networks and the Internet are not necessarily sustainable business models. Differentiation in the marketplace has been hard to achieve on any factor other than price. The downturn in the dot-com and broadband industries proved that "market-share gains at any cost" or "if you build it, they will come" were not sound business strategies, either. New entrants and intensified price competition made profitability virtually impossible to achieve, at least within the expected time frames set by venture capitalists. So given this history lesson, wireless carriers must ensure that they don't become just "dumb" transmission pipes for content and application services because, as recent times have shown, the only means for differentiation will be price. With ARPUs in mind, carriers now are re-evaluating their business strategies and market positions to capitalize on the explosive growth in demand for wireless Internet and content services projected by industry analysts.

Protect Existing System Investments

Wireless carriers have traditionally viewed themselves as providers of mobile voice services—an extension or complement—to traditional wireline telephony service. Only recently, due to economies of scale and the maturing of wireless technologies, has mobile telephony been regarded as a viable substitute to its wireline counterpart, at least from an end user's perspective. So naturally, the focus has been on customer acquisitions and the build-out of circuit-switched network capacity to handle more voice traffic. This focus is now all about to change.

Now, operators must carefully re-evaluate their business strategies and market positions to capitalize on the explosive demand for wireless Internet and content services. As service providers transition themselves from the second generation (2G) by means of 2.5G, to 3G broadband wireless data capabilities, they must redefine internal operational and business processes. This self-examination is essential to accommodate new requirements resulting from the dynamic Internet protocol (IP) world and growing customer expectations.

One of the greatest challenges facing these carriers is centered on preserving their existing operations support system (OSS)/BSS environment. Operators have invested substantial capital in these systems to automate and streamline operations and businesses processes, as most operators are not inclined to invest more capital in replacing their legacy back-office systems. A billing and customer-care system typically accounts for 20 to 30 percent of total OSS and BSS investments and often requires a significant number of dedicated systems specialists to run and maintain this complex environment.

Although support systems have evolved over time to accommodate newer services, such as CallerID®, voice-mail, and others enabled by 2G digital networks, their core functionality has been to support millions of customers with circuit-switched voice networks. Voice services have generally been priced on three simple dimensions: duration, destination, and time-of-day, where duration is the "real" metric for network capacity utilization. With the introduction of packet-based networks and services, these pricing metrics are no longer adequate.

Given the enormous capital outlay required to transition into 3G, carriers will need tools to effectively price new packet-based services based on nonstandard dimensions such as customer's perceived value, competitive forces, and network utilization. To further complicate things, carriers will also need to include partners in its value chain—adding the requirement for relationship management. Traditional legacy systems were simply not intended to support, or capable of supporting, this new industry paradigm.

So what are the viable alternatives? A total replacement is certainly an alternative; however, the sizeable capital outlay will place enormous stress on the finances of the carrier—and it's risky, given the uncertainties of future system's functional requirements.

Another approach is to invest in a dedicated IP solution and run it in parallel with the existing legacy system. This certainly will reduce the risk and the cost, but there are some apparent drawbacks, such as operational inefficiencies of having to operate and maintain two complex systems as well as making it difficult to effectively bundle voice and data services into attractive, convergent offerings. Additionally, there is the possibility of having to generate two separate invoices to the same customer (one for data services and one for voice).

A more cost-effective and even less risky alternative may be to explore enhancement opportunities to the existing system environment. Because many key business processes will essentially remain the same (invoicing, payment handling, taxation, account reconciliation, etc.), why replace the entire environment? The core changes in transitioning to 3G will stem from the network side and how to collect, process, and rate the usage records, price the delivered service, and share revenue where partners are involved—before the information is passed on to the billing and settlement systems.

Existing OSS/BSS systems support the voice business well, which will also remain the key revenue source for some time to come. However, with the introduction of IP networks and content-based services, carriers need a dedicated focus on content mediation.

Content mediation is a term applied to represent the collection, aggregation, and processing of raw usage data generated in IP–based networks such as the Internet. In a traditional circuit-switched voice network, mediation is relatively straightforward task, because the central point of collection is the switch itself, which typically generates all the required information to bill for the call; this information is often referred to as CDRs or call detail records. However, in an IP network, this represents a much bigger challenge, because there is no single device from which to collect all the necessary usage details. To capture meaningful usage information, IP mediation platforms must collect from several devices and elements in the network. And since there is no true industry-wide standard with regards to the information such IP elements should generate, hardware vendors have taken a proprietary approach to this issue. Fortunately, the IP industry recognized this problem early on and formed several standardization bodies that are now making great progress and are expected to have a solid framework in place in the near future. Another challenge has been to design mediation solutions with capabilities to collect and process millions, if not billions, of daily IP events. This has been a major impediment to full-scale adoption by the industry, but we now are overcoming these hurdles and actually proving that IP events can be collected, aggregated, and processed even at extremely high volumes.

Raw usage data is usually collected directly from the elements themselves, such as IP switches, gateways, routers, and application or Web servers. A content-mediation system should collect this information in real time, aggregate and filter out unnecessary and redundant data, and then process the usage information and prepare it for other systems, such as rating and billing, network management, fraud-detection applications, etc. It should also have the capability to automatically distribute the usage data to comprehensive network-mediation system for enhanced processing, e.g., apply additional business logic so that cross product and/or volume discounts can be calculated. Content-mediation systems are unique systems that must to support a number of network elements, such as the following:

- AAA servers running RADIUS or TACACS+
- Web servers
- Mail servers
- Firewalls
- LDAP servers
- DNS
- Routers/IP switches (SNMP, NETFLOW™, etc.)
- Gatekeeper/gateways for WAP/SGSN/GGSN

The collection method should support user datagram protocol (UDP), transmission control protocol (TCP)/IP, file transfer protocol (FTP), software agents, simple network management protocol (SNMP), and remote authentication dial-in user service (RADIUS)/TACACS+. Software agents must enable the real-time collection and data-record creation of billing information from server application log files. This is applicable for games, news applications, and other services that have user-defined value.

To support the services enabled by faster data transmissions, there is a need to collect data from many sources and handle large data volumes, whether from the network elements or from the content elements—or a combination of the two—such as Web and application servers. To assure revenue streams in this complex flow, mediation-processing capabilities are extremely critical. If the switches send the same IP detail record (IPDR) twice to the mediation system, this needs to be identified. The mediation system needs to provide an easy-to-use interface to ensure that faulty IPDRs in a file can be detected and corrected before being forwarded to the billing system.

Formatting is important when collecting IPDR files from a variety of network elements (switches, access nodes, gateways, servers, etc.). This is to protect the billing application from too much change so that operators can quickly bill for new services using their existing systems.

Different formats are collected, converted into a standard file format, and thereafter distributed to the downstream systems. Validation capabilities are also important to secure the new revenue streams. The mediation system must enable the operator to do the following:

1. Validate that the file contains billable data records
2. Consolidate partial records; filter and aggregate data records
3. Stream/burst or filter data records to downstream systems

When collecting information from routers and other Internet elements, it is vital to reduce the superfluous information in order to process only the information that is relevant for rating and billing purposes. When collecting router data, for example, the filtering should be performed within the content-mediation server. If a software probe or IP agent is deployed in a content or application server, the probe should filter out unnecessary information and send only distinct or relevant billing information to the mediation server.

The burst functionality enables the operator to send the same data records to several downstream systems. This feature optimizes the use of business intelligence applications, fraud-analysis software, as well as other support applications.

The content-mediation software should be configurable as either a standalone application or as a fully distributed solution. The key advantage of having this flexibility is that when huge amounts of data are collected in real time, specific nodes close to the network elements can perform some initial filtering and aggregation of data, which in turn can be sent to a central mediation server, which deals with the final aggregation and consolidation of all the billable data. This means that there are no real limitations as far as data and performance are concerned

Many carriers, especially the incumbents, have invested significant resources in their existing support systems, and naturally they seek to protect these investments whenever possible. As already argued, existing support systems such as billing and service provisioning are not agile and flexible enough to support the emerging business models of tomorrow, yet their core functionality is still needed to automate and carry out the processes that generate the bulk of the revenues. Making changes to or replacing such systems often requires substantial resources. Consequently, decisions to replace systems or implement any changes must be carefully scrutinized and produce an attractive return on investment (ROI) potential.

Accelerate Time to Market

Increased competition in the mobile voice service sector has resulted in a more homogenous, commodity-like offering. Carriers experience great difficulty in differentiating their service offerings in the marketplace. Essentially, pricing or carriers' "bundling of minutes," and to a certain extent, their networks' overage area, are the only means that they have to stand out from competition. New revenue sources are desperately needed, not only to rise above the competition, but also to justify the huge capital investment in infrastructure replacement and spectrum licensing. It is also clear that this "new" revenue must come from existing customers as well as new ones. Time-to-market and revenue

FIGURE 1

Filtering of IP Events

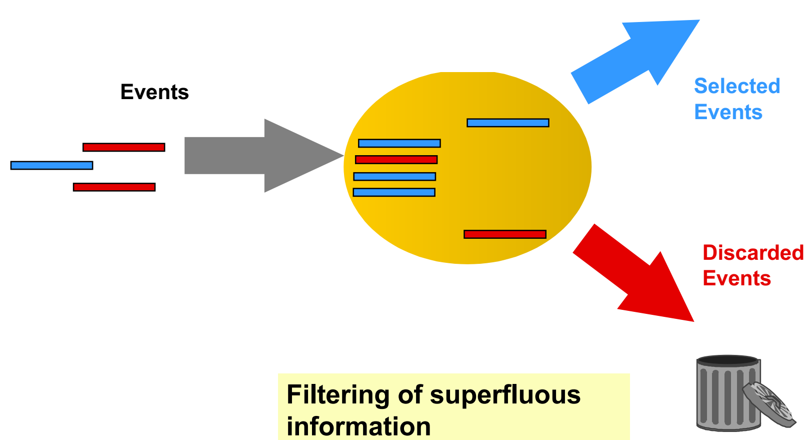


FIGURE 2

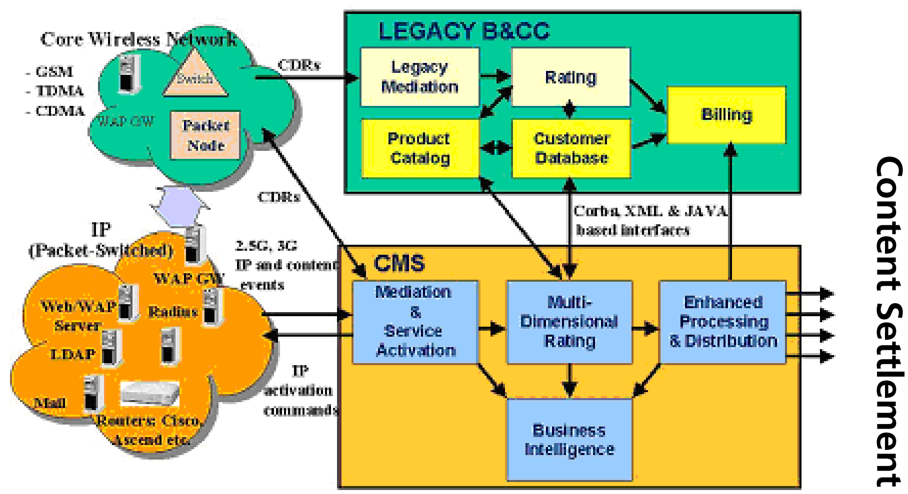
Overview of Ericsson Customer-Management Solutions



pressures are growing quickly and competition is intensifying even more.

The wireless industry has recognized that branding can often be a potential differentiator. Verizon and Cingular seek to distance themselves from the outdated "baby bell" image, using new and creative names to shed this out-of-fashion skin. North American wireless carriers have the added challenge of delivering mobile IP connectivity and content services to an already experienced Internet user base. Americans are familiar with the dynamic nature of the Internet, and their expectations will naturally be extended to the mobile Internet as well. However, it is extremely important that carriers effectively educate their customers and set realistic expectations as they introduce these new services. The user experience, at least in the near future, will be vastly different from desktop "surfing."

One potential key to the successful introduction of wireless mobile data service will greatly depend on the effective management of customer expectations. Carriers need to "flirt" with various business models and take proactive steps to become more "customer-intimate." Japan's DoCoMo® has witnessed tremendous success with its i-Mode® platform. Within 13 months, it attracted more than five million subscribers. Its success can be attributed in part to DoCoMo's willingness to experiment. Service providers often do not know what users want from wireless portals, and the only sure way to find out is by exploration.

Regardless of the chosen market entry strategy and target segments, wireless carriers need cost-effective and flexible management tools for introducing new IP–related services and products. They need to create and adopt an environment where business and marketing decisions can be implemented "on the fly." First-mover advantage can be extremely valuable in terms of quickly building a critical mass and a sizable market-share. Carriers can then expand the scope to attract new, targeted customers with highly personalized application and content services.

Network operators and service providers will require support systems that not only automate and carry out many of the operational processes, but also a system environment that can cost-effectively evolve with changing market needs and business drivers. Next-generation OSS/BSS software needs a layered architecture to enable swift and drastic changes in business models and service offerings. Such support systems need to be easily configurable and driven by rule-based logic. In addition, the need for intuitive user interfaces is critical to ensure effective administration of the support systems.

The amount of new IP–based services that general packet radio service (GPRS) and 1xRTT networks can provide is only limited to operators' creativity and the perceived value in the marketplace. Intense competition demands that new services should be introduced very rapidly—in days, rather than months. Customer agreements will also change, and different promotions may be active at the same time. The rating or pricing logic must be flexible enough to support all types of measurement units and pricing schemes—including duration-based, volume-based, subscriber-based, value-based, or any combination of these. Because of this, the rating architecture needs to handle any possible service and without additional programming. The volume of events created from IP–based services will be much higher than circuit-switched voice traffic; therefore, the performance and scalability of the rating core must reflect this and allow for massive scalability.

IP and content usage data records will be received in multiple formats, from multiple sources, including import of prerated data. The tariff calculation mechanism must be distributed to the content servers, thereby removing the burden of updating an ever-expanding product catalog and its associated price list in the central billing system. The price or the price group information must be placed in the usage data record.

Moreover, there is a need for a flexible, set-up driven interpretation of these records. Events must be rated in real time.

One single traffic event must be allowed to generate multiple charges in an environment where more than one party may be charged or compensated. For example:

- Revenue sharing with content partners and advertisers
- Charge for both volume and duration and the associated QoS

Many customers, especially business customers, are seeking special agreements with service providers because of their unique needs. There is a need for a straightforward pricing structure for the standard services offered, as well as unique pricing agreements that are discounted based on standard service offering. This will significantly reduce the maintenance cost of price lists and customer agreements.

Furthermore, services will cross-subsidize each other, and cross-discounts will be used to encourage customer loyalty. Mobile Internet access, personalized content, and value-added services need to be bundled into product packages to create "sticky" offerings. The package will also need to have a lower price than the sum of the integral components. Therefore, there must be a user-friendly approach to version handling of the price lists.

There is also a great need for service activation functionality when delivering IP services over wireless infrastructures. Services such as mobile virtual private network (VPN) with access to corporate Intranets and databases need to be activated rapidly and securely. To achieve operational efficiency, activation of services must be automated and executed in real time. It should not take more than a few seconds to activate a new service because customers expect a service to be available immediately after it has been ordered.

Activation is primarily about receiving activation requests from order-management systems, translating the requests into network-element commands and distributing these commands to network and content elements. When the activation is carried out in the network, the billing system should also be notified. Deactivation, modification, and cancellation are usually supported in the same manner.

When activating consumer services at content and/or applications providers, an activation system will handle the command sessions with the servers running applications such as authentication, authorization, and accounting (AAA); Web; mail; domain name server (DNS); music; and games. When provisioning mobile Internet access, an activation system could be used as a mediation layer to communicate with element managers or directly with the network devices.

A single service-activation system that interfaces with the network elements in multiple network technologies will simplify the implementation of support for bundled services. For instance, a service package including 500 minutes of voice service and GPRS access, plus one or multiple content services, could then be handled as a single activation request. Because new services are continuously introduced in the network, there is a strong requirement for activation systems that are easily adapted to support new service logic and new versions of network elements without operational disruptions.

The Critical Need for Business Intelligence

Not withstanding the challenges facing wireless carriers as they introduce mobile Internet access, it becomes obvious that there is a need to carefully monitor business metrics such as customer usage, service profitability, and capacity utilization. During periods of heavy investment in new network technologies and spectrum licenses—compounded by extreme pressures to be profitable—early identification of profitable services now commands the attention of a much wider business audience.

As wireless carriers and service providers introduce new IP–based offerings, they will need to examine and analyze the uptake of such offerings. As addressed previously, carriers and content providers cannot predict which services and applications users will find valuable. Supply-chain players are going to have to experiment with several promotional offerings and closely monitor usage behavior. With real-time data on customer behavior and to what degree promotional services are performing, service providers will have the means to become *proactive* rather than *reactive* with their customers, which can minimize churn and maximize market-share. And that means increased revenue potential.

A business intelligence reporting tool must be easily adapted to a carrier's specific business requirements—current as well as future needs. The business intelligence application should, at the very least, monitor and simplify the analysis of network performance.

High-speed wireless data access technologies such as GPRS and 1xRTT enable "always-on" connection to the packet-switched network, unlike cellular digital packet data (CDPD) or first-generation wireless application protocol (WAP) phones, where users must initiate a connection to the IP network. The notion of "always on" must be explored to its fullest, as location-based services will potentially add significant revenue streams to wireless carriers. However, this opportunity will come at some cost and risk. Although the technology allows for "always-on" connection, actual coverage and the number of cell sites combined with roaming limitations will impede on this concept. Hence, it becomes particularly important to monitor the quality of service (QoS) delivered and relate it to the service-level agreement (SLA) promised. With a powerful business intelligence module, carriers can set SLA violation triggers that can automatically notify the rating engine or billing system to calculate discounts based on the pricing policy contained within the SLA. Furthermore, such applications can effectively assist in forecasting service usage as well as network or capacity expansion planning.

Share Revenue with New Partners

Advertising has been the primary sponsor of content in the fixed Internet world. Generic content has, to a large degree, been free to visitors because advertisers have subsidized the cost of producing the content in exchange for banner ads.

Advertising models will certainly play a positive role in the wireless Internet space; however, they have to be carefully evaluated and positioned for the new medium, namely small handset devices with a very limited display size and much lower resolution than a modern desktop or laptop monitor. Advertising must also be linked to the audience in a much more sophisticated manner. It needs to be connected to the end users via content, locations, and/or m-commerce. In the long term, advertising can still prove to be a viable revenue source for carriers, but until the arrival of full-fledged location-based push and pull services, carriers should focus on offering premium, value-added content and applications that are appealing to customers.

Typically, mobile operators' core business focus is running and managing voice traffic over wireless networks. With the advent of Internet access via mobile phones, an entirely new world of business opportunities emerges. For example, a mobile operator providing access to, say, Amazon.com, for example, is essentially also acting as a point-of-purchase agent. The carrier enables Amazon.com to receive orders from mobile customers that may not have taken place otherwise. In this scenario, the mobile operator becomes a valuable player in Amazon.com's value chain and potentially entitled to be compensated for generating new revenue. By inferring this philosophy to the banking and financial world, the revenue opportunities become enormous—assuming that privacy and security concerns are resolved.

It is crucial that wireless carriers are able to monitor and track the transactions and events generated within their networks and to automate the process of settlements—and revenue sharing—with on-line merchants and content providers. Voice traffic and airtime will most likely continue to account for the bulk of carrier revenues in the short term. However, there are already many different business models emerging in the marketplace, and carriers must start implementing new marketing and service-offering strategies.

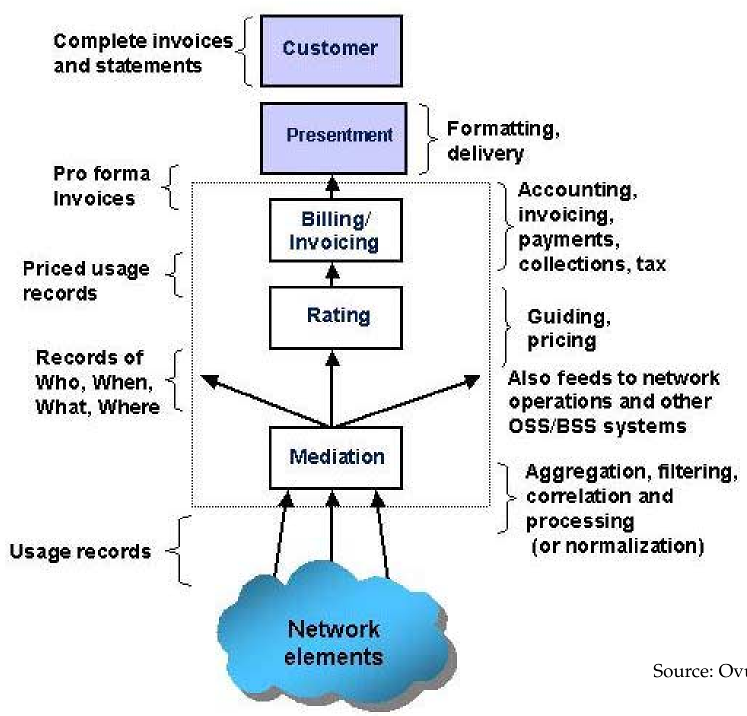
The traditional rating function has been to apply a tariff or a retail price to a voice call, where metrics such as duration, time and day of the week, and distance have determined the final charge for the service. As deregulation opened up the market for competition and the increase in capacity that digital networks provided, the wireless industry witnessed the introduction of many creative offerings aimed at targeting various segments with different volume discounts. These "buckets of minutes" offerings required some changes to the billing systems, but these were fairly simple to implement because the main functionality remained the same, namely keeping count of the minutes spent on the network.

With the introduction of IP–based services, carriers must find ways to maximize the revenue potential. To do so, carriers are advised to involve new players and strategic partners in their value chains to develop and create rich content and application services that can be delivered over their wireless infrastructures. As many industry analysts predict, the wireless industry of tomorrow will be characterized by cross-industry partnerships and collaborations, massive reorganization of the value chain, and a competitive environment that rewards innovation and differentiation

The fundamental challenge essentially is how to treat the events occurring in IP networks. Next-generation services, such as high-quality videoconferencing, CD–quality audio streaming, and wireless productivity applications, will

FIGURE 3

The Billing Process



Source: Ovum

require more bandwidth and network resources than, for example, an e-mail with a small attachment. Therefore, it becomes crucial for service providers to ensure that network resource utilization or consumption is compensated for or recovered by the actual users of these bandwidth-hungry applications. As these types of premium services evolve and become part of the offering, new pricing strategies also must evolve. The new billing models must reflect the perceived value of these types of services in order to maximize the revenue potential and achieve sustainable, long-term profitability.

The following are a few emerging revenue-sharing scenarios that the rating component must accommodate:

- Shared revenue
- Sponsored revenue
- Referral revenue
- Billing on behalf of others

A next-generation rating application must be very agile and flexible to support ongoing changes expected in the near future. As already implied, carriers have limited insights of the potential demand and perceived value of these prospective services offerings and therefore will require systems that can easily change business logics, pricing and discount plans, service bundles, limited promotional offerings, and so on. The rating module must also feature the ability to rate events or service delivery on any perceivable dimensions, such as per use, data volume, QoS, number of clicks, and more. To better illustrate the complexity, consider the scenario in the following paragraph.

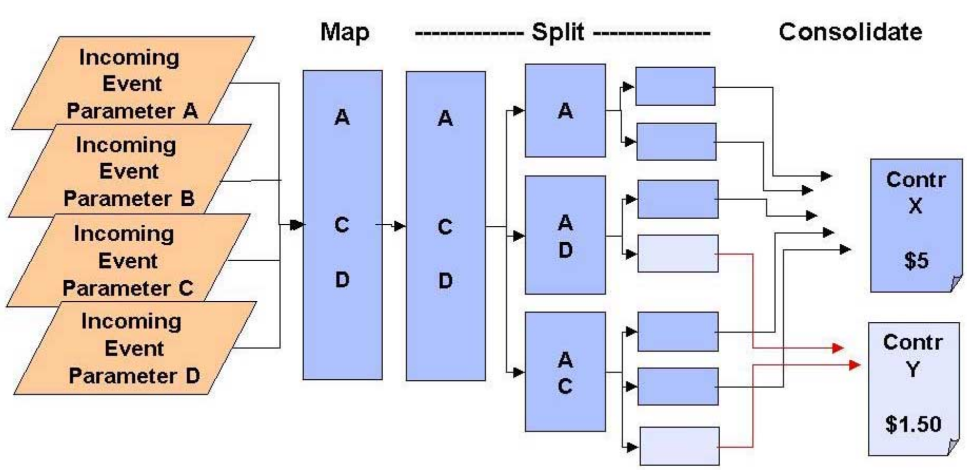
A business traveler is staying in a city that he/she has not yet visited. In the morning, the individual decides that a cup of Starbuck's coffee is a "must" to start the day. The phone book is full of Starbuck's locations, but the street addresses are unfamiliar. The concierge desk is not yet open, and the staff at the front desk is busy checking out long lines of guests anxious to depart for the airport. However, using his/her mobile phone, finding the closest Starbuck's and receiving directions guiding him/her to that craved cup of coffee is quick, easy, and relatively inexpensive—he/she is charged a nominal 50 cents for this service. Also, consider how the revenue streams can be divided by the parties involved in this information request. For example, Starbuck's may offer the driving directions free of charge to the requestor, while the requestor pays for only the incoming data. Alternatively, Starbucks might sponsor 25 percent or even 50 percent of the information request, including the cost of delivering the data; or they could pay for all of it if the requestor actually went to the coffee shop and spent more than a specified amount of money, say $3. In addition, any of these may have a limited promotional time offer attached to it. This is exciting news for the business traveler and the mobile operator—adding value to voice services by providing content-related Internet services. The business traveler receives a value-added service, and the mobile operator opens a new revenue stream.

Such a simple scenario delivers real value to the end user who doesn't really care how the revenue streams are divided as long as the end user receives the information that he or she is requesting. However, it is a very complicated transaction from a carrier's point of view. Managing such relationships and transactions is a brand new domain for mobile operators, and their current support systems are not intended for such functionality.

As the scenario illustrates, a rating engine needs to be extremely flexible and adaptive to accommodate such fast-changing business logic. The engine must enable carriers to price events and transactions on multiple dimensions as well as the ability to split and calculate the revenue streams—both at the retail and wholesale levels. By having well-defined interfaces based on industry standards such common object request broker architecture (CORBA), extensible markup language (XML), and Java, carriers have the opportunity to cost-effectively integrate a powerful standalone rating component to their existing billing

FIGURE 4

Split Rating for a Single Traffic Case to Allow for Revenue Sharing



system. Even if customized interfaces are required, such an approach could yield a favorable ROI scenario compared to re-engineering efforts or replacement of the existing billing system.

The main objective with rating module architecture is to effectively handle the rating of any conceivable service without the need for additional programming. All rating characteristics should be managed through set-up definitions of the business rules that a service provider wants to apply, without any customization needed. Furthermore, the rating module must be capable handling extreme performance requirements. Even with the advanced analysis, consolidation, and processing functions, hundreds of millions of daily event records may reach the rating engine, which should be able to handle such a massive volume in a single-server environment.

Conclusion

To gain and sustain a competitive edge, wireless carriers must take a proactive approach to all aspects of their operations. Their long-term success is in the marketplace is largely dependent on their ability to deliver quality services at prices, which the customers are willing to pay. With the enormous amount of capital being invested in next-generation infrastructure and spectrum rights, carriers are simply forced to roll out new services and products in record speed to an increasingly sophisticated and demanding customer base. These new services will not be delivered in the traditional supply chain to which mobile operators have been accustomed but rather through a dynamic value chain consisting of a multitude of players, which dictates entirely new business models and partnership strategies for carriers to implement and execute.

In an industry where change is the only constant, Ericsson Customer-Management Solutions (CMS) for mobile Internet can help to make the difference in ensuring accurate revenue accounting and sharing between multiple partners and seizing the new opportunities that m-commerce will provide. Ericsson CMS can help wireless service providers to capitalize on these opportunities through extensive knowledge and solutions that protect existing system investments; accelerate new market launches; and capture valuable customer, service revenue, and network intelligence while enabling revenue sharing with new partners.

Deploying Voice Portals in a Network

Michael Krasner

Vice President and General Manager, Voice Solutions

Comverse

1. An Introduction to Voice Portals

The word *portal* comes from Medieval Latin and means "city gate." Through a portal comes access to all that is within. Yahoo!® used the word portal to describe its one-stop directory service to nearly everything the Web has to offer. Voice portals are a logical extension of Web portals. Simply defined, a *voice portal* allows users access to information, check voice, e-mail messages, and place calls over the telephone using nothing but their voices. The objective of a voice portal is to simplify the way people use telephones to communicate, access information, and conduct business.

Voice portals use powerful computers and software to recognize speech commands, find information, listen to audio streams, convert text into an audible format, and help users to keep in touch. A voice portal may be best thought of as a voice version of a Web browser that accepts spoken commands and returns audio data and responses. The potential breadth of commands, applications, and information that can be accessed with a voice portal is limitless. For example, a voice portal can add custom applications, such as a voice equivalent of a contact management program. In addition, voice portals can be integrated into existing telephone networks and aid in the basic user functions of that phone system, such as placing calls and handling voice-mail. Today, voice portals can read e-mail, manage your voice-mail, provide directions, read the latest news and sports scores, play a game, manage your schedule, and much more. In the future, voice portals will book your flights, arrange flower delivery to your loved ones, and serve as your personal concierge.

2. Voice-Portal Drivers

The phenomenal success of the Internet demonstrates our insatiable desire for information. However, accessing the Internet is generally a task that requires sitting down at a computer or some other Internet appliance to fully take advantage of its services. In an attempt to mobilize the Internet experience, mobile phones have started to offer Internet content. Adequately displaying the Internet's data-intensive information has been difficult to accomplish on mobile phones that are constantly shrinking in size. This is further complicated by the increasing demand for safe and hands-free solutions. The only truly mobile and hands-free Internet solution is voice interaction.

The voice marketplace has been driven by several factors that have evolved over the last few years. First has been the development of inexpensive and powerful computer technology, which has led to the development of reliable and reasonably priced voice-recognition systems. Second, speech-recognition applications have matured to recognize a broad array of speech patterns and words, enabling systems to be very user-friendly. Third, the availability of a broad array of information and data that can be transmitted wirelessly, such as e-mail and news feeds, has helped introduce new wireless services. Fourth, the end-user cost of entry is very low because voice-portal technology is transmitted completely via voice, which means any phone can access a voice portal, regardless of the phone's brand or technology within the phone. Finally, the amount of time that people spend using mobile phones in their cars has greatly increased, making a hands-free solution a critical safety concern.

3. Voice-Portal Market and Opportunity

According to the technology research firm Ovum, there are nearly 100 million cell phones in use in the United States alone. In 1999, 2.1 billion wireless calls were placed to 411 for information (Strategis Group, 2000). North American voice-portal use among wireless users is expected to mushroom from 1 million users in 2001 to 56 million by the end of 2005 (Allied Business Intelligence, 2000). Another report by the Kelsey Group estimates a conservative 45 million voice-portal users by 2005 in North America and estimates that 18 million users will use voice portals to shop for products (see *Figure 1).*

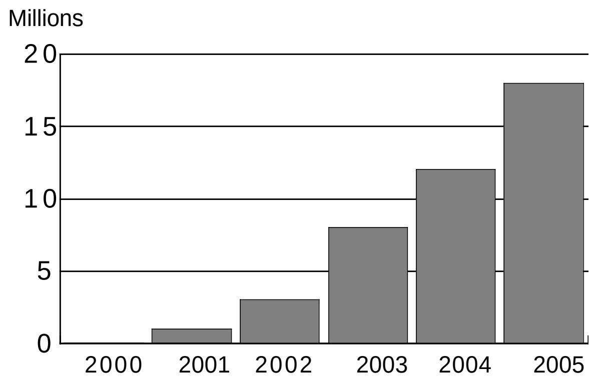
Estimates for potential revenue vary considerably among analysts because of the many possible models for income. The Cahners In-Stat Group predicts at least $1.6 billion in revenue by 2005 through local advertising, national advertising, sponsorships, hosted content, and revenue from third-party sales. They note that significantly higher revenue could be generated—upward of $32 billion—if customer profiles are sold. More aggressive estimates come from the Kelsey Group, which predicts $5.4 billion by 2005 from advertising and commerce revenue only.

4. What to Look for When Deploying a Voice Portal

Deploying a new technology, such as a voice portal in a wireless network, is an elaborate process that requires extensive

FIGURE 1

Number of Voice Portal Shoppers



Source: The Kelsey Group, 2000

vendor analysis. The following topics are important issues to consider when looking for a voice-portal vendor.

4.1. Applications

Voice-portal technology is only as good as the breadth and depth of the applications designed to support it. Minimum requirements must include voice-activated dialing and voice-controlled messaging. Voice dialing must accommodate dialing by phone number and by name. Phone number dialing must accommodate both single number speaking (e.g., "one, eight, zero, zero") and shortcut dialing (e.g., "one, eight hundred"). Ideally, voice dialing should be integrated with a personal address book that provides a great deal of flexibility. Some of the more advanced address-book options include a preprogrammed list of major vendors (e.g., major airlines) and allow the user to synchronize his or her personal information manager (e.g., Palm™ Pilot) with the voice portal using a traditional Web interface. Address-book dialing must allow voice dialing with both name and location options. For example, "call Mike at the office" must be distinguished from Mike's home and mobile phone numbers. Additionally, voice-controlled messaging must provide an intuitive and simple interface that enables users to listen, filter, store, send, and delete messages verbally.

More advanced applications include a voice browser for accessing topical content, such as weather, traffic information, and news. A good voice browser must allow content to be customized and localized to each user. For example, a user can indicate the city in which he or she lives and perhaps news topics of personal interest, providing customized content not available over alternative communication mediums, such as a radio. Some more advanced browsers allow users to preset their interests using a computer and a Web browser. In addition, live content is critical to the user experience. With a voice browser, the phone becomes a mobile Web radio and enhances traditional news radio content.

4.2. Language and Human Factors

For global telecommunications companies, it is important to implement new technology localized to different cultures and that supports different languages and dialects. When implementing voice-portal technology, select a vendor that can deploy internationally and has experience with system implementation and language localization. In addition, users should be able to profile their language of choice in environments where multilingual support is critical.

In addition to language considerations, a user interface that is natural and creates a positive experience—also known as human factors—is critical to wide-scale consumer adoption of a voice portal. A good voice-portal vendor must understand the limitations of the mobile telephone channel and design voice commands that do not confuse the portal yet are very user-friendly. The science of human factors is not well-understood by most voice-portal vendors and is critical to the overall user experience. Similar to a conversation with a live person, a voice portal must know how to handle idiosyncrasies common in speech interactions. For example, the ability for a user to interrupt the voice portal at any time and initiate new commands is critical to the user experience. A good voice portal will know how to smoothly handle such interruptions.

Verbal commands that are easy to remember and speak are also critical to the user experience. A more basic voice portal will constantly review a list of options and sub-options that users have, similar to a voice-mail system. The problem with this approach is that it is complicated, time-consuming and not the way people speak in natural situations. A natural-language interface must use short prompts that are easily controlled by the user.

4.3. Branding

An essential factor to consider when implementing a voice portal is how easy it is to develop a recognizable brand for the service. This user experience is accomplished primarily via the personality of the voice portal. Much like a person, a voice portal should have a unique demeanor communicated by its voice, tempo, and language formality. The personality style should be conveyed by prompts and the grammar of the voice portal. Possible options may include the following:

- ***Impersonal:*** "Mailbox action?"
- ***Trendy:*** "I got your mailbox open. What now?"
- ***Friendly and Informal:*** "What should I do with your mailbox?"
- ***Professional:*** "I have opened your mailbox. How shall I proceed?"

Coupling the above grammars with verbal personalities—such as a robotic voice, a young person, a happy person, or a butler—will reinforce the brand experience. Personality creation is a complex yet important process that requires a thorough analysis of your target audience and an understanding of what type of verbiage will elicit expected results with users.

Advanced voice-portal vendors will allow customized demographic content for your various audiences. For example, the list of preprogrammed vendors in a public voice directory may be tailored for specific age groups. A teenager profile might include local pizza, arcade, and movie-theater listings. Additional branding considerations should include customized help message content, modifiable prompts, unique chimes, and grammar modifications.

4.4. Customization and Scalability
A voice portal should integrate with your existing mobile telephone network without requiring you to adopt proprietary technology. An advanced voice portal will be customizable to comply with the varying standards and billing systems used by the telephone industry. With the incredible growth of mobile users, the voice-portal platform must also scale to accommodate up to millions of users and support distributed architecture (e.g., include support for roaming). It is also important to integrate third-party directory and Web servers via standards such as lightweight directory access protocol (LDAP) and VoiceXML.

4.5. Speech Recognition and Text-to-Speech
The ideal voice portal is not limited to a single vendor for speech-recognition or text-to-speech capabilities. With the evolving software techniques for recognizing speech and converting it to text, a voice-portal vendor should have a flexible system that allows new technology from other vendors to be integrated with the system in the future.

4.6. Deployment
When deploying a voice portal, it is important to work with a vendor that has established a systematic procedure for the service launch. Issues to consider include the following:

- ***Internal Testing:*** This phase should test general functionality with a small sample of users and identify areas that need to be optimized or corrected.
- ***External Testing:*** This type of testing should be conducted on a large scale and includes testing acoustic models, voice-recognition parameters, grammar quality, and ease of use.
- ***Off-Line Tweaking and Internal Lab Testing:*** This phase should include testing the voice portal's listening capabilities and assessing if the voice portal became confused or erred in any transactions.
- ***Soft Launch:*** During this phase, the voice portal should be integrated with existing voice-mail systems, and support personnel should be trained on the hardware, platform, administration tools and the nature of speech systems. In addition, a Web interface may be aligned with the voice portal at this stage.
- ***Hard Launch:*** This phase is the official launch, where marketing collateral would be released and the entire system would be available for use. An ideal voice-portal vendor should be able to aid in every one of these phases of deployment.
- ***Follow-Up:*** This recommended step will allow for future refinement of the system and help gauge the user experience.

4.7. Vendor Experience
When selecting a voice-portal vendor, it is important to assess their track record and experience relative to your marketplace. A voice-portal vendor should be well established and stand by its claims.

5. Summary

From the beginning of time, no communication method has been more important than the spoken word. It is no surprise that we seek to enhance our verbal communication with everything from answering machines to mobile phones. Modern technology has removed the physical boundaries of communication and helped to create a mobile society.

The next step for voice technology is to extend the flexibility and functionality of the Internet—fundamentally a visual medium—to voice-driven applications. Today, this can best be accomplished by voice portals—speech-driven applications that listen, respond, read, and record commands and content. Voice-portal technology is best applied to contexts in which normal Internet access is restricted or nonexistent. The largest business opportunity lies in the mobile marketplace. With the wide adoption of cellular phones, mobile consumers are the ideal target audience for speech portals.

MIMO: The Preferred Choice for Last-Mile Access

Rajeev Krishnamoorthy
Vice President, Technology Development
Iospan Wireless Inc.

This article addresses some of the fundamental technical challenges related to mass deployment of next-generation fixed wireless access (FWA) systems. It presents and discusses state-of-the-art wireless multiple-in, multiple-out (MIMO) technology recently developed to overcome the perennial challenges of line-of-sight dependency, spectral inefficiency, and multipath and installation difficulties.

1. Technical Challenges for FWA

The demand for broadband Internet access is booming. Delays in the deployment of 3G high-speed wireless networks (wideband code division multiple access [WCDMA] and CDMA2000 are unlikely to be widely available before 2003 or 2004) and slow progress in satisfying demand for wireline access place extraordinary expectations on alternative last-mile technologies such as FWA. This is especially apparent for the lower bands (multichannel multipoint distribution system [MMDS] or 2.6 GHz, and 3.5GHz) dedicated to mass-market residential, small office/home office (SOHO) use. *Figure 1* illustrates the main network components of FWA.

Despite strong customer demand, current rollout of first-generation FWA equipment by service providers such as Sprint and WorldCom is stumbling due to fundamental technical limitations, including line-of-sight dependency and costly, time-consuming subscriber antenna installation. In addition, it is widely believed that current FWA technology cannot meet the forecasted demand for capacity because of its inefficient way of using of spectrum. To successfully respond to demand and to carry their future share of the access traffic, it is necessary for the second generation of FWA systems to deal with the following requirements:

1.1. High Performance

The demand for high capacity and the competition with landline (digital subscriber line [DSL] and cable modems) and upcoming wireless data services (2.5G and 3G) make high performance a premium requirement for FWA networks. This is especially true, given that these networks will not support mobility. Superior performance of FWA over competing access solutions can be achieved in three key areas:

- Aggregate user rates
- Spectrum efficiency
- Coverage

High aggregate data rates must be offered in order to support rich multimedia services, in both downlink and uplink. The aggregate rate is the rate that a single user will experience averaged over all possible subscriber locations.

Because spectrum is a scarce resource, especially in the sub-5 GHz band, it must be used efficiently. The spectrum efficiency can be defined as that ratio of aggregate rate to the product of bandwidth used and frequency reuse factor. To be efficient, 2G FWA must reuse frequency aggressively, and, as such, the transmission technology should be made tolerant to interference.

To get the most of every installed base transceiver station (BTS) in initial rollouts, the coverage performance is critical. This can be measured by the cell radius served by the base, with a constraint on the ratio of home locations that must be covered, typically 90 percent.

Finally, link latency and reliability are also important measures, and the performance there should be comparable to existing wired access technologies. Overall, the typical performance requirements for 2G FWA systems are shown in *Table 1*.

1.1.1. Unfriendly Channel Environment

Because it is desirable to serve most of the cell area, the dependency on a line of sight at the subscriber's home must be eliminated. In many locations, this results in deep channel fading caused by multipath propagation, similar to what is observed in standard cellular networks. In addition, broadband transmission over multipath channels introduces frequency-selective attenuation, also due to intersymbol interference. Finally, reuse of the frequency in neighboring cells causes co-channel interference at the receiver. In practice, the severity of fading and interference will vary from location to location and time to time. However, due to the stringent link reliability requirement imposed by the service providers, the transmission technology must cope with the worst-case channels at all locations

TABLE 1

Performance Requirements for 2G BWA

Figure of Merit	Requirement
Aggregate Rates	4 Mbps
Spectrum Efficiency	1 Bit/Hz/BTS
Coverage	3 Miles (90% area)
Latency	Comparable to DSL
Link Reliability	0.999

1.2. High Level of User Friendliness

In addition to high performance requirements, the success of FWA rollouts depends on the ability of the service provider to quickly install the equipment. Current technology requires skilled, accurate pointing of the rooftop antenna toward the line-of-sight direction. This results both in many unsuccessful installation trials (since it is difficult to predict the existence or not of a line of sight at the subscriber location) and costly, difficult installations at those locations that have line of sight. Ideally, of course, the subscriber's unit is self-installable, with no constraint on the room/location where the antenna will be put. As a nearer goal, however, 2G FWA networks can be made much more flexible than current systems by the use of low-height, compact-size, wide-beam subscriber antennas.

Unfortunately, the use of user-friendly antennas as described often means further degradation in the channel characteristics, because this type of installation introduces higher path loss and more multipath, as well as increased interference. The ability for the modem to operate at low levels of signal to noise (SNR) and interference ratios (SINR) is therefore essential.

1.3. Low Deployment and Maintenance Cost

For the subscriber unit, the cost should be comparable to xDSL and cable modem (while presumably offering higher performance). On the network side, in addition to the fast deployment that is inherent to wireless, significant cost savings can be gained by having a high coverage performance in initial rollouts and high spectrum efficiency in mature deployments with high subscribership. In all cases, the cost of deployment is tightly coupled to the network performance.

2. Design Features for 2G FWA

To meet the challenge of high data rates, high coverage, and high spectrum efficiency in an unfriendly propagation environment, state-of-the-art wireless research and techniques can be applied. In this article, we touch on selected technologies addressing this problem. We distinguish the physical layer (Layer 1) from the link layer (Layer 2), although a successful design calls for layer integration.

For Layer 1, key design features include antenna diversity, MIMO processing and spatial multiplexing, adaptive interference canceling, orthogonal frequency division multiplexing (OFDM), and intelligent rate adaptation mechanisms. For Layer 2, we focus on the link-level retransmission mechanism and fragmentation (ARQ/F).

2.1. Physical Layer

2.1.1 Spatial Diversity

Spatial diversity (SD) is obtained through the use of multi-element antennas at either the BTS and/or the customer-premises equipment (CPE). Antenna combining can be used to deal efficiently with multipath fading. The basic idea of antenna or SD is that several uncorrelated fading signal are much less likely to fade simultaneously than a single one, hence intelligent combining of the antennas can offer a much more stable link for the upper layers to work with (see

FIGURE 1

FWA Network Components

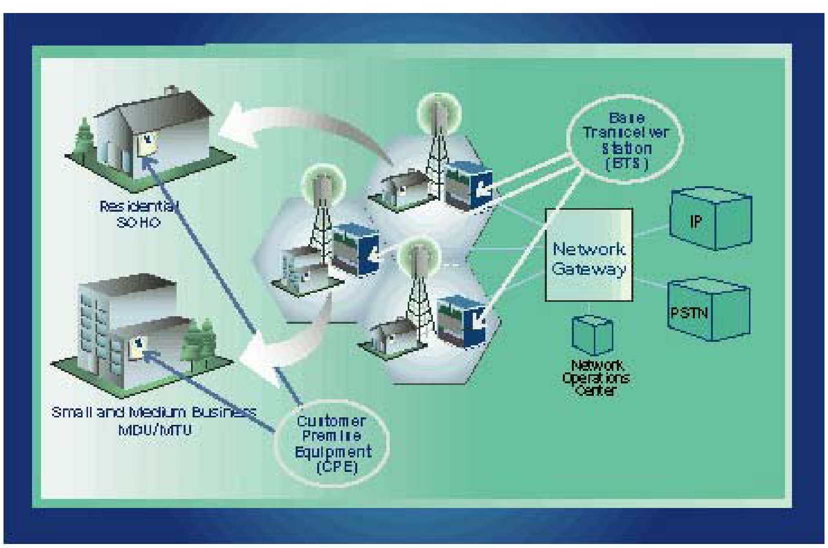


Figure 2). In addition, SD is a robust form of diversity, because low antenna correlation (less than 0.7) is almost always guaranteed with sufficiency antenna spacing. Typically, one wavelength of separation will suffice at the subscriber's side, for instance. Without diversity, the transmitter is obliged to operate with large margins of power for fading to achieve a target packet-error rate (PER), thus resulting in a much smaller coverage compared to a system with SD. In stationary wireless Internet protocol (IP) access, the ability to combat fading is even more critical, due the fact that fades last typically longer than in mobile links (up to a few seconds), which can cause the transmission control protocol (TCP)/IP connection to reset its congestion window and result in unacceptable delays.

Use of SD can reduce the SNR requirement by 10 to 15 dB with no loss of TCP/IP performance. This can be exploited not only to extend the coverage, but also to increase data rates and to allow a tight frequency reuse that will work in arbitrary terrain (flat or hilly). Antenna decorrelation can also be realized by using orthogonal polarization states of the antenna elements.

2.1.2 MIMO Diversity and Spatial Multiplexing

FWA can benefit much by using multi-element antennas at both ends of the link (so-called MIMO). MIMO can be used for enhanced SD because transmit *and* receive antenna elements can be jointly combined to combat fading. However, the most spectacular benefit of MIMO is a form of transmission called spatial multiplexing (SM). In MIMO–SM, the data rate is literally multiplied, at no cost in bandwidth or power, by exploiting simultaneous transmission over the so-called eigen-modes of the (matrix) channel [Paulraj94, Foschini96]. In practice, this means that several transmit antennas can send independent signals over the same frequency and time slots. The bits are mixed through the channel but are recovered through spatial and temporal processing at the array of receive antennas, as shown in *Figure 3*. The gain in data rate with SM is proportional to the minimum of the number of transmit and receive antenna. A key backer of this technology, Iospan, has developed specific algorithms to optimize this technique under various channel conditions. MIMO–SM is particularly well suited for FWA because, unlike handsets, compact multi-element subscriber units can easily be designed with two or three elements. For example, for a two-transmitter two-receiver system, the peak data rate is doubled.

2.1.3 Adaptive Interference Canceling

Adaptive interference canceling (AIC) is another form of spatial combining technique that aims at mitigating interference originating from neighboring cells for the purpose of reusing the frequency more efficiently. AIC exploits the idea that the desired signal and the interfering signal do not usually have the same spatial signature. Therefore, by placing a "null" in the direction of the interferer's signature, it is possible to suppress it.

2.1.4 Frequency Diversity in OFDM

In traditional wireless systems, the problem of inter-symbol interference tackled through the use of equalizers—i.e., time-domain filters implemented at the receiver that seek to invert the channel multipath response. Although easier to implement, one disadvantage of this approach is that the complexity of such filters grows exponentially or at best linearly, with the bandwidth making it unsuitable for future very-high–rate systems. Recently, competing multicarrier approaches, such as OFDM modulation, have gained popularity because of their robustness. OFDM works by splitting the original high-rate bit stream into low-rate substreams,

FIGURE 2

Multiple Antennas Provide a Robust Source of Diversity in Non–Line-of-Sight Channels

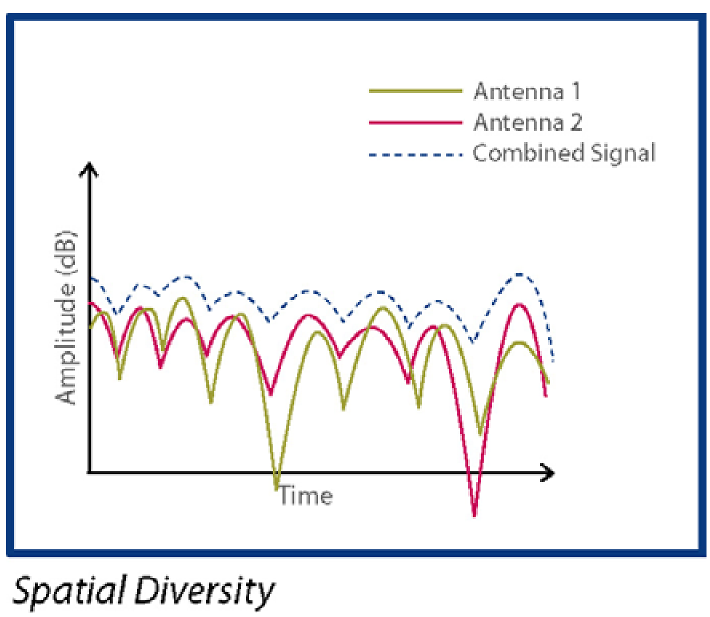

FIGURE 3

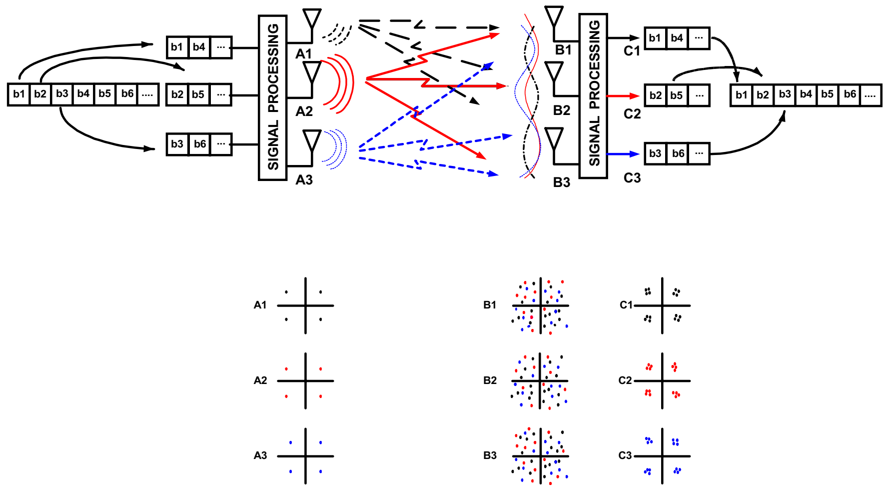
Simplified Spatial Multiplexing Scheme with Three Antennas
This gives three-fold data-rate improvement.



each mapped onto one of many adjacent subcarriers. Each subcarrier is small enough to remove the need for equalization. In practice, the OFDM is implemented efficiently using fast Fourier transforms. One bonus of the OFDM approach is that is effectively converts multipath into a benefit through the idea of frequency diversity, as shown in *Figure 4*. This can be realized by overlaying coding techniques on top of the OFDM modulation, which has the effect of spreading information bits equally over the entire modulation band. If the delay spread is large and the fading is frequency-selective, the subcarriers with good SNR help to mitigate the effect of fading occurring at other subcarriers, making the channel effectively look like a non (or less) fading one. Such techniques lead to several decibels (dB) of gain in the link budget, extending coverage and improving reuse performance.

2.1.5 Adaptive Modulation

Adaptive modulation (AM) and coding is a key technique for enhancing the spectrum efficiency of FWA. AM has been first popularized in the enhanced data rates for GSM evolution (EDGE) cellular standard. AM lets a user adapt its data rate as a function of channel conditions (e.g., SINR, fading rate). In doing so, it gives two important benefits. First, it makes CPE installation easier and more forgiving, because mispointing of the antennas can be compensated automatically by switching to a lower modulation and stronger code at the physical layer. Also. Edge-of-cell users can be more easily covered by these low-rate modes of transmission. Second, the overall spectrum efficiency is improved several-fold because all subscribers who enjoy better than edge-of-cell channel conditions can use their margin of SNR to increase their rate proportionally. By comparison, a non-adaptive system will have to be deployed with the most conservative modulation/coding for all users in order to preserve good coverage and frequency reuse.

Furthermore, a reasonably fast adaptation rate (every 100 ms or so) will allow the modem to track the time variation, such as fast fading of the channel at the subscriber's location. This feature is especially important to deal with unforeseen change of line-of-sight conditions that can occur due certain obstacles (trucks, tree leaves, etc.). In the case of OFDM modulation, advanced algorithms that track channel characteristics in the time and frequency domain can be developed.

The adaptation algorithm can also be designed to react to spatial properties of the channel so as to optimize not only the modulation/coding level, but also the way in which input signals are mapped onto the antennas, again for the sake of maximizing data rates. For example, if the link is in a SM mode and the number of usable eigen-modes suddenly collapses due to adverse propagation conditions, the system falls back to a MIMO diversity scheme, and vice versa.

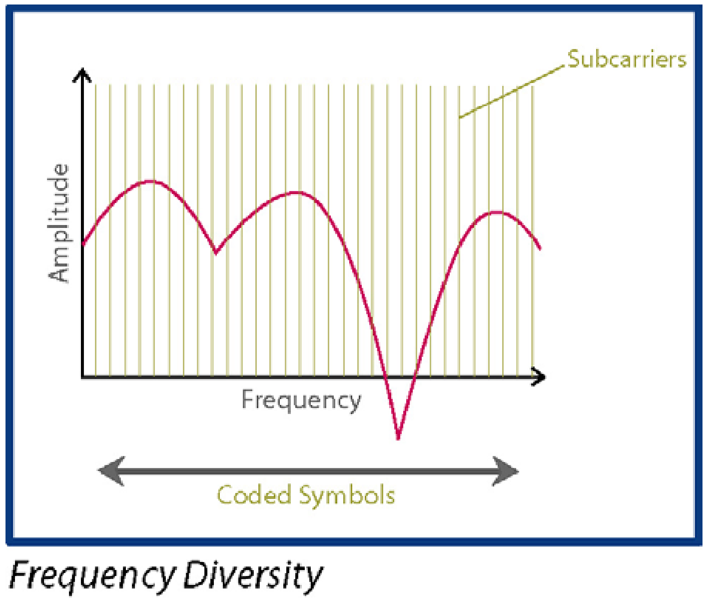
2.2. MAC and Link Adaptation Layer

2.2.1 Automatic Retransmission Request/Fragmentation (ARQ/F)

Despite the use of coding and diversity techniques at the physical layer, it is virtually impossible to hide all channel impairments from the protocol layers. In fact, a sensible system design of FWA calls for a physical layer that operates at a high level of PER (more than 1 percent) to minimize the SINR requirements at the receiver, making it possible to extend the coverage and tolerate aggressive frequency reuse. To achieve high TCP/IP throughput, on the other hand, excellent IP PER (less than 0.1 percent) must be passed on to the network layer by the link layer. This can be done using automatic retransmission request/fragmentation (ARQ/F) algorithms. ARQ/F consists of implementing an acknowledgment and retransmission mechanism at the link layer between the subscriber unit and the BTS. The media access control (MAC) layer performs IP fragmentation over the air into "atomic" data units (ADU), so only errored ADUs are retransmitted. A technique complementary to channel coding, ARQ/F has the merit of introducing redundancy only during the small fraction of time when data gets corrupted. A finite bufferization mechanism makes ARQ/F efficient in dealing with short as well as long

FIGURE 4

OFDM with Coding Transforms Multipath into a Source of Anti-Fading Diversity



fades. ARQ/F removes packet errors at the cost of only moderate additional link latency. For this reason, ARQ/F–based systems can be designed to operate at high PER levels while still providing satisfactory quality of service (QoS). The higher operating PER will routinely translate into SINR gains of up to 6 dB in the link budget.

3. Conclusion

Successful deployment of 2G FWA networks poses important technical but solvable challenges. Chief among those is the requirement to perform at a high level of performance in an unfriendly wireless channel environment. Multipath mitigation techniques such as antenna diversity and OFDM modulation appear as essential design elements of FWA. Enhanced processing techniques such as MIMO–SM and adaptative modulation can give the desired higher data-rate performance. Finally, interference canceling and retransmission mechanisms will provide enhanced robustness for higher frequency reuse and coverage.

Implementing Distributed Look-Up Services in Wireless Ad-Hoc Sensor Networks

Alvin Lim
Professor, Department of Computer Science and Engineering
Auburn University

Abstract[1]

Wireless sensor networks are becoming increasingly important in the implementation of pervasive computing systems. Real-time information can be gathered directly through a very large number of mobile sensor devices scattered over a wide area and disseminated to various applications and end users over the ad-hoc sensor network with little or no fixed network support. Distributed computation, such as collaborative target tracking and remote surveillance, can be done on the fly as the sensor data are disseminated through the sensor network. These large surveillance sensor networks must adapt rapidly to dynamic changes in sensor node configuration. Appropriate distributed services and network protocols are required to solve the problems of mobility, dynamic reconfiguration, dispersion, weak and intermittent disconnection, and limited power availability. We provide three main distributed services to deal with these issues: look-up service, composition service, and dynamic adaptation service. In this paper, we focus on the implementation of the distributed look-up service that manages changes in the available services in the sensor network, migration of sensor nodes, and changes in task and network requirements. The distributed look-up service is implemented using directed diffusion network. The distributed look-up service provides more efficient and large-scale support for these changes than would be possible using directed diffusion alone. Through a distributed implementation of the look-up services, other application-specific network and system services can be defined spontaneously in the sensor network.

1. Introduction

Real-time information gathering is critical in many dynamically changing enterprise systems, such as the battlefield and commercial inventory and distribution systems. This real-time information can be efficiently gathered and disseminated via integrated low-powered sensors and mobile devices [11,19,21] that are deployed throughout the enterprise pervasive computing system. These mobile and miniaturized information devices are equipped with embedded processors, wireless communication circuitry, information storage capability, smart sensors, and actuators. These sensor nodes are networked in an ad-hoc way, with little or no fixed network support, to provide the surveillance and targeting information for dynamic control of the enterprise. Sensor devices are mobile, subject to failure, deployed spontaneously, and repositioned for more accurate surveillance. Despite these dynamic changes in the configuration of the sensor network, critical real-time information must still be disseminated dynamically from mobile sensor data sources through the self-organizing network infrastructure to the components that control dynamic re-planning and re-optimization of the theater of operations based on newly available information.

With a large number of sensor devices being quickly and flexibly deployed in most impromptu networks, each sensor device must be autonomous and capable of organizing itself in the overall community of sensors to perform coordinated activities with global objectives. When spontaneously placed together in an environment, these sensor nodes should immediately know about the capabilities and functions of other sensor nodes and work together as a community system to perform cooperative tasks and networking functionalities. Sensor networks need to be self-organizing, because they are often formed spontaneously from a large number of mixed types of nodes and may undergo frequent configuration changes. Some sensor nodes may provide networking and system services and resources to other sensor nodes. Others may detect the presence of these nodes and request services from them.

Other challenges in implementing ad-hoc sensor networks are as follows: First, many different types of sensors with a range of capabilities may be deployed with different specialized network protocols and application requirements. Data-centric network protocols are becoming common in sensor networks [5,6]. With many mixed types of sensors and applications, sensor networks may need to support several data-centric network protocols simultaneously. Second, these mixed types of sensor nodes may be deployed incrementally and spontaneously with little or no pre-planning. Third, the sensor network must react rapidly to changes in the sensors' composition, task or network requirements, device failure and degradation, and mobility of sensor nodes. Finally, distributed services and network protocols for a sensor network must address the problems of weak connection, intermittent disconnection, and limited power availability.

The underlying principle for building self-organizing sensor networks that can overcome the aforementioned challenges is to provide the fundamental mechanisms upon which other networking and system services may be spontaneously specified and reconfigured. The three fundamental mechanisms are service look-up, sensor-node composition, and dynamic adaptation. Through a distributed implementation of these look-up servers, composition servers, and adaptation servers, other network and system services can be defined spontaneously in the sensor network. They also dynamically adapt these services in response to device failure and degradation, movement of sensor nodes, and changes in task and network requirements.

Application-specific network and systems services may be provided impromptu by sensor nodes and supporting nodes, including application-specific information dissemination and aggregation services. A sensor network application may utilize negotiation methods [10] for information dissemination. Sensor nodes will instead register these services with the look-up server.

2. Architecture

We use an approach that integrates three self-configuring system layers: sensor-application systems, configurable distributed services, and the network and physical-device layer. The sensor-application layer contains self-configuring sensor applications, collaborative signal processing, and adaptive sensor query processing. The runtime reconfigurable distributed system contains appropriate distributed services for supporting self-configuring sensor applications. The network and physical layer contains data-centric network routing protocols, physical wireless transmission modules, and sensors that generate the raw data.

The main functions of these key system layers (see *Figure 1*) are as follows:

1. ***Self-organizing application systems***, e.g., sensor information-processing layer and collaborative signal processing
2. ***Configurable distributed systems*** that provide distributed services to the self-configuring application systems
3. ***Sensor-networking and physical-devices layer*** that routes messages through the ad-hoc sensor network and gather real-time sensor data

At the physical-device layer, different physical sensor and mobile devices may be assembled impromptu and reconfigured dynamically in an ad-hoc wireless network. Each sensor node contains a battery power source, wireless communications, multiple sensing modality, a computation unit, and limited memory.

Dual processors may be included for computation and real-time sensor processing. Three common sensing modalities are supported: acoustic sensing using commercial microphones, seismic vibration using geophones, and motion detection using two-pixel infrared imagers. Wireless transceivers in the nodes provide communications between nodes using time division multiplexing (TDM) and frequency hopping spread spectrum. In each cluster, neighboring nodes communicates through a master node that establishes the frequencies used by the nodes. Each node contains a global positioning system (GPS) receiver that allows the node to determine its current location and time.

At the networking layer, ad-hoc routing protocols allow messages to be forwarded through multiple physical clusters of sensor nodes. Directed diffusion routing [6] is used because of its ability to dynamically adapt to changes in sensor network topology and its energy-efficient localized algorithms.

To retrieve sensor information, a node will set up an interest gradient through all the intermediate nodes to the data source. Upon detecting an interest for its data, the source node will transmit its data at the requested rate.

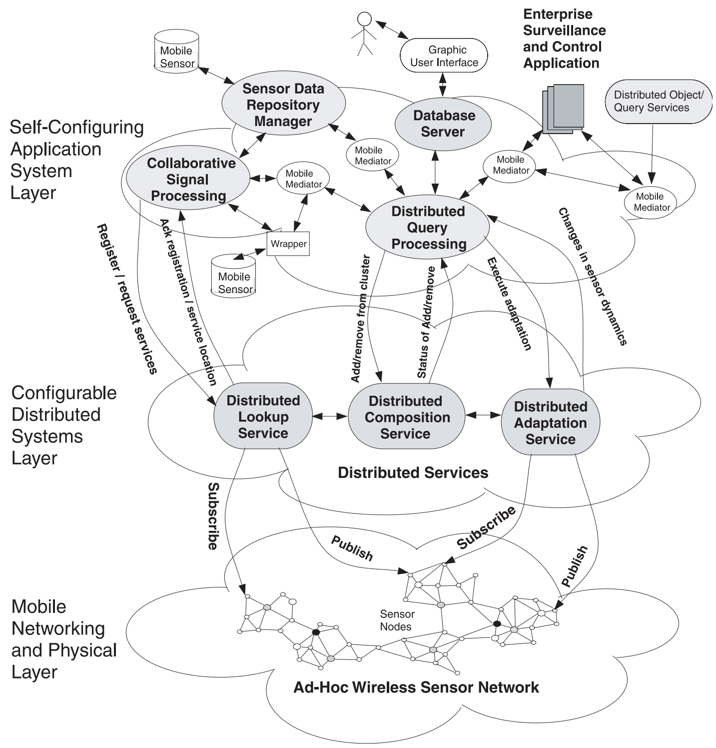
The configurable distributed system uses the diffusion network protocol to route its messages in the presence of dynamic changes in the sensor network. These distributed services support self-configuring sensor applications systems, such as distributed query processing, collaborative signal processing, and other applications. Through the distributed look-up services, application and system programs can be spontaneously and independently fielded and will be able to determine each other's services and self-organize themselves to perform collaborative tasks. Another advantage of the distributed look-up services is that applications programs may use simpler communication interfaces and abstraction than the raw network communication interface and metaphor (e.g., subscribe/publish used in diffusion routing).

Furthermore, these distributed services may enhance the overall performance, such as throughput and delay. These services will be implemented on top of the directed diffusion protocol, which can still be used by applications concurrently with these distributed services. Directed diffusion can still be the preferred method for retrieving sensor data and will be used by some of the services.

At the self-configuring application system layer, distributed sensor query processing and collaborative signal-processing modules communicate with each other to support monitoring, surveillance, and tracking functions of the enterprise. In sensor information systems, the cooperation between mobility-aware mediators, sensor agents, and collaborative signal-processing modules provide efficient access to diverse heterogeneous sensor data, surveillance, and tracking information through the sensor network. The mobile sensor information layer is supported by three major components: interoperable mobile object, dynamic query processing, and mobile transactions. In the interoperable mobile object

FIGURE 1

Architecture of Self-Organizing Sensor Networks



model, a cooperative network of mobility-aware mediators and sensor agents will be configured to support interfaces to remote sensor data sources through multi-hop wireless network protocols.

3. Data-Centric Network Protocols

We use directed diffusion protocol [8] to implement all of the distributed services and for retrieval of data through dynamically changing ad-hoc sensor networks. Diffusion routing converges quickly to network topological changes, conserves mobile sensor energy, and reduces the network bandwidth overhead, since routing information is not periodically advertised. Routing is based on the data contained in sensor nodes rather than unique identification. Directed diffusion is a type of reactive routing protocols that only updates routing information on demand. In contrast, proactive routing protocols, such as links-state routing, frequently exchange routing information. For sensor networks that experience greater dynamic changes, reactive routing algorithms are more appropriate, whereas for those that are more static and experience infrequent topological change, proactive routing algorithms are more efficient.

Directed diffusion is a data-centric protocol, i.e., nodes are not addressed by Internet protocol (IP) addresses but by the data that they generate. Data that are generated by a node are identified by their attribute-value pair. A sink node requests for a certain data by broadcasting an *interest* for the named data in the sensor network. The interest and gradient is established at intermediate nodes for this request throughout the sensor network. When a source node has a data that matches the interest, the data will be "drawn"' down toward that sink node using this interest gradient that was established. Intermediate nodes may cache, transform data, or direct interests based on previously cached data. The sink node can determine if a neighbor node is in the shortest path whenever it received a new data earliest from that node. The sink node will reinforce this shortest path by sending a reinforcement packet with a higher data rate to this neighbor node that forwards it to all the nodes in the shortest path. Other non-optimal paths may be negatively reinforced so that they do not forward data at all or at a lower rate.

Distributed services and applications use the publish and subscribe application programming interface (API) provided by directed diffusion. Through the subscribe() function, an application declares an interest that consists of a list of attribute-value pairs. The subscription is then diffused through the sensor network. A source node may indicate the type of data it offers through the publish() function. It then sends the actual data through the handle returned from the publish() function. The sink node then received the data that has propagated through the sensor network using a recv() function call with the handle returned from the subscribe() call.

4. Distributed Services Overview

Self-organizing sensor applications may be implemented using distributed services that permit the distributed sensor applications to adapt their functionalities and reconfigure their task requirements, manage mobility, and recover from sensor failure. Three main types of distributed services are look-up service, composition service, and adaptation service (see *Figure 1*). These servers enable sensor nodes to form spontaneous communities in ad-hoc sensor networks that may be dynamically reconfigured and hierarchically composed to adapt to real-time information changes and events.

These distributed servers may be replicated for higher availability, efficiency, and robustness. Distributed servers coordinate with each other to perform decentralized services—e.g., distributed look-up servers may work together to discover the location of a particular remote service requested by a node.

4.1. Reconfigurable Smart Components

By exploiting these distributed services, sensor applications can be enabled to be self-aware, self-reconfigurable, and autonomous. Sensor applications running in each sensor node are known as reconfigurable smart components. They are the building blocks for constructing large, scalable, and self-organizing sensor networks. (In this paper, we refer to reconfigurable smart sensor components as smart components or simply sensor nodes.) Smart components may represent sensor nodes or other types of mobile nodes, fixed nodes, or clusters of these nodes. They may simultaneously be service providers for other smart nodes and clients of services that other smart nodes provide.

Smart nodes interact with other smart nodes through well-defined interfaces (for networking and systems operations) that also maintain interaction states to allow nodes to be dynamically reconfigured. These explicit interaction states and behavior information allow localized algorithms with the adaptation servers to maintain consistency when autonomous nodes and clusters are reconfigured dynamically, move around, or recover from failure.

4.2. Look-Up Server

The look-up service enables new system and network services to be registered and made available to other sensor nodes. Methods for calling the services remotely are also provided.

A sensor node that provides a service is called a service provider, and a node that uses the service is called a service client. Because service providers may be introduced or removed from the sensor network at any time, a look-up server is needed to keep track of the availability of these services. A sensor node may register a resource that it maintains or service that it can perform with a look-up server (see *Figure 2*). A look-up server may contain information on services or resources at multiple clusters. Other nodes that require the service may request the service through a look-up server. If the service is recorded in the look-up server, it will return the location of that service to the requesting node. Otherwise, if the service is not recorded in the look-up server of the region, a discovery protocol is invoked to locate the service through other look-up servers (see *Figure 2*). A request message is propagated to all of the look-up servers, and the server that contains the service registration information will return the reply with the service location.

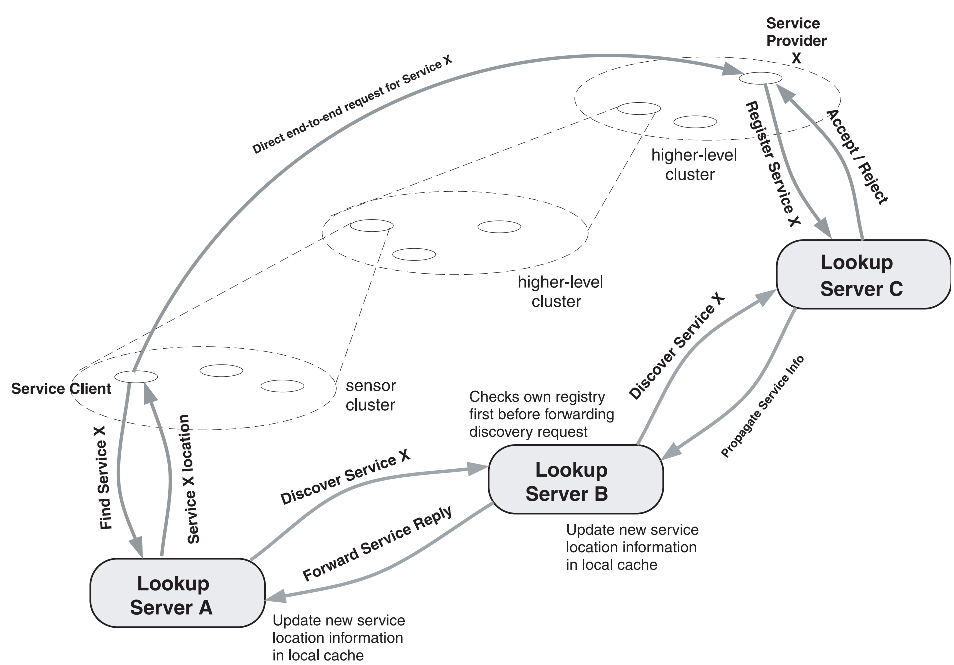
The look-up server that made the request will then store that service location information in its local registration table. At a regular frequency, service and resource registration information may be exchanged among the look-up servers.

4.3. Composition Server

The composition service allows clusters of sensor nodes to be formed and managed. It allows various smart nodes to be

FIGURE 2

Discovery of Services with Distributed Look-Up Server



added to (or removed from) clusters in the sensor network. Hierarchical clusters are also possible for larger-scale sensor networks. A cluster of sensors may also provide distributed services by coordinating the tasks among the sensors, such as aggregating summary information. Clustered smart nodes encapsulate the networking and system capabilities provided cooperatively by the group of smart nodes. There will be a head smart node in the cluster that is responsible for the control of the cluster and inter-cluster communications and networking functions. Group communication to nodes in a cluster can be efficiently implemented by sending a message first to the cluster head, which then multicasts it to the member nodes. Member nodes will elect a cluster head from the set of nodes with the most powerful networking and system capabilities. Smart nodes in a cluster may cooperate to perform the networking and system functions for the cluster. Synchronization constraints associated with network protocols and system services among smart nodes may be specified in clustered smart nodes. The capability to specify hierarchical composite clusters enables designers to build large and complex sensor networks by clustering together smaller network-enabled sensor devices at each level.

4.4. Adaptation Server

The adaptation service allows sensor nodes and clusters to reconfigure dynamically as a result of sensor-node mobility, failure, and spontaneous deployment. Adaptation servers utilize information from the composition server, look-up server, and analytical tools to control smart nodes during dynamic reconfiguration and failure recovery of the agile sensor network. Each smart node may execute autonomously to control different network operations in the sensor network and may interact and coordinate independently with other smart nodes to perform collaborative networking operations.

Adaptation servers monitor clusters of smart nodes during normal execution, either through the spontaneous signal from the sensors, probing of the smart nodes, or explicit network-management directives for reconfiguration and failure recovery. When a runtime reconfiguration is requested or triggered, the adaptation server will generate the appropriate schedule of reconfiguration operations that will ensure that the reconfigured and affected sensor nodes are globally consistent. When smart nodes are added or removed from the agile sensor network, a suite of analytical tools may be utilized to ensure that the sensor network still maintains its safety and liveness properties [13].

5. API for Look-Up Service

Applications use the look-up service through the following API. We focus primarily on the look-up service API in this paper, because it is responsible for enabling sensor networks to be self-organizing. In the next section, we will describe how these API functions are used by the various application systems of a surveillance sensor network.

These API functions use the following parameters:

- ***service_type*** is the generic type of service for which there may be several instances. For example, a type of service may be temperature monitoring, whereas specific instances of temperature sensors may be sensor *X* at location *Y*.
- ***service_name*** is the specific name that identifies an instance of a service provider.
- ***input_list*** is a list of attribute-value pairs containing the input parameters to the service invocation.
- ***output_list*** is a list of attribute-value pairs containing the output values from the service invocation.
- ***lifetime*** is the time period in which a service information will be stored in a look-up server.
- ***interface_type*** is one of the following three types of interfaces that the callee of the service uses:
  1. *Location or Address:* This is used by the service client if it knows the interface for interacting with the service provider—e.g., using remote procedure calls. The service client merely needs to retrieve the location or address of the service provider to be used for invoking the service request.
  2. *Interface Definition:* This is used by the service client to retrieve the definition of the interface for interacting with the service provider. The service client must have the interpreter or compiler for the interface definition.
  3. *Mobile Code:* This is used by the service client to retrieve the mobile code that implements the protocol for interacting with the service provider. The mobile code must then be dynamically linked to the service client.

The following is a description of the purposes and the side effects of the look-up service function calls:

- ***service_call(service_name, input_list, output_list, interface_type):*** This function is used by a service client to find and make a call for a service where the service client does not know the location or address of the service provider and/or the interface for using the service. It is implemented as a combination of the look-up_service() and service_exec() calls described below. This function requires specific a service name to be provided. A generic service type cannot be used because several service-provider instances may match the service type.

- ***status = look-up_service(service_type, service_name, input_list, output_list, interface_type):*** This function allows a service client to find the location or address of a service provider and/or the interface for using the service. If service_type is defined and service_name is NULL, then all service providers registered with the look-up server of that type is returned. Service look-up can also be based on cluster or predicate matching. The cluster information and predicate for matching service providers are contained in the input_list. Depending on the interface_type used—i.e., location, interface definition, or mobile code—the respective results of the look-up_service() call will be placed in the output_list.

- ***status = service_exec(service_name, input_list, output_list, interface_type):*** This function allows a node to request for the service and gets the results back from the service provider. The input parameters are supplied by the client via the input_list. The service provider performs the requested service or remote procedure call and returns the results in the output_list. The interface_type defines the method used by the service client to communicate with the service provider.

- ***status = service_register(service_type, service_name, lifetime, input):*** This function allows a service provider to register its service with a look-up server in the region. Services will remain in the look-up server for the lifetime specified by the service provider. In the input_list, the service provider may supply one or more of the following service information: location or address, interface definition, or mobile code. Look-up servers for different regions may coordinate with each other to update their list of service information.

- ***status = service_deregister(service_type, service_name):*** This function allows a service provider to remove its service from the look-up server registry.

6. Implementation of Look-up Service

The look-up service is implemented using a directed diffusion routing protocol that is capable of adapting to changes in the ad-hoc sensor network topology.

6.1 Discovery of Look-Up Servers

When a node (that may implement a look-up server, a service provider, or a service client) moves into a new area or is rebooted, it first sends out a discovery interest to search for a nearby look-up server. If there is a look-up server available, the look-up server will send an acknowledgement with the information of itself—such as its name, ID, location, and other information—to the node by publishing this information.

If several look-up servers reply, the node will accept the first one that replied and ignore the others. The node stores the look-up server information in a table called "look-up table" for future reference.

To reduce bandwidth usage, the service client will only broadcast its discovery interest to within a limited region in its vicinity. The size of the region will depend on number of look-up servers in the sensor network. Each intermediate node runs an application-specific routing filter program that checks whether the node is outside the region for the discovery interest. If it is, the node will not propagate those interests any further. Otherwise, it will broadcast the discovery interest to its other neighbors.

The following are the pseudocodes for look-up server discovery:

Node Discovery Client

```
setupFindingInterest();
while (not found)
    waiting;
unsubscribe();

callback::recv()
{
    if (receive Discovery publication)
       store look-up server info in cache
        set found;
}
```

Look-Up Service Discovery Server Daemon

```
Handle = setupDiscPublication();
while (1)
{
    send(my_location);
}
```

In the node discovery clients, the function setupFindingInterest() sends out the discovery interest. It then waits for the reply from a look-up server. The callback function will be activated when a reply arrives. In the look-up server node, there is a discovery daemon that handles discovery requests and publishes its information.

6.2 Look-Up Server Registration

When a look-up server moves into a new area, it tries to find another existing look-up server and registers with the other look-up server. It sends to other look-up servers in the vicinity the registration interest containing information about itself. Each existing look-up server will update its look-up server table with information from the interest packet and return a list of all look-up servers that it is aware of. It then forwards the registration packet to all those look-up servers, through shortest reinforced routes created by the diffusion protocol.

The following are the pseudocodes for look-up server registration:

Client for Look-Up Service Registration

```
setupRegReqInterest();
while (not succ_reg)
    waiting;
unsubscribe();

callback::recv()
{
    if (recv ACK from Server)
    {
        get shared information;
        set succ_reg;
    }
}
```

Server for Look-Up Service Registration

```
setupSvrRegSvrInterest();
while (not received incoming interest)
    waiting;
// Include shared information;
setupSvrRegACKPublication();
send(ACK, shared LkupSvr information);
unpublish();

callback::recv()
{
    if (matched income interest)
    {
        set signal;
        store in its table();
        // Forward interest to other
        // look-up servers.
        update_lkup();
    }
}
```

The look-up service registration client executing in the look-up server tries to register itself with another look-up server through the look-up service registration server. This registration server will continually publish its information on other look-up servers of which it is aware in response to any registration request from another look-up server. The callback function will be activated when there is a new registration interest. The information from registration interest will be stored in its local table. The information is then forwarded to other look-up servers via the function update_lkup().

6.3 Service-Provider Registration

When a service provider moves into a new area or restarts a service, it first tries to find a new look-up server and registers its service with the look-up server. This is done by sending out the registration interest to the look-up server that includes the information on the service provider itself, such as its location, ID, name, and other information on the service and interface. It then waits for acknowledgement from the look-up server.

For registration that involves transferring mobile codes or interface definitions that implement the service-provider interface, there are three steps in the registration process that includes a Go-Back-N protocol. In the first step, the service provider sends an interest for registering its service. The look-up server then publishes its acceptance or rejection of that request. In the second step, the look-up server sends its interest in receiving the mobile code packets. (Large mobile codes must be fragmented into smaller packets.) The service provider then publishes the packets to the look-up server. When the transmission of the packets is completed, the service provider sends an interest in the third step for receiving an acknowledgement from the look-up server that the mobile code transfer and the registration are successful. If successful, the look-up server will publish an acknowledgement. Otherwise, it publishes a negative acknowledgement.

The following are the pseudocodes for the registration of service providers:

Client for Service Provider Registration (implemented in the service provider)

```
//Step 1.
setupRegInterest();
while (not succ_reg)
    waiting;
unsubscribe();

callback::recv()
{
    if (recv ACK from Server)
    {
        set succ_reg.;
    }
}

//Step 2.
Publish();
Initialize timer;
Send packet with pckcnt and set GBN_Window;

// Step 3.
Create_thread_for(RegACKListener);
Subscribe interest;

Callback::recv()
{
    if (it's a new ACK)
    {
        set GBN_Window;
        set ACKNUM;
        call GBN_timer();
    }
}
```

Server for Service-Provider Registration (implemented in the look-up server)

```
// Step 1.
setupSvrRegSvrInterest();

callback::recv()
{
    StoreInCache();
    Send ACK;
    // Step 2. Interest in receiving
    // mobile code packets
    Subscribe interest();
}

// Step2. Receiving packets
Callback::recv()
{
    StoreInCache();
    // Step 3.
    Send ACK;
}
```

Since diffusion network routing is based on events and notification model of communication, we implemented an end-to-end automatic repeat request protocol based on Go-Back-N to ensure reliable transmission of the mobile codes and interface definition that could be large.

6.4 Service Deregistration

When a service provider wants to terminate its service, it first deregisters the service with the look-up server by sending it a deregistration interest. After the look-up server receives the deregistration interest, it purges the service record from its service table and sends the update interest to all other look-up servers.

6.5 Service Look-Up

When a node needs to find information on a specific service and the relevant service provider, it calls its local service look-up function that sends a look-up interest to the look-up server to fetch the updated service information. After the look-up server received the look-up interest, it searches its local service table first. If it finds the service record, it will return a data packet to the node by publishing the data. Otherwise, it will send the look-up request interest to all other look-up servers. If the service still cannot be found, it will return a failure message to the requesting node.

The requesting node can look up a service using a service type instead of a specific service name. The service type is the generic type of the service—for example, a generic type of a detector may be "Detector", whereas the service name of that detector is "Detector_AA_trace_01." If the look-up server received a service-type interest, it will return the number of matched service providers as requested. The default number of service providers is 1.

The following are the pseudocodes for service look-up:

Client of Service Look-Up (executes in the service requester)

```
GetserviceCache();
if (no record)
{
    setupLKUPInterest();
    while (no succ_sig)
        wait;
    unsubscribe();
}

callback::recv()
{
    if (recv look-up return)
       cache provider's info;
        set succ_sig;
}
```

Server of Service Look-Up

```
setupLKUPSvrInterest( );
while (1)
    ;

callback::recv()
{
    unpack interest;
    look-up the cache;
    if (no record in cache)
    {
        setupLKUPInterest();
        // Forward the interest to
        // other LKUP Servers.
        While(no succ_sig)
            Waiting;
        Unsubscribe();
    }
    store results in local table;
    setuplook-upPublication();
    send();
    unpublish();
}
```

The look-up server sets up a local interest by calling the function setupLKUPSvrInterest(). When it receives a corresponding matched global interest from the client, this local interest will activate the callback function to search and return the service provider's information. It returns this information through publish and send functions. If no information on the service provider is found in the local table, the request interest will be forwarded to other look-up servers. The results will be stored in its local table and then sent to the requesting node.

6.6 Remote Service Execution

When a node wants to execute a service from a service provider, it searches its local service table to get the information on the service and the service provider. If it cannot find the relevant information, it will call the service look-up function to update its local service table. Three types of service interfaces may be specified by the service provider's information: Location or address of the service provider with known interface, interface definition of the service, or mobile code for the interface protocol. These interfaces were described in Section 5.

Consider the example in which the service client uses remote procedure calls (RPC) to request remote services from the service provider. RPCs are implemented as follows: The call to service_exec() will first send an interest to the service provider through subscribe() function in the SetupserviceExecInterest() function. The service provider then sends a data to the client containing the permission to send the request. The client then sends a request and all the input data. If the input data is large, several packets may be sent reliably through an automatic repeat request protocol with retransmission. The service provider will then process the service remotely. The client will request the result of the service through another subscription. The provider then returns the result in a data in response to the interest.

The following are the pseudocodes for remote service execution:

Client of Service Execution

```
SetupserviceExecInterest();
while (not execget)
    wait;
unsubscribe( );

callback::recv()
{
    if (recv Result from service Provider)
    {
        collect service Execution result;
        set succ_reg.;
    }
}
```

Server of Service Execution

```
SetupserviceExecSvrInterest();
while(1)
    sleep;

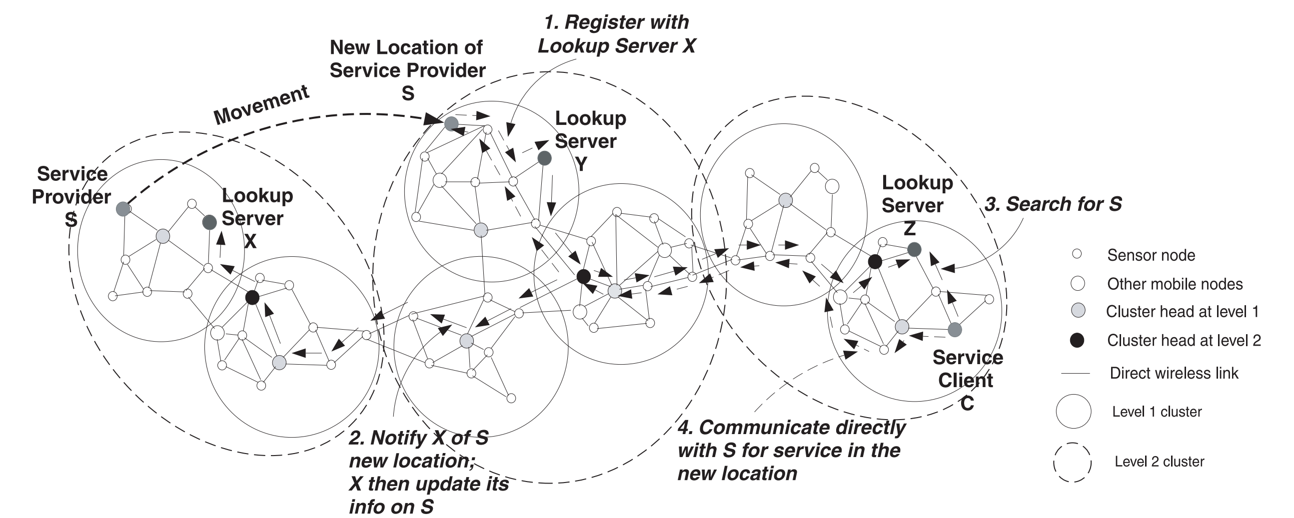
callback::recv()
{
    if(recv service Execute Interest)
    {
        collecting the data;
        setupserviceExecSvrPublication();
    }
}
```

7. Support for Sensor Node Mobility

Look-up servers support the mobility of sensor nodes. When a sensor node moves to a different cluster at another location, it notifies, whenever possible, the previous look-up server that it is moving. When it arrives at another cluster in a new location, it will register with the new look-up server that will notify the previous look-up server (see *Figure 3*). The new look-up server will propagate the change in the node's location to other look-up servers. The look-up server responsible for a sensor node that is interacting with the mobile node will notify the sensor node of the service location change. Existing interactions between the mobile node and other nodes will thus be handed over to the new location. Adaptation servers may be involved in the handover operation to preserve global consistency during the handoff resulting in uninterrupted use of the service.

FIGURE 3

Mobility of Smart Nodes



8. Application Systems

In the following, we discuss how the look-up service enables various application services for collaborative signal processing to be self-configurable in ad-hoc sensor networks.

In target recognition and tracking [3], the multiple reading of the sensor values can be statistically combined to derive more accurate tracking data. Sensors in a region may be clustered together through the distributed composition server, where their sensor reading may be combined using a weighted voting algorithm [18] to provide more accurate data. For each cluster, a sensor node may be elected to be the head of the cluster. Readings from multiple sensors in the clusters will be propagated to the cluster head through diffusion routing, where the algorithm is applied. Results from each cluster head may be propagated to higher-level cluster heads for data fusion.

In many sensor applications, data generated by the sensor node may be very large. The cost of propagation of these sensor data as in the previous scheme will be prohibitive. One solution to address this problem is to use mobile agents to migrate from node to node to perform data fusion using the local data [17]. Instead of transferring large amounts of data throughout the sensor network, this approach only transfers the mobile agent code that is smaller than the sensor data. The result is an improvement in the execution time of the collaborative signal-processing algorithm.

A sensor node that needs to execute a mobile agent code must download the mobile code from a mobile code repository manager in its region. It may use the look-up_service() call to first locate the repository manager that stores the relevant mobile code. It then calls service_exec() to the repository manager to download the code. An alternative method is to store the mobile code with the look-up server. The sensor node can then use look-up_service() to retrieve the mobile code directly from the look-up server.

The entire surveillance area is split into several sub-areas. Each sub-area is controlled by a signal-processing agent, also known as a processing element (PE), which may dispatch several mobile agents into that sub-area. The signal processing agent may register itself with the look-up server using service_register() to allow other nodes, such as the mediators, to access its tracking results. Each mobile agent will migrate from node to node to perform data fusion, for instance using a multi-resolution data integration algorithm [17]. Each mobile agent, addressed by an identification, contains an itinerary, data, method, and interface. The identification is a 2-tuple composed of the identification of the dispatcher and the serial number assigned by the dispatcher. The itinerary describes the migration route assigned by the dispatcher. The data is the agent's private data that contains the integration results. The method describes the multi-resolution data integration algorithm. The interface is the function by which the agent communicates with the PE and for the PE to access the agent's private data.

When mobile agents migrate from node to node, the results of the sensor integration algorithm from previous nodes are cached in the mobile agents. This state information must be transferred with the mobile agent as it migrates from node to node. Agent migration and state transfer are supported by the distributed adaptation service. As the mobile agents visit each node, it may register with the look-up server. The primary signal-processing agent (PE), may find these mobile agents as they move around and retrieve results using the service_call() function. A mobile agent may also retrieve intermediate results from other mobile agents through service_call().

For migration of mobile agents far beyond a region managed by a look-up server, the agent will register with another look-up server in the new region. A service client may try to contact the mobile agent through the first look-up server and may need to use several intermediate look-up servers to get the information about the mobile agent's current location.

Multi-resolution signal processing algorithms may be implemented using a hierarchical clustering of sensors provided by the distributed composition server. Results from a sensor cluster may be passed to agents responsible for signal processing for higher-level clusters. Agents for higher-level clusters may send messages to multiple sensor clusters using a group communication method provided by the service_exec() call by specifying the appropriate service_type parameter.

9. Related Work

In recent years, the development of new integrated low-power sensor devices [11,19,21] has spurred more research on sensor networks for remote surveillance [3], pervasive computing, mobile computing, and computing continuum. Some research on sensors and RFID tags have also focused on the technical issues in wireless links between the sensor and the interrogator [12], low power consumption [19], sensor types and capability [14], position determination [20], and identification. Many of the current commercial systems transmit data from sensors to interrogators through wireless links, but forward them through direct static connections to a fixed network, either through a cable or wireless link. However, over-reliance on fixed network infrastructure is not feasible for a large sensor information network. Instead, sensors must themselves be capable of assembling ad-hoc networks when they are deployed spontaneously in an area. The sensors must self-organize in spite of changes and failure in the sensors and the network topology.

Several novel concepts and protocols have been developed for many aspects of self-organizing sensor networks' design and implementation. In ad-hoc network routing, localized algorithms have been developed for autonomous sensor devices to route information in an energy efficient way. A directed diffusion routing protocol [8] based on the localized computation model provides energy-efficient and robust communication for dynamic network with small incremental changes. For dynamic networks with large-scale changes and high level of mobility, directed diffusion may not adapt very well. Similar diffusion routing concepts have also been presented in other work [16]. Another localized protocol for information dissemination in sensor networks uses meta-data negotiation to eliminate redundant transmissions [10]. Other self-organizing network routing protocols are dynamic source routing [9] and destination-sequenced distance vector [15], although it is not clear if these algorithms are energy efficient enough for sensor networks. In this paper, we allow sensors to form high-level clusters and use directed diffusion within clusters. Clusters may be formed using a localized algorithm [6] for coordinating among sensors to elect extremal sensors.

The discovery of services in mobile systems provides critical support for self-organizing sensor systems when sensors are being deployed and removed on the fly. In Jini [1], service discovery relies on mobile Java codes and is implemented based on transmission control protocol (TCP) and user datagram protocol (UDP). It is not clear how these may be implemented using data-centric, ad-hoc sensor networks with services based on more generic mobile codes. Service-location protocol (SLP) [7] is an Internet Engineering Task Force (IETF) protocol for service discovery that is designed solely for IP–based networks. Bluetooth [2] devices have a range of 10 meters and can directly communicate with at most seven other Bluetooth devices in a piconet. Bluetooth service-discovery protocol (SDP) [2] allows devices to browse and retrieve services by matching service classes or device attributes. Only services within the range of the device are returned. Our look-up service may retrieve services that could be multiple hops from the requesting node.

Communications in sensor network are data-centric, since the identities of the numerous sensors are not as important as the data that they contain [5,6]. The networking infrastructure may provide a more efficient dissemination of data through replication, caching, and discovery protocols [5]. Communications protocols must be energy efficient because sensors [11] have very limited energy supply. In our architecture, the caching and aggregation of information may be provided by some sensors. The discovery of these sensors can be made through the distributed look-up servers that are implemented using diffusion routing. Changes in the sensor network are propagated to other caching and aggregation services through the adaptation servers. Our framework facilitates the consistent adaptation of networking and system services as well as distributed sensor applications. Unlike other centralized control networks [4], our servers are associated only with sensors in a vicinity. Servers in different clusters will coordinate among themselves through information diffusion.

10. Conclusions

We have described how distributed look-up services can be implemented using directed diffusion network protocols. The look-up service supports self-organization of sensor networks that are useful for many sensor applications, such as sensor information retrieval and remote surveillance. The look-up service is implemented in the overall distributed service architecture that consists of three basic distributed servers: look-up servers, composition servers, and adaptation servers. Through the look-up servers, sensor nodes may be placed together impromptu in spontaneous environments, and these sensor nodes will immediately know about the capabilities and functions of other sensor nodes and work together as a community system to perform cooperative tasks and networking functionalities. These distributed services are implemented using directed diffusion network routing that provides energy-efficient and data-centric data communications. While diffusion routing can adapt dynamically to limited mobility and topological change, the distributed look-up services support large mobility and changes in sensor nodes in a large-scale ad-hoc network. Diffusion uses a data-centric communications model, whereas in distributed sensor applications, it may be more convenient to use end-to-end process-oriented communications.

Wireless LAN: Its Benefits and Implications

Gordon K. Lin
President and Chief Executive Officer
Lintel Communications, Inc.

Introduction

Wireless local-area network (LAN) technology is rapidly becoming a crucial component of computer networks. According to the IEEE 802.11 wireless LAN standard, wireless network technology has emerged from the world of proprietary implementations to become an open solution for providing mobility as well as essential network services where wireline installations proved impractical. Now companies and organizations are investing in wireless networks at a higher rate to take advantage of mobile, real-time access to information.

Wireless LAN Benefits

The emergence and continual growth of wireless LANs are being driven by the need to lower the costs associated with network infrastructures and to support mobile networking applications that offer gains in process efficiency, accuracy, and lower business costs. This section explains the mobility and cost-saving benefits of wireless LANs.

Mobility

Mobility enables users to move physically while using an equipment/instrument, such as a handheld personal computer (PC) or data collector. Many jobs require workers to be mobile, such as inventory clerks, health-care workers, policemen, and emergency-care specialists. Of course, wireline networks require a physical connection between the user's workstation and the network's resources, which makes access to these resources impossible while roaming about the building or elsewhere. This freedom of movement results in significant return on investments (ROIs) due to gains in efficiency.

Mobile applications requiring wireless networking include those that depend on real-time access to data—usually stored in centralized databases. If your application requires mobile users to be aware immediately of changes made to data, or if information put into the system must immediately be available to others, then you have a definite need for wireless networking. For example, for accurate and efficient price markdowns, many retail stores use wireless networks to interconnect handheld bar-code scanners and printers to databases having current price information. This enables the printing of the correct prices on the items, making both the customer and the business owner more satisfied.

Installation in Difficult-to-Wire Areas

The implementation of wireless LANs offers many tangible cost savings when performing installations in difficult-to-wire areas. If rivers, highways, or other obstacles separate buildings that you want to connect, a wireless solution may be much more economical than installing physical cable or leasing communications circuits, such as T1 service or 56K lines. Some companies spend thousands or even millions of dollars to install physical links with nearby facilities. If you are facing this type of installation, consider wireless networking as an alternative.

The asbestos found in older facilities is another problem that many companies encounter. The inhalation of asbestos particles is extremely hazardous to your health; therefore, you must take great care when installing network cabling within these areas. Some companies, for example, remove the asbestos, making it safe to install cabling. This process is very expensive. Obviously, the advantage of a wireless LAN in asbestos-contaminated buildings is that you can avoid the asbestos removal process, resulting in tremendous cost savings.

Some municipalities may restrict you from permanently modifying older facilities with historical value. This could limit the drilling of holes in walls during the installation of network cabling and jacks. In that case, a wireless network might be the only solution. Right-of-way restrictions within cities and counties may also block the digging of trenches in the ground to lay optical fiber for networked sites. Again, in this situation, a wireless network might be the best alternative.

Increased Reliability

A problem inherent to wired networks is downtime due to cable faults. In fact, a cable fault is often the primary cause of system downtime. Moisture erodes metallic conductors via water intrusion during storms and accidental spillage or leakage of liquids. With wired networks, a user might accidentally break his/her network connector when trying to disconnect his/her PC from the network to move it to a different location. Imperfect cable splices can cause signal reflections that result in unexplainable errors. The accidental cutting of cables can bring down a network immediately. These problems interfere with users' ability to use network resources, causing destruction for network managers. An advantage of wireless networking, therefore, results from the use of less cable. This reduces the downtime of the network and the costs associated with replacing cables.

Reduced Network-Installation Time

The installation of cabling is often a time-consuming activity. For LANs, installers must pull twisted-pair wires or optical fiber above the ceiling and drop cables through walls to network jacks that they must affix to the wall. These tasks can take days or weeks, depending on the size of the installation. The installation of optical fiber between buildings within the same geographical area consists of digging trenches to lay the fiber or pulling the fiber through an existing conduit. You might need weeks or possibly months to receive right-of-way approvals and dig through ground and asphalt.

The deployment of wireless LANs greatly reduces the need for cable installation, making the network available for use much sooner. Thus, many countries lacking a network infrastructure have turned to wireless networking as a method of providing connectivity among computers without the expense and time associated with installing physical media. This is also necessary within the United States to set up temporary offices and rewire renovated facilities.

Long-Term Cost Savings

Companies reorganize, resulting in the movement of people, new floor plans, office partitions, and other renovations. These changes often require recabling the network, incurring both labor and material costs. In some cases, the recabling costs of organizational changes are substantial, especially with large enterprise networks. The advantage of wireless networking is again based on the absence of cable: You can move the network connection by simply relocating an employee's PC.

Wireless LAN Implications

Wireless LANs offer tremendous benefits, as described in previous section of this paper. However, project managers and design engineers should take the following issues into consideration when implementing wireless networking:

- Multipath Propagation
- Path Loss
- Radio Signal Interference
- Network Security
- Application Connectivity
- Installation Predictability

Multipath Propagation

Transmitted signals can combine with reflected ones to corrupt the signal detected by the receiver. This is known as multipath propagation. Delay spread is the amount of delay experienced by the reflected signals compared to the primary signal. As delay spread increases, the signal at the receiver becomes more distorted and possibly undetectable even when the transmitter and receiver are within close range. Office furniture, walls, and machinery are obstacles that can redirect parts of the transmitted signal. Wireless LAN manufacturers compensate for the effects of multipath propagation by using special processing techniques. As examples, equalization and antenna diversity are methods for reducing the number of problems arising from multipath propagation.

Path Loss

Path loss between the transmitter and receiver is a key consideration when designing a wireless LAN solution. Expected levels of path loss, based on the range between the transmitter and receiver, provide valuable information when determining requirements for transmit power levels, receiver sensitivity, and signal-to-noise ratio (SNR). Actual path loss depends on the transmit frequency, and it grows exponentially as the distance increases between the transmitter and receiver. With typical indoor applications, the path loss increases approximately 20 decibels (dB) every 100 feet.

Radio-Signal Interference

Wireless networks can interfere with other nearby wireless networks and radio wave equipments. Radio-signal interference can be inward or outward. A wireless LAN can experience inward interference from the harmonics of transmission system or other products (e.g., microwave ovens) using similar radio frequencies in the local area. Outward interference occurs when a wireless network's signal disrupts other systems, such as adjacent wireless LANs and navigation equipment on aircraft.

When dealing with interference, you should coordinate the operation of radio-based wireless network products with your company's frequency-management organization, if one exists. Government organizations and most hospitals generally have people who manage the use of transmitting devices. This coordination will avoid potential interference problems. If no frequency-management organization exists within your company, run some tests to determine the propagation patterns (radio frequency [RF] site survey) within your building. These tests let you know whether existing systems might interfere with, and thus block and cause delay to, your network. You will also discover whether your signal will disturb other systems.

Network Security

Network security refers to the protection of information and resources from loss, corruption, and improper use. The main security issue with wireless networks is that they intentionally propagate data over an area that may exceed the limits of the area that the organization physically controls. For instance, radio waves easily penetrate building walls and are receivable from the facility's parking lot and possibly a few blocks away. Someone can passively retrieve your company's sensitive information from this distance without being noticed. Someone can maliciously jam the radio-based network and keep you from using the network. Remember, most wireless networks utilize a carrier sense protocol to share the use of the common medium. If one station is transmitting, all others must wait. Someone can easily jam your wireless network by using a wireless product of the same manufacturer that you have within your network and setting up a station to resend packets continually. These transmissions block all stations in that area from transmitting, thereby making the network inoperable.

Wireless LAN vendors solve most security problems by restricting access to the data. Most products require you to establish a network access code and set the code within each workstation. A wireless station will not process the data unless its code is set to the same number as the network. Some vendors also offer encryption as an option.

Application Connectivity
The use of traditional wired-based protocols over wireless networks introduces problems with maintaining connections between the user's device and the application residing on a server. Transmission control protocol (TCP)/Internet protocol (IP), for example, over wireless networks is susceptible to losing connections, especially when the device is operating in an area with marginal wireless network coverage.

A solution to this problem is to use wireless middleware software, which provides intermediate communications between the end-user devices and the application software located on a host or server. The middleware enables highly efficient and reliable communications over the wireless network, while maintaining appropriate connections to application software and databases on the server/host via the more reliable wired LAN.

The mobile nature of wireless networks can offer addressing problems as well. Most networks require the IP address loaded in the user's device to be within a specific address range to maintain proper connections with applications. When a user roams from one IP subnet to another with a wireless device, the device and the application may lose the capability to connect with each other. As a result, implementers should consider the use of MobileIP as a mean of maintaining connectivity while traversing different IP domains.

Installation Predictability
With wired networks, planning the installation of cabling is fairly straightforward. You can survey the site and look for routes where installers can run the cable. Once the design is complete, installers can run the cables, and the cable plant will most likely support the transmission of data as planned. A wireless LAN installation is not as predictable. It is difficult to design the wireless network by merely inspecting the facility. Predicting the way in which the contour of the building will affect the propagation of radio waves is difficult. Walls, ceilings, and other obstacles attenuate the signals more in one direction than the other and even cause some waves to change their paths of transmission. Even the opening of a bathroom door can change the propagation pattern.

To avoid installation problems, an organization should perform propagation tests to access the coverage of the network. Neglecting to do so may leave users outside the propagation area of wireless servers and access points. Propagation tests give you the information necessary to plan wired connections between access points, allowing coverage over applicable areas.

Conclusion

Wireless LAN is moving toward open architecture implementation due to the introduction of the Institute of Electrical and Electronics Engineers (IEEE) 802.11 standard and is growing rapidly. It offers great benefits such as mobility and cost savings. When implementing wireless networking, the following issues should be taken into consideration: multipath propagation, expected path loss, radio-signal interference, network security, connectivity, and installation predictability.

Mobility—it is the hallmark of 21st century communications, with mobile voice services having already transformed both business and personal interactions. But the full potential of mobile communications won't be realized until the capability extends to data. This next stage—extending seamless mobility to the Internet—has begun, and it will represent the true mobile communications revolution, empowering users with anywhere, anytime, anyway access to the world's greatest reservoir of information and entertainment, and the capability to instantly share this wealth with others.

The development of third-generation (3G) networks, with their tremendous capabilities, will spur the creation of unprecedented amounts and types of content available on the Internet, including video, voice, and images. Combine that with the number of wireless subscribers expected to reach one billion by 2004[1] and the number of Internet users projected to reach 600 million a year later[2], and the demand for mobile Internet access is inevitable. So, too, will be the demand for convergent devices that provide both voice and data.

The communications industry already provides rudimentary mobile data services via wireless application protocol (WAP) and general packet radio service (GPRS) devices. On the horizon, though, are an exciting wave of mobile communications products and services made possible by a revolutionary new network-layer protocol called Internet protocol version 6 (IPv6). For the communications industry, mobile IP will indeed mean going new places. And Compaq Telecommunications will be there with the cutting-edge products and technology that make it possible.

Mobile IP: Telecom Challenges and Opportunities

No telecom company needs to be convinced about the desirability or viability of mobile communications. In a very short time, mobile telephony has changed the world. Soon, the number of mobile handsets will overtake the number of fixed lines. For business, mobile communications today means that deals are hastened, products and services are more rapidly developed and delivered, and productivity is enhanced. On a personal level, mobile communications today provides the comfort and assurance that friends and family are immediately available.

The coming ascendance of mobility in the computing world will be just as revolutionary. Soon enough, we will live in a world where accessing e-mail, receiving sports scores or stock prices, playing games, or downloading critical information will be as easy with a data device as it is with a cellular one. Indeed, *these devices will be one and the same*.

After all, consumers will ask, why should mobile communications exclude the world of multimedia content that is data? Why not download information from someone and immediately discuss it with them on the same device, regardless of where you are or where they are, or where either of you is going?

Compaq believes—and the historical development of the Internet confirms—that consumers will not just want more and better products and services, but that they'll also want to access these benefits as conveniently as possible. Until now in the computing world, that meant tailoring information and devices. But as important as those steps have been, the next advance is even more impressive: making the instant information of the Internet available in a way that addresses today's mobile work and lifestyle demands.

For telecom companies, the opportunities are immense. One obvious advantage is the sheer traffic volume that will be enabled by mobile Internet protocol (IP). But mobile IP will also make possible an astonishing new range of services, from gaming to global messaging services to home gateways that control your air conditioning or security. These new services will open the door for usage-based billing and other revenue streams for service providers.

Even at this early stage, it's clear that consumers want these capabilities.

This new world of mobile communications, where voice and data join, will also challenge telecom companies. It will first and foremost require a mindset that recognizes the importance and viability of mobility as it pertains to the Internet. The rewards of mobile IP won't be realized unless and until the new networking protocol known as IPv6 is embraced by the overall ecosystem of communications—the Internet, cellular, land-line, transport, and access networks

Mobile IP will take all of us one step closer to realizing the true meaning and potential of mobile communications. Consumers and the businesses that serve them will reap the rewards of convergence, as telephony and network computing merge. For telecommunications companies, Internet service providers (ISPs), and content developers, the time to prepare for this new world is *now*.

Mobile Internet Access Today: Limits and Frustrations

Back in the days when the Internet was a data-sharing network for the military and a few research facilities, no one foresaw its growth as a communications powerhouse, and mobility was barely a concept. The current- IP, Internet protocol version 4 (IPv4), has been remarkably useful, as the growth of the Internet attests, but its limitations are now obvious.

The most pressing deficiency is a limited number of addresses allowed by IPv4's 32-bit address. Fortunately, the Internet Engineering Task Force (IETF) has developed IPv6—a next-generation protocol with a 128-bit address that not only resolves the address shortage and other issues (see Appendix), but also provides the foundation for greatly improved mobile access.

Because mobility was not a factor when IPv4 was developed, there was no need to distinguish between who you were and where you were; it was assumed they were one and the same. There is no information in the IPv4 address that indicates a new geographic point of attachment.

As a result, today's users have portable networking capability, but it's far from ideal. The correct delivery of packets requires a new IP address associated with the new point of attachment. One has to establish a new connection whether one moves 100 feet or 1,000 miles. As far too many people know, connecting to the Internet from different locations can be a very frustrating exercise.

It can be a costly exercise as well. Because mobility via IPv4 necessitates informing any agent in the routing process about a new location, additional infrastructure is required—something not always deployed in IPv4 nodes. A system has to be configured with a new address, a correct netmask, and a new default router every time one establishes a connection from a new location. Consequently, the time and effort benefits one might realize from having mobile Internet access can be dissipated because of the hardships required to attain that very access—hardly what today's time-pressed consumers expect or demand.

In designing IPv6, IETF added key functionality to the protocol so that mobile IPv6 could take advantage of such features as next headers, destination options, source routing, and neighbor discovery. Then the IETF was able to require key mandatory support elements in all IPv6 implementations to assist with those features.

Mobile IPv6: Reaching the Net Anywhere, Anytime, Anyway

With mobile IPv6, location is no longer an issue when connecting to the Internet. The mobile node sends information about its point of attachment to a home agent—a node on the home network that allows the mobile node to be reachable at its home address, regardless of its actual geographic location. Packets addressed to the mobile node are intercepted by the home agent and tunneled directly to the mobile node's current location.

Mobile IPv6 resolves the mobility issue by utilizing two addresses for a mobile node: a home address and a care-of address. The care-of address is created whenever the mobile node changes its point of attachment to the Internet and is no longer connected to its home network.

The care-of address can be assigned by a dynamic host configuration protocol (DHCP) server, but one of the great advantages of IPv6 is stateless auto-configuration, where the mobile node creates a unique IPv6 address by combining its local-area network (LAN) media access control (MAC) address with a prefix provided by the network router. There's no need for a manually configured server because no server has to approve or distribute an address. This reduces end-user costs because trained staff is no longer required at the receiving network for the mobile node.

Whenever the mobile node moves, its new care-of address is first registered with the home agent in a process known as "binding." It does this by sending a packet, called a binding update, that contains the mobile node's care-of address and registration lifetime, which dictates the length of time to use the binding, along with a home-address destination option that contains the mobile node's home address. For authentication purposes, the home agent registers the binding and returns a binding acknowledgement to the mobile node.

With mobile IPv6, the home agent automatically forwards data sent to the mobile node's home address to the care-of address in a process known as tunneling. Mobile IPv6 also allows for route optimization, whereby data is sent directly from a correspondent node—a mobile or stationary node that directly communicates with the mobile node, utilizing such applications as e-mail, instant messaging, and streaming audio or video—to the mobile node. The mobile node accomplishes this by sending a binding update to inform the correspondent that it is no longer at home. The correspondent node then sends packets directly to the care-of address of the mobile node, with a routing header that contains the mobile node's home address.

When the mobile node sends packets to another node, its care-of address is set as the source address, and a home-address destination option is included. This preserves the end-to-end model of transmission control protocol

(TCP)/IP, allowing mobility without interrupting any open connections.

For mobile users, location will no longer be an obstacle when connecting to the Internet. The additional time, infrastructure, and cost of today's mobile connection will no longer exist—factors that will certainly spur greater use of these connections.

The Mobile IP Timetable

Mobile IP will one day certainly become as commonplace as mobile telephony, but it won't happen overnight. To talk about the future of mobile IP is to talk about the future of IPv6.

For some time, we will live in a dual IP world with IPv4 and IPv6 coexisting. Fortunately, IPv6 was designed with such a transition in mind. The IETF recognizes that upgraded hosts and routers will need to retain downward compatibility with IPv4 devices for many years. It's expected that we'll live in this dual-IP world for at least another decade.

The global benefits of IPv6—not just mobility, but improved security, functionality, and quality of service (QoS)—will only be realized when IPv6 is the dominant protocol. In essence, the weakest link determines the strength of the network, but many factors will work in favor of IPv6's ascendance. IPv6 has already been adopted as the protocol for next-generation networks by the third-generation partnership project (3GPP), a worldwide standards-setting organization. This endorsement will greatly speed the adoption of IPv6 by future networks, beginning with 3G mobile networks.

Underlying factors also favor IPv6. The lack of addresses in developing and emerging economies; the increasing popularity of wireless in those lands and others; the continued rise of the Internet as the single most robust source of information; the need for anywhere, anytime, anyway access; the natural progression toward convergence—all these point to a bright future for IPv6.

Compaq expects IPv6 deployment to occur in stages, beginning with regional IPv6 networks. These networks will be deployed in order to launch new subscriber services and to gain competitive advantages. These regional IPv6 networks will interoperate with national and international IPv4 networks, thereby assuring global, end-to-end service delivery. Subsequent stages will feature the development and deployment of additional products and services made possible by the advanced features of the new infrastructure. In time, the entire national and global IPv4 infrastructure will migrate to the superior IPv6.

As the 3G infrastructure is built around the world, IPv6 is certain to be a core component. Just as surely, the vast improvements and capabilities of 3G networks will spur a multitude of innovative services accessed by an equally wide array of devices. Making it all possible will be IPv6.

Appendix: Other Advantages of IPv6

While IPv6 makes mobile Internet connections possible, that's only one of its benefits. It's not simply a new address; it provides for a "smarter packet" as well. IPv6 provides increased functionality in such commercially important areas as security and QoS and opens the door to new services.

Security—a crucial element for modern e-commerce—was not a priority when IPv4 was developed. With IPv4, servers usually can't determine whether packets are being received from a legitimate end node. Source address masquerading, known as spoofing, can be used to acquire confidential data or to gain control of a server. Solutions such as firewalls can combat these challenges, but they often hinder connectivity as well.

With IPv6, necessary authentication, security encryption, and data integrity safeguards are an integral part of the protocol. The IPv6 standards-based authentication header extension assures that a packet is truly from its source address. End-to-end encryption at the network layer is provided by another standard header extension—the packet itself is never touched.

Quality of service (QoS) issues are also addressed by IPv6. This improved protocol enables differentiation between non-urgent communications and highly critical applications, such as video conferencing. While these capabilities can be constructed within the IPv4 framework, they're built-in with IPv6. A new traffic flow identification field lays the foundation for QoS functions as bandwidth reservation. In addition, traffic flows can be distinguished for best routing, and those labels can be set to assure a desired security level or cost. This capability opens the door to new services—and increased customer satisfaction as well.

IPv6 also advances the art of multicasting, which is important because there will be increased demand for streaming audio, video, and animated content. The improved address defines a large multicast address space, thereby limiting the degree to which multicast routing information is carried throughout an enterprise. IPv6 hosts and routers are required to support multicasting. And IPv6 also introduces the concept of "anycast" services, whereby a group of nodes can be designated as an anycast group, and a packet addressed to the group's address is delivered to only one of the nodes.

The Rise of the 3G Empire: Even Rome Wasn't Built in a Day

Brian Modoff
Senior Analyst, Wireless Equipment

Michael Thelander
Associate Analyst, Wireless Equipment
Deutsche Banc Alex. Brown

Over the last several months, the mobile wireless industry has faced a number of challenges that have caused some to doubt whether or not third-generation (3G) mobile services will ever happen. Carriers spent billions of dollars obtaining 3G spectrum without anticipating that the capital markets would contract, making it more challenging to obtain necessary funds to deploy their 3G infrastructures. The worldwide economy has turned south, which has resulted in consumers limiting discretionary spending (cell phones) and wireless carriers refocusing their resources on strengthening their balance sheets. At the same time, the capital markets have contracted, thus limiting carriers from gaining access to reasonable financing terms. Finally, actual data rates are well below expectations and technical challenges and network interoperability problems persist, causing some well-publicized 3G launches to be delayed.

We still believe 3G will happen. However, instead of just providing market segment forecasts and hyping the possibilities of 3G applications, we are going to take a step back and focus on the underlying technologies that give us 3G services.

As depicted in the following chart, regardless of the network technology, the 3G standards are the same. As you will find after reading this report, the paths carriers choose to meet these standards are substantially different.

In *Figure 1*, we provide the target data rates for 3G and how these higher data rates can make download times more reasonable. Just as you can drive faster on an open highway, the higher data rates will only be achieved when network capacity is not being constrained by other subscribers. We should also point out that the download times are not an International Mobile Telecommunications (IMT)-2000 requirement, but are based upon our calculations that assume the minimum required data rate is available throughout the duration of the download.

The Mobile Network: Anatomy 101 of Cellular Technology

In order to understand—and, hopefully, appreciate—the evolutionary path to 3G, you need to start with the basics of telecommunications networks. For, you see, the path to 3G includes a lot more than creating "gee-whiz" handsets, obtaining frequency spectrum and swapping out some radio equipment. Instead, the path involves software and hardware upgrades throughout virtually the entire telecommunications network.

The Radio Access Network

The radio access network (RAN) is comprised of three basic components: the handset, the base transceiver station (BTS), and the base-station controller (BSC). If you fall into the 42 percent of the U.S. population (our apologies to the international readers) who own a cellular phone, then you are already intimately familiar, and in some cases frustrated, with the first component in the radio network. Cell phones are designed for a specific carrier and the frequency band (800 MHz, 1900 MHz) and mode (Global System for Mobile Communications [GSM], time division multiplexing [TDMA], etc.) they use.

Some operators use frequency bands in their networks that vary by markets due to spectrum limitations that prevent them from owning enough spectrum in the same band. If your carrier falls into this category, you need a multi-band (800 MHz and 1900 MHz) phone. A multi-mode phone is also required if you leave the comforts of modern civilization (digital networks) to go fishing for walleye in the Boundary Waters of Northern Minnesota, where they only have analog service.

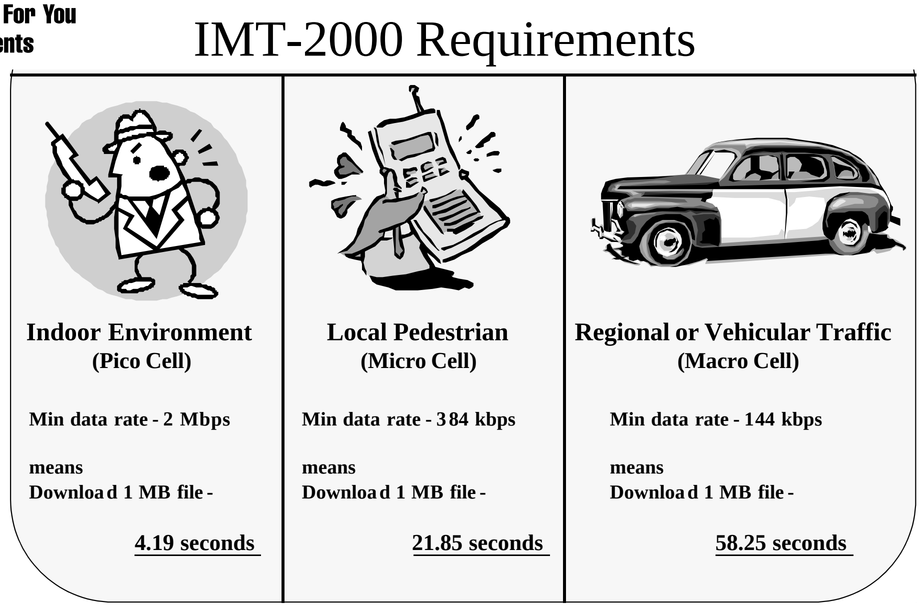
The next component in the radio network is the BTS. BTSs are available in three sizes: pico (shopping malls, convention centers), micro (highways), and macro (coverage up to a 200 km radius). Generally, pico stations operate in indoor environments and are quite small.

Micro stations are usually deployed within the coverage space of a macro cell to provided additional capacity or along major rural highways. The BTS is comprised of the radio equipment, including processing equipment, filters, cables, antennas, and power amplifiers.

Macro cells are popular with operators because of their wide coverage area, which allows operators to cover a large, low-subscriber-density, geographical region with a relatively limited number of cells. Macro cells are also the most

FIGURE 1

3G—What It Means For You
IMT-2000 Requirements



Source: DBAB

visible of the three cell types and can be readily spotted in rural areas—just look for the antenna tower.

The BSC is the final major component of the RAN.[1] In addition to determining the power output between the BTS and mobile phone as well as managing the handover of mobile phones between base stations, the BSC consolidates the transmissions from the BTSs and sends the transmissions on to the mobile switching center (MSC).

The Backhaul

The backhaul portion of a mobile network refers to the transfer of voice and data traffic from the base station to the BSC or between base stations if base stations are daisy-chained together—for example, along a major freeway. There are three physical mediums that are primarily used to transport this traffic: microwave radios, leased T1/E1 lines[2], or fiber-optic cable.

With 2G networks, carriers typically have used one or perhaps multiple T1 or E1 (Europe) leased lines as the physical medium. Even then, the cost could reach 30 percent of network operation costs. However, with the higher-capacity 3G cell sites (up to 10x capacity), the required throughput generated from one cell site can easily reach up to 5 Mbps initially, and we have heard this throughput could increase to as high as 15 Mbps. Daisy-chain a few base stations together, and the data-capacity requirement increases even further. *Figure 2* provides Nokia's view on the future demand for bandwidth in the backhaul network.

Alcatel has also done a number of market studies regarding current and future backhaul requirements. Based upon their studies, European carriers currently require between 1 to 2 Mbps on average with backhauls in denser areas, such as Italy, requiring up to 4 Mbps. One European carrier, who shares their backhaul with another carrier(s), uses more than 2.5 Mbps on average. With 3G, Alcatel's survey of European carriers suggests that initial backhaul demand will be a modest 2 Mbps but could grow to 5–18 Mbps over the next 5–10 years.

The Core Network

The "core network" refers to the portion of the mobile network that is behind the BSC and includes the MSC, as well as the gateways, or entrance points, to other networks.

As mobile networks transition to 3G, changes need to be made to the core network as well, including implementing software upgrades, adding new servers and gateways (connecting points) to other networks, and using new protocols to transport and route traffic through the network. In general, these changes are required to ensure that the core can support applications such as voice, data, and video; higher data rates; and new transport and switching technologies. Wireless operators need to also have the ability to add subscribers while decreasing capital and operational costs.

These networks and their various components provide and/or support a number of functions in the mobile world:

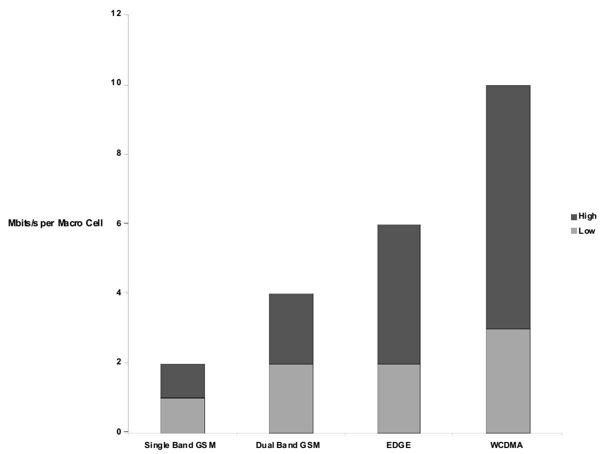
- Billing services
- Phone registration into a home or foreign network
- Call set-up and tear-down
- Interface to the "fixed Internet world" and public switch telephone network (PSTN)
- Real-time voice and data service

Just as importantly, a lot of the debate between code division multiple access [CDMA]2000 and wideband code division multiple access [WCDMA][3] centers around the required changes to the respective core networks.

In the past, the interface between the RAN and the core network was unique to each vendor. As a result, operators were virtually forced to select the same vendor to provide the

FIGURE 2

Mbps for Macrocell Base Station



Source: Nokia

RAN and core solution. Now, vendors have accepted an open standard, called IOS v.2 and IOS v.4, which gives operators more options. The third-generation partnership project (3GPP) is trying to take the concept of an open standard to the next level. Their ultimate goal is to have interoperability throughout the entire network—for example, between Vendor A's RNC and Vendor B's Node B.

At the time of publication, original equipment manufacturers (OEMs) and carriers were conducting interoperability tests between the mobile stations and the base stations, with plans to test between the RAN and core network in fall 2001. The 3GPP also intends to have interoperability between 2G and 3G solutions, for example Vendor A's WCDMA solution deployed on top of Vendor B's GSM network. This scenario would support seamless handovers between WCDMA and GSM networks and would also allow more open competition.

All Roads Lead to 3G

The road(s) to 3G vary by technology with different starting points, ending points, and forked roads in between. *Figure 3* shows how the various second-generation (2G) technologies evolve to 3G.

Global System for Mobile Communications

In the beginning (circa 1980s), man created five incompatible analog cellular systems in Europe, and it was good. However, incompatibility problems resulted in a virtual Tower of Babel scenario when cellular subscribers ventured outside of their native countries (networks). In the north, there was NMT 450 and 900. The United Kingdom had TACS and E-TACS, France had Radiocom 2000, Italy used RTMI/RTMS, and TCS as well, and West Germany (yes, there were once two Germanys) had something called C-Netz and D-Netz.

Further, over time, it was realized that these first-generation analog systems would quickly have too many subscribers for the networks, despite the disparity of the different systems. Thus, in keeping with the theme of a unified Europe and to limit research and development costs, a unified *digital* cellular system was needed. As a result, the Conference of European

FIGURE 3

All Roads Lead to 3G

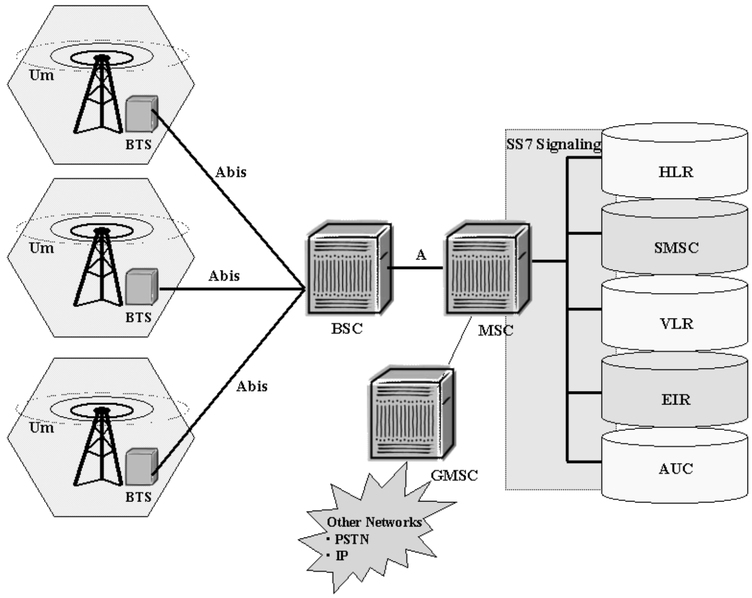
FIGURE 4

GSM Network Diagram



Source: DBAB

Posts and Telecommunications (CEPT) established what became known as GSM,[4] with an objective to develop universal specifications for mobile communications in Europe.

One important aspect of GSM is short message service (SMS), although SMS is also available in TDMA (receive only) and CDMA. SMS is a short message delivery technology that is comprised of a fixed length of characters with the newly defined, but not necessarily deployed, standard supporting a far greater number. Since SMS messages are sent using a separate network (the signaling network and signaling channels on the radio interface), a user can send and receive a SMS while engaged in a telephone conversation.

Currently, nearly 20 billion SMS messages are sent per month, even though it has not really taken off in the United States due in large part to the interoperability between carrier's networks, relatively few SMS–enabled phones, and the lack of customer awareness. However, several carriers, including Verizon (CDMA) and Cingular (GSM and TDMA), are beginning to actively market this feature, and for good reason.[5] In Europe, Vodafone (GSM) reported that nearly 10 percent of its FY00 revenues came from SMS traffic. In addition, because SMS messages are so economical to deliver, SMS is one of the most profitable services offered by wireless carriers.

SMS also has its own evolutionary path that coincides somewhat with the path to 3G. Enhanced messaging service (EMS) will allow new font styles (e.g., bold), simple melodies, pictures, and sounds to be attached to messages. Multimedia messaging service (MMS) follows EMS and will allow short video or audio clips (e.g., MP3, MPEG 4) to be attached. Carriers will likely charge extra for these services.

In *Figure 4*, depicting a GSM network, you can see we have listed the U_m, Abis and A interfaces that define the standards between the mobile station and the BTS (U_m), between the BTS and the BSC (Abis), and between the BSC and the MSC (A). The technical description for one of these interfaces is a standalone document that contains a lot of technical jargon and minutiae that we believe are beyond the interests of any investor. However, after a cursory review of the documents, it should become readily apparent that changing and interpreting (for interoperability) these standards can become a cumbersome task. Here is what we believe you need to know about these three interfaces, starting with the U_m.

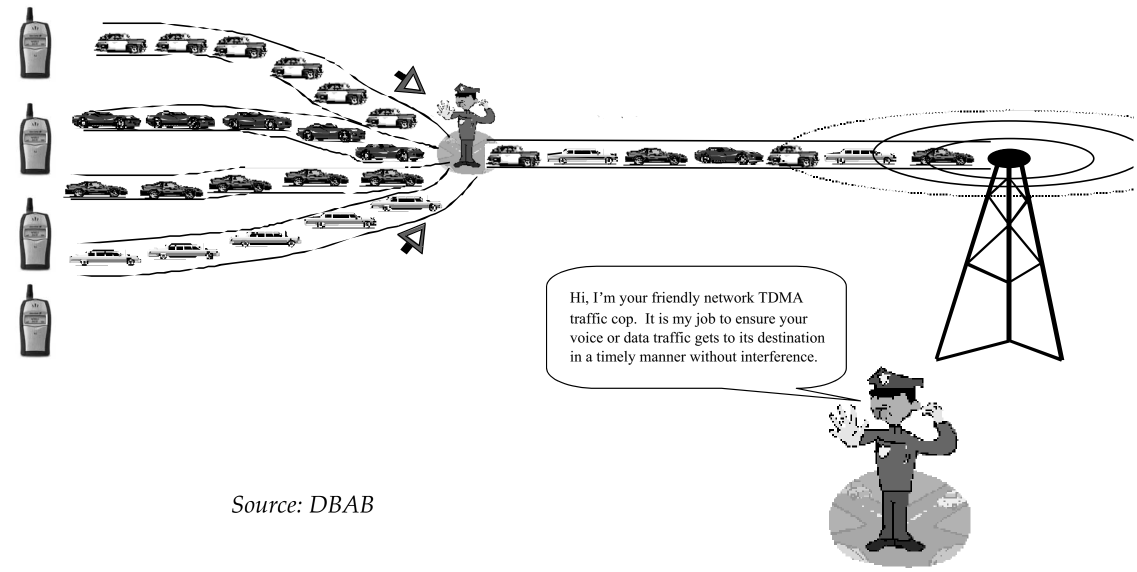
***U_m*:** The GSM air interface standard is referred to as the U_m. The GSM frequency spectrum is 25 MHz wide and is divided into 124 individual carrier frequencies along with a 200 KHz guard band. One or more carrier frequencies are assigned to each BTS, depending on how many sectors the cell site contains. The division of frequencies into multiple frequencies, or traffic lanes, is called frequency division multiple access (FDMA). Each of these carrier frequencies subsequently uses a radio network access technology called time division multiple access (TDMA).

TDMA is a digital multiplexing technique that facilitates multiple users accessing a single radio frequency (RF) channel. Imagine a traffic cop merging four lanes of traffic into a single lane of traffic. The cop sequentially signals to the driver in each of the four lanes. When signaled, the driver proceeds ahead without fear of sideswiping a car in an adjacent lane (see *Figure 5*).

With TDMA, a time frame is divided into time slots, in this case eight slots that last for 0.577 milliseconds (ms). Therefore, the time frame is 4.615 ms (8 * 0.577 = 4.615 ms) in length. These slots are allocated to users on the network in order to let the user to "talk" without experiencing interference. Another way of looking at it is that each time slot represents a logical channel that is assigned to a subscriber.

FIGURE 5

Our TDMA Analogy



Source: DBAB

The signaling channels, part of the "extended" signaling network, are broken down into three groups. The broadcast channels (BCH) carry downlink traffic only and provide time synchronization and frequency correction information that the mobile device uses to maintain an optimal link with the base station. Additionally, the BCH carries point-to-multipoint SMS messages (one base station to many mobile subscribers). The common control channels (CCCH) handle call notification (downlink) and network access requests (uplink). Finally, the dedicated control channels (DCCH) handle roaming, handovers to other cell sites, and encryption.

While it may seem a bit technical and burdensome to discuss an aspect of a network that you cannot even see, let alone reach out and touch, there is a method behind this madness. First, it should now be apparent why a subscriber can receive an SMS message when talking on the phone—the SMS message is transmitted on a separate channel. We also provided this discussion to illustrate that there is more than basic voice traffic using up the precious spectrum and that the network uses these signals to control each subscriber as they move throughout the network.

A_{bis}: The A_{bis} defines the interface between the BTS and the BCS. Currently, leased T1/E1 lines predominantly provide the physical link for this interface. However, we believe wireless and fiber connections will play a more dominant role with 3G due to the required data link between the two components. Like the U_m, the A_{bis} consists of traffic and signaling channels, with each transceiver requiring its own signaling channel. Since the location of the traffic and signaling channels is not necessarily consistent across various vendors' platforms, incompatibility issues can develop if a carrier mixes and matches its BSC/BTS solution. Of course, this problem is supposed to go away with the 3GPP standard. Finally, the A_{bis} carries operating and maintenance information to and from the BTS.

A: The A interface lies between the BSC and the MSC, which we will discuss in the next paragraph. The A interface uses 32 time slots with a maximum of 30 time slots for traffic and the remaining time slots dedicated for sending control and signaling information. Like the other two interfaces, there are also a number of defined protocols that exist on lower levels of the open system interconnection (OSI) model.

The next major component in the GSM network (or, for that matter, all mobile networks) is the MSC. A MSC is a switch that sets up connections to other MSCs or BSCs. If the MSC also interfaces with another network, such as the PSTN, it is referred to as a gateway MSC (GMSC). A number of interfaces, each with its own defined protocol, extend off the MSC to other MSCs, the signaling system 7 (SS7) network, other networks, or database servers. Each of these interfaces uses SS7–based protocols. We should also point out that some vendors provide an integrated BSC/MSC platform even though our network diagram implies a physical separation of the two components.

The home location register (HLR) is a database that contains user-specific subscriber information. When you first subscribe to a carrier's service, you are registering your phone with the HLR. The HLR also supports charging and accounting features. If you venture into another region of the network (outside of the domain of the HLR) or into another carrier's network, the visitor location register (VLR) is responsible for registering the phone into the network and informing the subscriber's HLR of where the subscriber is currently located. Thus, when a call is placed to the mobile subscriber, the HLR knows where the subscriber is located (which MSC) and routes the call accordingly. Of course, all of this signaling traffic is done using the SS7 network. There is one VLR per MSC, and generally the VLR is integrated with the MSC.

The authentication center (AUC) database generates and stores security-related data that is used in order to prevent fraudulent use by an unauthorized person. The final major database we are mentioning is the equipment identity register (EIR). The EIR contains a list of all valid devices by recording each terminal's international mobile equipment identity (IMEI). If a mobile phone were reported stolen, the EIR would prevent the device from gaining access to the network.

In actuality, a GSM handset is technically subscriberless. Instead, a GSM subscriber is assigned a subscriber identity module (SIM) card that has its own unique international mobile subscriber identity (IMSI). The SIM, or smart card, contains all of the user's personal information, such as security information, address book, and assigned telephone number. Thus, any SIM–enabled phone becomes a personal phone once the SIM card is inserted. Although currently available in Europe, SIM technology is making its way to the United States and is being incorporated into CDMA and TDMA protocols.

SIM cards are also a cheap way to provide worldwide global roaming. Instead of buying a tri-mode GSM phone, subscribers can just take their SIM card to Europe and rent a phone. With the SIM card installed, the subscriber can receive calls just as if he or she had their personal phone. Callers would also be oblivious to the fact that the SIM cardholder was in another country.

General Packet Radio Service

General packet radio service (GPRS) is the next step along the GSM evolutionary path to 3G and is often referred to as 2.5G.

Perhaps the most talked about (and overhyped) advantage of GPRS is increased data rates over 2G solutions. GSM networks are limited to 9.6 kbps for data, since data and voice are digitized using the same technology and subsequently transmitted over the same path (circuit). While 9.6 kbps is more than adequate for even the fastest-talking research analyst, it pales in comparison to data rates that we have grown accustomed to while at work or at home (even if you lack broadband access). GPRS, on the other hand, features speeds of up to roughly 115 kbps (theoretical maximum of 172.2 kbps), although actual speeds will be substantially less, on the order of 20 to 40 kbps.

Recall that in GSM radio access networks, each mobile subscriber is assigned one channel, or time slot, in which to transmit data in the upstream and the downstream directions (TDMA). Further, this time slot is allocated to the user even if data is not being transmitted—hardly efficient use of spectrum.

In GPRS, a mobile subscriber can be assigned multiple time slots for data traffic (still using TDMA) in each direction. Initial deployments will support several time slots in the downlink and only one time slot in the uplink (Note: Web browsing requires greater throughput in the downlink). If the channel (time slot) is being used for data traffic, the channel is called a packet data channel (PDCH). The ratio of PDCH to "regular" voice channels is based upon current demand for both channels. Further, the data packets are interleaved among the voice traffic for further efficiency.

There are also a number of packet-signaling channels. In summary, these signals provide point-to-point and point-to-multipoint (downstream) network information, such as network timing and notification of an arriving packet.

Our final comment on the GPRS RAN concerns data coding. There are four data coding/modulation schemes that are used, depending upon network conditions. Under ideal conditions, the fastest technique, called convolutional coding, can achieve a data rate of 21.4 kbps per time slot. If a carrier is generous enough to allocate all eight TDMA time slots to a subscriber, one could obtain the theoretical maximum GPRS data rate of 171.2 kbps (8 * 21.4 = 171.2). However, just as driving on the Autobahn does not guarantee that you can play Mario Andretti, it should also be obvious why you will never achieve the maximum GPRS data rate. Instead, average data rates will probably be between 20 and 40 kbps.

Early GPRS handsets also have a throttle on them that limits the number of time slots they can support. Although a number of handset OEMs claim their GPRS handsets can support 115 kbps, the published specifications imply otherwise by stating that the handset supports four slots in the downlink and one slot in the uplink. A few handsets only support two slots in the downlink.

Figure 6 shows how data rates (Y axis) increase as the number of assigned time slots (X axis) increases and the data-coding scheme (Z axis) is changed. The upper right corner of the chart represents the theoretical maximum data rate, while the white circle represents reality—20 to 40 kbps.

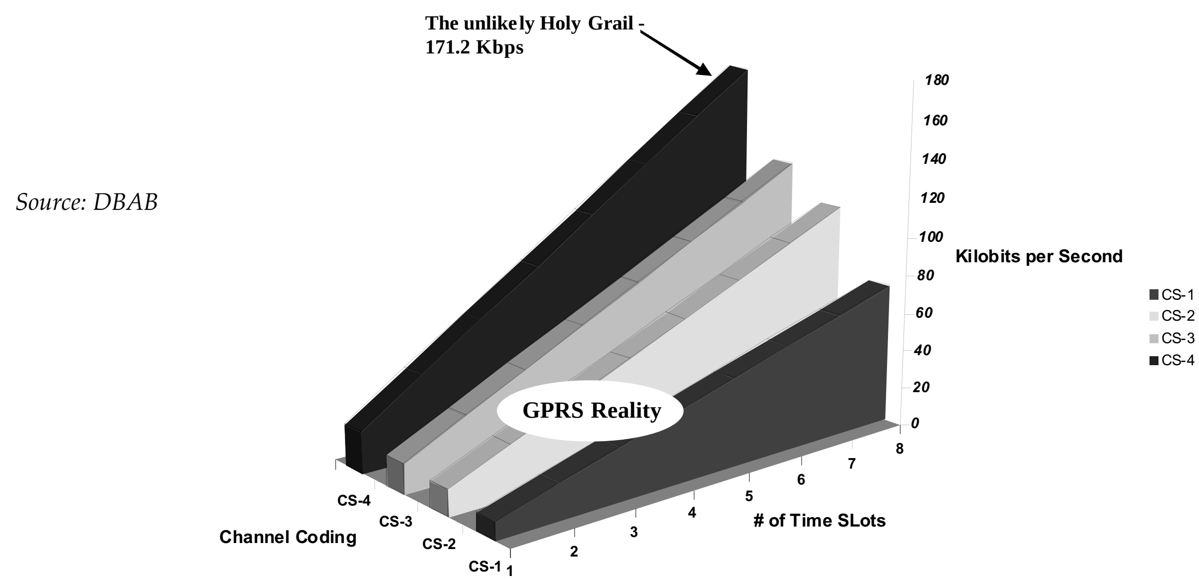
At first glance, actual GPRS data rates may not sound like a lot of bandwidth, especially when compared to the maximum data rates that are often quoted in the press. However, keep in mind that nearly 80 precent of U.S. households that use the Internet access the Internet using a 56 kbps modem, and even then actual data rates are almost always lower. Thus, GPRS can potentially deliver practically the same bandwidth to the mobile device that most U.S. households have grown accustomed to at home. Further, Web applications on a mobile handset require less bandwidth than their fixed wireline counterpart. As a result, actual GPRS data rates should suffice for some applications, or at least be an improvement over 2G networks.

We believe an even more compelling reason than the speed advantage is that GPRS is "always on," meaning that your phone is always connected to the network and ready to receive and notify you of incoming messages (trade confirmations or stock-price alerts). This is also called immediacy. Further, carriers can now charge you based upon how much data you send or receive, versus on a per minute basis. For example, Japan's NTT DoCoMo charges $0.0024 for 128 bytes of data. In Europe, Vodafone was recently charging $5.66 a month plus $0.03 per kilobyte of data downloaded. AT&T Wireless is charging $50 per month for 1 MB and 400 voice minutes per month, with additional data packets priced at less than $0.01 per kilobyte. Finally, Cingular, which launched service in Seattle in late August 2001 and plans to have coverage in all of its GSM networks in 2002, offers an entry-level data package for $14.99 that includes 0.5 MB of data and 100 messages.

Although your phone is always connected to the network, it is not tying up a radio channel unless data is being sent

FIGURE 6

Varying Parameters and Sample GPRS Data Rates



to or from the GPRS handset (due to packet versus circuit switching). Thus, network capacity is more efficiently used (for data traffic only) with GPRS technology. GPRS does not address voice capacity in mobile networks. However, GPRS can be a heavy user of GSM voice capacity if not properly controlled.

Two additional nodes are added when GPRS is overlayed on a GSM network. The serving GPRS support node (SGSN) is responsible for routing incoming and outgoing Internet protocol (IP) packets that are from, or intended for, any GPRS subscriber within the area served by the SGSN.

In addition, the SGSN provides encryption/decryption, session management (call set-up), mobility management (cell handover), and connection to other nodes. If a mobile subscriber moves to a location in the network that is supported by a different SGSN, the new SGSN requests information from the old SGSN and, if necessary, notifies the HLR, VLR, and MSC (of course, using the SS7 signaling network).

A gateway GPRS support node (GGSN) is the interface between the GPRS network (see *Figure 7*) and other packet data networks. The GGSN converts packets received from the SGSN into the appropriate protocol (e.g., encapsulates a foreign packet with an IP protocol for IP networks) that is required by the network receiving the GPRS packet. Conversely, the GGSN receives packets from other networks, coverts them to GPRS format, and sends the packet to its intended SGSN. In general, one GGSN connects to multiple networks and has connectivity with multiple SGSNs in the GPRS backbone network. The GGSN also assigns a packet data protocol (PDP) address when requested by the mobile subscriber (requested through the SGSN). The PDP includes the newly assigned IP address as well as the quality of service (QoS) and address of the GGSN that is connected to the targeted packet data network.

The actual number of deployed SSGNs and GGSNs is dependent upon the number of active data subscribers and the capacity limits of the vendor's solution.

Enhanced Data Rates for GSM and TDMA Evolution (EDGE)

For some carriers, EDGE represents the next step in the GSM/TDMA evolutionary path to 3G. In fact, by definition, EDGE is a 3G service that could become the final resting-ground for some carriers—at least until 4G (whatever that is) comes around. EDGE is broken down into three areas: standardization of the physical layer, protocol changes for enhanced circuit-switched data (ECSD) and enhanced GPRS (EGPRS), and two phases. EDGE Phase 1 is concluded with Release '99.[6]

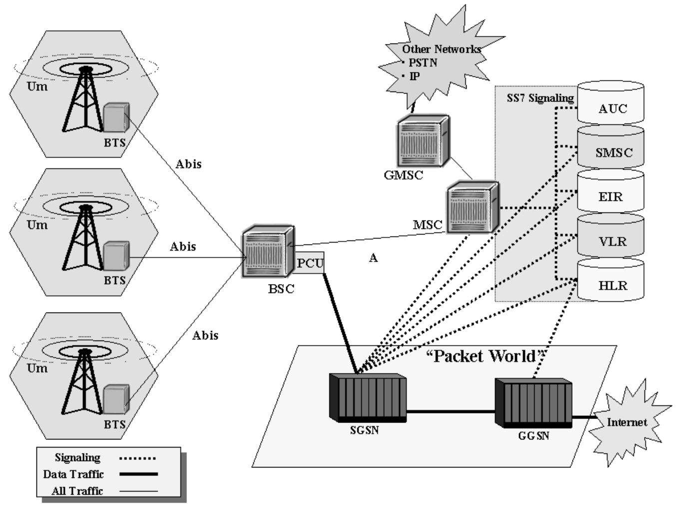
As you probably noticed, the transition from TDMA/GSM to GPRS was not a simple task, and a number of new components were added to the network. Fortunately, the transition to the first phase of EDGE is more like a little schoolyard skip than a giant leap.

In fact, the only part of the network that is affected in Phase I is the radio network, due to the introduction of a new, higher-order modulation technique called eight phase shift key (8PSK). The rest of the network, assuming it made the transition to GPRS, already has enough capacity and processing power in reserve to handle the increased data rates.

In order to have higher bit rates per time slot without impacting the underlying channel structure (maintain GSM/GPRS service), the modulation type needs to be changed. EDGE uses 8PSK. 8PSK is a linear modulation scheme in which three consecutive bits are mapped onto one symbol in the I/Q plane. This rate is divided over eight time slots and, with interleaving, ciphering, and burst formatting,

FIGURE 7

GPRS Network Diagram



Source: DBAB

it results in a radio data rate of 59.2 kbps per time slot. 8PSK varies the waveform's phase (versus the amplitude or frequency) to one of eight positions. Thus, each symbol can support three data bits, and its theoretical bandwidth efficiency is 3 bits/sec/Hz versus 2 bits/sec/Hz. Under ideal conditions, the fastest channel-coding scheme is 59.2 kbps. If you are allocated all eight time slots, you can achieve the maximum EDGE rate of 473.6 kbps (8 x 59.2 = 473.6).

Figure 8 illustrates how EDGE data rates increase (Y axis) as more time slots are assigned (X axis) and a higher modulation and coding scheme (MCS) is used (Z axis). The first four coding schemes (MCS 1–4) use GMSK, and the remaining five schemes (MCS 5–9) use 8PSK modulation. As in the GPRS chart, the upper right corner represents the theoretical maximum data rate if eight time slots are allocated to one subscriber. If we assume that no more than four time slots are assigned, the typical user data rates should be between 36.2 and 236.8 kbps. Notice that we have included all nine coding schemes, since EDGE improvements to the physical layer of the RAN should support more widespread use of higher order modulation schemes than with GPRS.

The EDGE standard defines link quality control (LQC) procedures that are used to select the optimal channel-coding scheme based upon the quality of the radio link in order to provide the maximum data rate. In contrast to GPRS, EDGE allows the retransmission of previously sent data blocks using a *different* channel-coding scheme than the original scheme. Additionally, EDGE can determine the quality of the radio link more quickly than with GPRS. As a result, a higher-modulation scheme (e.g., MCS-9) can be used, regardless of the radio link quality. Unreadable packets are then retransmitted using a different coding scheme until decoding is successful. According to Ericsson, this approach means that for a given data rate per time slot, EDGE has better coverage than GPRS. This approach is comparable to always talking very quickly but having to repeat oneself on occasion until the listener understands what is being said.

One of the challenges with EDGE technology is being able to incorporate multiple modulation schemes (GMSK and 8PSK) into the same handset and still provide a relatively low-cost, compact phone that has acceptable battery life. The handset can also heat up and battery life can also be diminished if the handset transmits for an extended period of time (just like a machine gun barrel can overheat), as is often the case if more than one time slot is allocated to the subscriber. This is true in GPRS as well. The performance and reliability of overheated components are also impacted (recall that some early GPRS handsets overheated). One major handset OEM even informed us that it will be several years before an EDGE handset will be able to support more than five time slots due to heat dissipation issues.

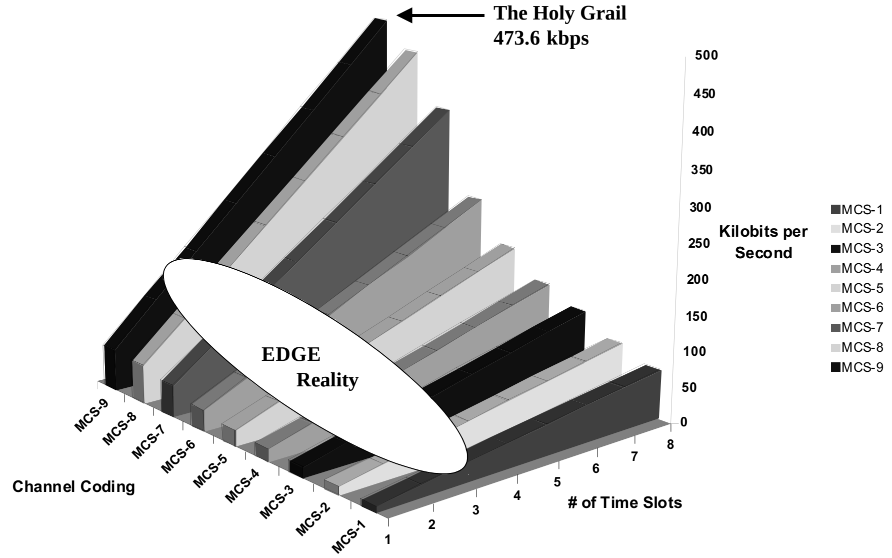
Although EDGE Phase I provides high data rates, Phase I does not support real-time services, such as videoconferencing and voice over IP (VoIP), nor does it provide the same QoS classes as the Universal Mobile Telecommunications System (UMTS). EDGE Phase 1 is concluded with Release '99.

3GPP is currently addressing EDGE Phase II, which was previously under the purview of European Telecommunications Standards Institute (ETSI). The scope was also expanded to include the alignment with UMTS and the provisioning of IP multimedia services. As a result, Phase II uses an interface to an all–IP 3G core network that is common with the UMTS core network. We will discuss the UMTS core network in a following section along with providing a network diagram that shows the primary components and interfaces.

The Phase II RAN, called GERAN (GSM EDGE RAN) supports several bearer classes (service levels), including maximum bit rate (analogy—being able to drive as fast as 100 MPH when possible) and guaranteed bit rate (analogy—always being able to drive 50 MPH). Header compression (less overhead) is used to achieve higher performance, QoS, and more efficient multiplexing. As a result, more than eight users can share the same carrier frequency. More importantly, half-rate speech channels, in which the voice packets

FIGURE 8

Varying Parameters and Sample EDGE Data Rates



Source: DBAB

are compressed, can be used to achieve higher voice capacity. Finally, GERAN also allows for faster handovers between cell sites.

A Word About Vocoders

In order to process a voice signal for transmission, the analog speech needs to first be converted into a numeric representation of the voice signal. This numeric representation is then processed by the digital circuitry of the handset before it is ultimately converted back to analog and transmitted over the airwaves. A vocoder is the hardware/software solution that is used to convert analog speech into a digital bit stream. There are a number of coding schemes that can be used. However, the 3GPP (WCDMA) has approved the use of adaptive multi-rate (AMR), which is a coding scheme that compresses the voice at varying bit rates—lower bit rates increase the number of concurrent users. The 3GPP2 (CDMA2000) is using what they call selectable mode vocoder (SMV). Like the AMR solution, the SMV can operate in several modes depending on the quality of the network and the desired voice quality. The SMV can increase the capacity of the network (up to 75 percent) if a lower coding rate is used. When AMR is available next year, Nokia believes it will increase GSM capacity by approximately 125 percent. For either solution, voice quality could be impacted—much like recording a television show at a compressed rate (longer tape life) may impact the quality of the recording.

Code Division Multiple Access in a Nutshell

Although it may be easier to say that CDMA is "magic" and leave it at that, we thought we could do one step better without providing Dr. Irwin Jacob's (Chairman and CEO of Qualcomm) private telephone number. Although CDMA and WCDMA are perceived to be entirely different solutions, the truth of the matter is that at a high level, there are more similarities than differences, with Qualcomm owning most of the intellectual property.

CDMA assigns a distinct code to each subscriber. Probably the best analogy is to imagine a room full of people from all over the world (say Finland, Sweden, and San Diego), each having a conversation with a colleague in their respective language. Although the conversations are occurring simultaneously and within the same frequency spectrum, the listener is able to filter out the unintelligible languages (noise) and only hear and understand the conversation that is meant for him or her (see *Figure 9*).

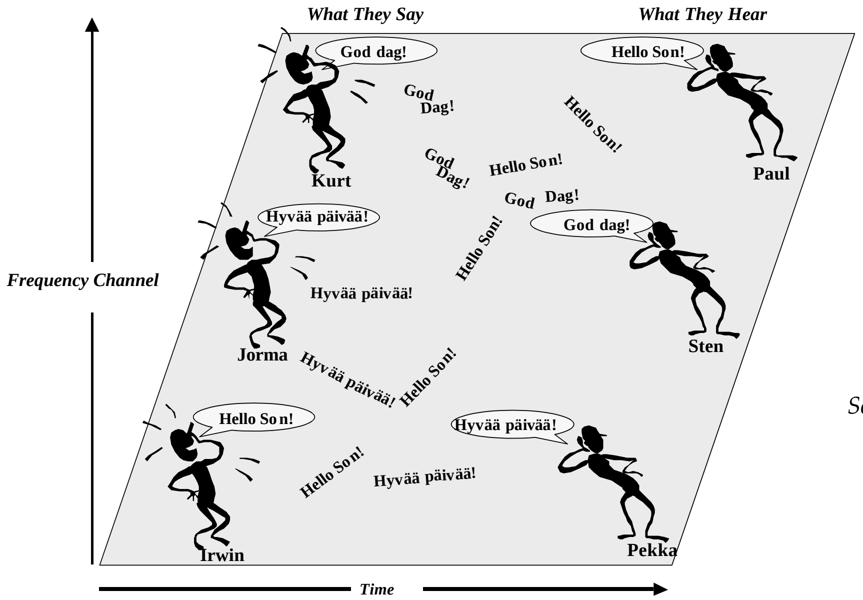
This code is used to spread the information signal. Since the bandwidth of the coded signal is much larger than the original signal, the term spread spectrum modulation is often used when talking about CDMA. Each code is also orthogonal (no correlation) to other codes, thus multiple coded signals can be transmitted over the same time and frequency domain.

Generally speaking, and we emphasize the word "general," WCDMA and CDMA have some common characteristics. In particular, both use a coding scheme to encrypt the data, and both use control channels to manage the network (signaling, power output, network access request) and traffic channels that are used for the data. However, WCDMA and CDMA2000 are not compatible. In addition to using 5 MHz channels, the WCDMA chip rate is different than its CDMA2000 brethren. WCDMA uses a chip rate (how fast the data is spread) of 3.84 Mchips/s in comparison with CDMA2000 that uses a chip rate of 1.2288 Mchips/s for a 1.25 MHz channel. Although it would appear that the higher chip rate and wider channels (5 MHz versus 1.25 MHz) would indicate higher data throughput using WCDMA, this is not necessarily the case. Instead, characteristics such as the channel structure, power control, and synchronization controls play a greater role.

WCDMA networks are asynchronous, which means the base stations do not have to be exactly in time sync in order to hand off—called a handover—a subscriber from one base

FIGURE 9

Our CDMA Analogy



Source: DBAB

station to another (CDMA2000 BTSs are time synched using GPS). Instead, the mobile devices measure the timing differences (sent on a control channel) between two base stations. This difference is reported back to the active base station that can then make an adjustment before switching the mobile device to the new base station.

As a result of the asynchronous and synchronous differences, the WCDMA and CDMA2000 codes are generated and assigned differently. Specifically, WCDMA base stations are separated by 512 unique scrambling codes, while CDMA2000 base stations are separated by a timing offset of the same sequence. Another difference is that WCDMA frames, used to "group" the voice/data/signaling traffic in the RAN, are of length 10 msec and CDMA2000 frames are of length 5, 10, and 20 msec.

Handovers occur between cell sites, frequencies, and across technologies. For example, the network may assign to a mobile phone a new frequency in hot spot areas where there are multiple carrier frequencies being used and interference develops. Additionally, if the phone moves outside of an UMTS network, the phone needs to switch to GSM or GPRS mode. Thus, the multi-mode phone needs to operate in UMTS mode while simultaneously capturing the synchronization information that is being transmitted in GSM mode. A multi-mode phone actually benefits carriers because it allows them to initially deploy WCDMA in a limited area and still provide universal coverage using their GSM network. Nokia has publicly commented that it should have a multi-mode (UMTS/GSM) handset in the second half of 2002, although we remain skeptical. In Japan, a single-mode phone will be offered, since WCDMA will be more widely available.

One interesting feature of CDMA (WCDMA and CDMA2000) is the concept of soft handovers (see *Figure 10*). Unlike GSM or TDMA, adjacent cell sites in a CDMA network use the same frequency. Typically, a mobile device is instructed to switch cell sites and frequencies when the signal strength from the adjacent cell exceeds the strength of the currently assigned cell. The switching between different frequencies is called a hard handover and can also occur within the same cell site if a new frequency is required—for example, if interference develops when using original frequency. However, in a CDMA network, the same frequency can be maintained when switching between cell sites.

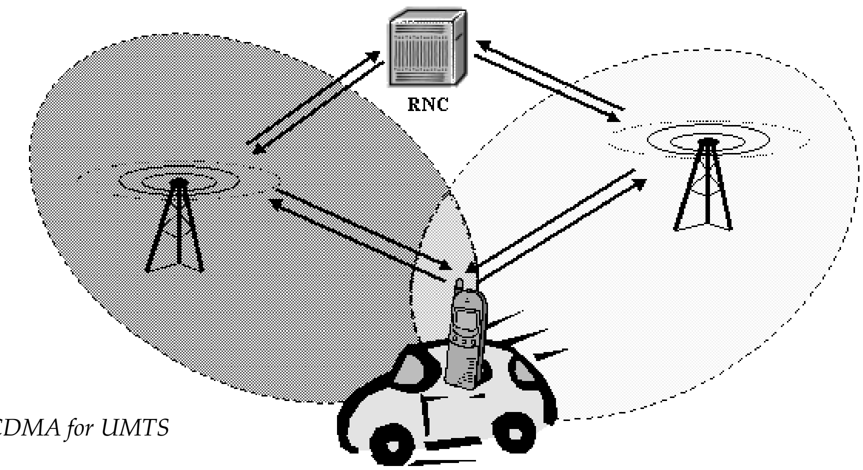
While soft handovers are clearly advantageous in a network, it does introduce overhead. Specifically, a handset that is communicating with two base stations can limit the number of additional subscribers that can access the network. Although the amount of overhead can vary, we have come across percentages that range between 25 percent and 35 percent or even higher, regardless of it being a WCDMA or CDMA2000 network.

When the CDMA phone is in a soft handover state, the phone is simultaneously transmitting and receiving from more than one cell site. The BSC keeps track of the signal from the mobile coming from multiple BTSs and selects the best quality signal. As a result, if a packet from one BTS is "clobbered," the same packet is picked up via the path from the other BTS. Thus, the near-instantaneous break in transmission associated with a hard handover is reduced to zero.

In receive mode, the CDMA handset actually combines the multiple signals, each with a slightly different amplitude and time shift due to the different distances traveled by multiple signals, into one cohesive signal.[7] A comparable example would be a disk jockey who uses two turntables to fade out/in music from different sources in order to continuously keep the music playing.

FIGURE 10

Soft Handover in a CDMA Network



Recreated from WCDMA for UMTS

WCDMA (UMTS) Networks

The Holy Grail for GSM–based carriers, at least those not considering CDMA2000, is WCDMA. To provide UMTS service, the RAN and the core network require changes in order to provide much higher data rates, enhanced QoS, and real-time service. In UMTS, the radio access network is called UTRAN (UMTS Terrestrial Radio Access Network).

The UTRAN includes a frequency division duplexing (FDD) mode and a time division duplexing (TDD) mode. The FDD mode is based on pure WCDMA, while the TDD mode includes an additional TDMA component. The air interface standard used by UMTS is called U_u. The U_u manages connections and handles signaling, paging, and timing information. At the same time, the U_m (GSM) interface remains in order to provide backward compatibility for the GSM phones and to provide coverage in areas where UMTS has not been deployed.

WCDMA uses 5 MHz channels, or multiples of 5 MHz. However, the current spectrum used by GSM in some markets lacks the room to provide UMTS service, since most of the spectrum has already been licensed to provide other services. Additionally, a guard band is required to prevent out-of-spectrum emissions. As a result, UMTS typically operates in newly licensed spectrum (prior to publication, the U.S. spectrum had not been defined). Even then, spectrum is a limited resource, so it did not make sense to define a standard that required more than 5 MHz. It was also felt that 5 MHz was adequate to provide the data rates required to provide 3G services

Chip Rates, Codes, Data Rates, and Coverage

In our discussion on GPRS and EDGE, we suggested that theoretical maximum data rates might never be achieved due to lower modulation and coding schemes being used and not all eight time slots being assigned. In the WCDMA (and CDMA2000) world, maximum user data rates (2 Mbps) are possible, but not probable. The reasons, however, are entirely different, and a bit more complicated.[8]

In CDMA networks, the limiting factor is the processing gain. Processing gain is expressed as a function of the spreading chip rate (3.84 Mcps or 1.2288 Mcps) and the user bit rate (for example, 12.2 kbps for voice). In CDMA networks, it is even possible to detect and decode a signal that is below the noise level, which is akin to being able to hear a whisper in a room of loud-talking people. However, as the user bit rate increases for a given chip-spreading rate (e.g., 3.84 Mcps), the processing gain is lowered.

The maximum user data rate for one assigned code is between 400 and 500 kbps. In order to increase the data rate further, additional codes are assigned, effectively creating a parallel data channel to the user. The maximum number of codes is six, which, even after data retransmission, can easily provide a user data rate of 2 Mbps (6*400 > 2000). In CDMA2000 networks, the lower chip rate requires additional codes and a higher modulation scheme to achieve the maximum data rate. WCDMA also uses a higher order modulation in the downlink (quadrature PSK—think four) than in the uplink (binary PSK—think two) to increase throughput in the downlink for a given number of codes. While additional codes can increase the data rate, it also increases the data rate, which requires additional processing requirements (e.g., decoding) for the handset and can reduce the battery life.

We believe operators will initially use lower kbps voice traffic as the determining factor for a WCDMA cell site's area of coverage. Operators will also consider the uplink, since mobile devices do not transmit at the same power level as base stations (on the order of 0.125 watts maximum versus 10–40 watts).

A number of factors can influence cell-site coverage and capacity, and we want to stress that the numbers we cite may not reflect actual values in a deployed network. However, on a relative basis, we believe that the numbers provide good insight into 3G capacity versus coverage.

Nokia calculated, based upon a number of assumptions, such as tower height and carrier frequency, that the cell range (for this scenario) in an urban environment for WCDMA voice traffic (12.2 kbps) is 2.3 km. Using the same assumptions, the maximum range for 144 kbps (indoors) is 1.4 km. We point out that AMR speech codec can increase the range for voice traffic with the trade-off being reduced voice quality.

Under another scenario, Nokia calculated the transmission range in the uplink for different data rates. As *Figure 11* illustrates, the uplink range at 2 Mbps is approximately one-third the range at 32 kbps. The reduced range is due to the lower processing gain achieved at higher user data rates. It should be noted that, at least initially, high data rates (>32 kbps) in the uplink may not be necessary and that it will be the downlink data rate that matters the most.

In the downlink, the base station transmits at a much higher power output than the mobile station can transmit in the uplink. As a result, Nokia states that a cell site can provide 1 Mbps rates in the downlink to any user who is within range to place a call (the uplink is the limiting factor). However, this would require high amplifier power and that no other users were utilizing capacity in that cell. These results suggest that 2 Mbps user data rates are possible in a 3G network, especially in a pico or micro cell. However, as Nokia points out, it would require that there are no other subscribers using capacity in that cell.

Additionally, if operators reuse their GSM 1800 MHz cell sites as WCDMA sites, Nokia estimates that 144 kbps data rates are possible throughout the cell. For GSM 800/900 MHz, this user rate drops to 64 kbps. Thus, operators do not necessarily have to increase the density of cell sites if they are content with the lower data rates.

Ironically enough, although maximum data rates decrease as the mobile device is transported more quickly in the network (e.g., in a car), coverage efficiency in a moving vehicle actually increases due to a phenomenon called fast fading.

UTRAN Infrastructure

The UTRAN introduces two new network components: the RNC and Node B.

Node B replaces the BTS. Specific Node B tasks include the following:

- Mobile handset control and communication
- Error correction
- Spreading and despreading of the signal
- Measuring the strength of the signal
- Providing power adjustment information to the mobile device

Node B is generally co-located with a GSM BTS and can support both FDD modes of operation. No vendor to date has announced support for TDD. However, the need for higher data rates (e.g., more than 64 kbps) may require operators to deploy additional cell sites, especially at 800/900 MHz.

We believe that UMTS will initially be deployed in "hot spot" regions and that ubiquitous 3G service will not be available for a number of years beyond the initially limited 3G deployments.

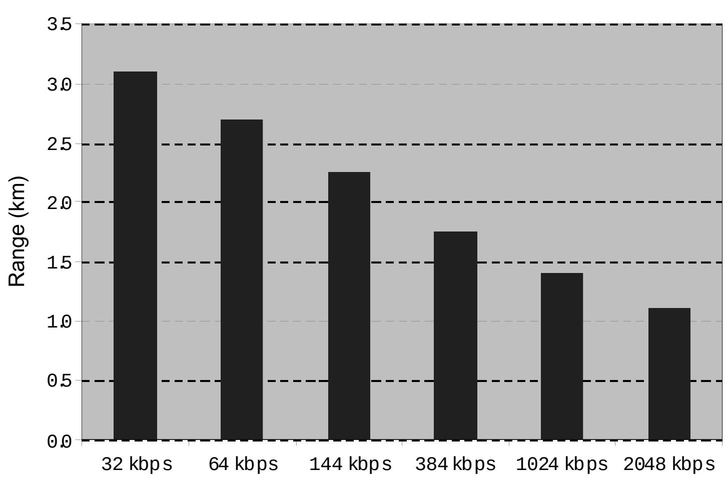
The radio network controller (RNC) is similar to the BSC. Specific tasks include the following:

- Resource management of the radio resources
- Protocol exchanges between its interface with the core network and the UTRAN
- Operation and maintenance of each cell (called a radio network system)
- Handovers between cell sites

What would a new technology be without new interfaces that have catchy and intuitive names? WCDMA introduces the Iub (between RNC and Node B—manages the common channels and controls synchronization and radio links), the Iu (–CS for circuit-switch data and –PS for packet-switch data—

FIGURE 11

Data Rate versus Transmission Range in the Uplink



Source: DBAB

note the voice and data are treated differently), and the Iur (RNC to RNC). All three initially use an ATM transport.

The UMTS core network uses an all–IP network with Release 5. In addition to some of the interfaces in *Figure 12* that impact the 3G core, a media gateway (MGW), if not already introduced into the network, is added as well. We should note that a MGW is not a "3G device," since it can be installed during any portion of the upgrade process and is also used in applications outside of mobile networks.

A MGW resides at the boundary between different networks (e.g., PSTN, TDM, ATM, IP) and is used to bridge the gap between transmission technologies by providing protocol conversion, QoS mapping, and voice encoding/decoding.

A MGW provides multiprotocol label switching (MPLS), real-time routing, VoIP, and Gigabit Ethernet termination. A separate media gateway controller (MGC) is used for call control so that the call control "intelligence" is handled outside the media gateways (more room for traffic). Eventually, the media gateways will completely replace functionality of the MSCs when an all–IP core is finally realized.

The home subscriber server (HSS) is an expanded HLR that maintains user profiles, user tracking, and services to which the user has subscribed. The HSS also provides the mobile IP functions that we discuss in more detail in our CDMA2000 section (no sense in having the same discussion twice).

The final new functionality worth mentioning is the call state control function (CSCF). The CSCF handles responsibilities such as call set-up/termination, address analysis, and address modifications, and it interacts with the HSS to obtain user profile information.

CDMA Networks (IS–95 to CDMA2000)

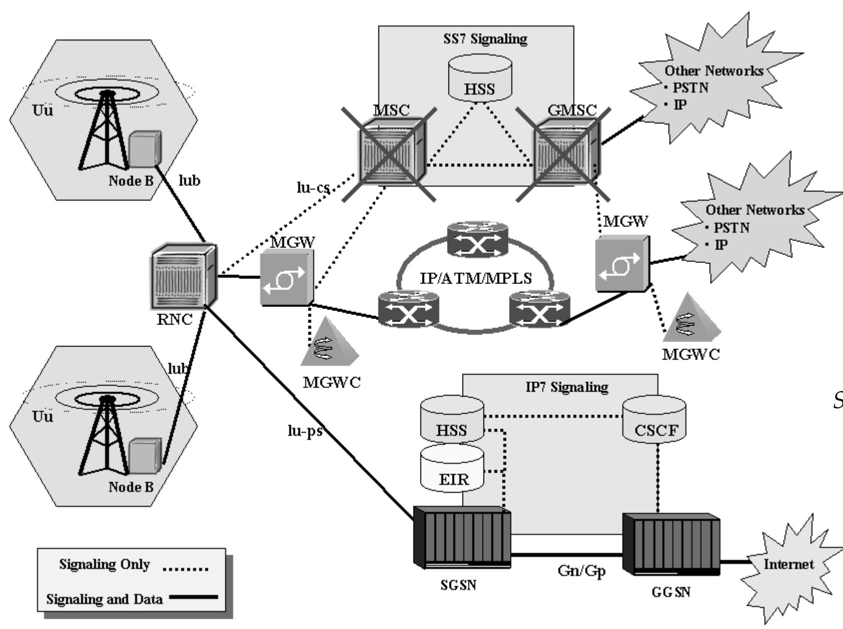
We could just tell you that the evolutionary path from cdmaOne (IS–95) to 1xRTT requires new channel cards and a software upgrade into the base station. Instead, we thought we would delve a bit deeper into the technical changes that result in the higher performance of the CDMA RAN as it evolves to 3G. Note that the chip rate remains at 1.2288 Mchips/s per 1.25 MHz band. One other interesting note is that all CDMA handsets, regardless of generation, are forward and backward compatible with the next-generation networks. What this means is that a cdmaOne handset works on a CDMA2000 network just as a CDMA2000 handset works on a cdmaOne network. We believe this is a distinct advantage in the evolutionary process.

IS–95 A/B

- IS–95A uses 64 unique codes (called Walsh codes) that encrypt the transmissions on the forward link (from base station to mobile phone). This equates into 55 traffic channels plus a pilot channel, seven paging channels, and a synchronization channel.
- IS–95B, like IS–95A uses a vocoder (voice coder) at 9.6 kbps or 14.4 kbps. At 14.4 kbps, the voice signal has higher quality, but the trade-off is reduced network capacity. Depending upon traffic requirements, an IS–95B base station can assign a mobile unit up to seven supplementary channels, each supporting 9.6 kbps or 14.4 kbps. When combined with the original channel, the theoretical maximum 115.2 kbps is achieved (8x14.4 = 115.2). However, current data rates in Korea, where IS–95B is deployed, only achieve 64 kbps.
- Other IS–95B enhancements include better power-control capabilities and improved handoff features that

FIGURE 12

UMTS Network Diagram during Transition



Source: DBAB

are intended to decrease dropped calls and reduce soft handoff times.

1xRTT

- New transceiver cards at the base stations and a software upgrade at the BSCs are required to support higher-speed packet data traffic. An upgraded handset baseband chip is also required.
- 1xRTT uses 128 unique Walsh codes, which theoretically double the capacity of each 1.25 MHz carrier channel. Recall that IS–95 uses 64 codes (64x2 = 128). However, interference is still the limiting factor with CDMA, so doubling of number of codes does not double the radio access network capacity.
- 1xRTT introduces changes to the RAN channel structure. The changes include extending the pilot channel to the reverse link as well increasing capacity in the reverse link, faster power control to improve network capacity and reduce power consumption at the base station, and a faster paging channel that can reduce the power consumption of the mobile device.
- In order to support packet services, 1xRTT can dynamically assign additional supplementary code channels in the forward and reverse links.

1xEV-DO

- 1xEV-DO is a data-only solution that separates data onto its own radio channel. In order to support the higher data rates, additional base stations may be required. 1xEV-DO also requires a new channel card and software upgrade to handle the higher data rates.
- Handsets need to have an upgraded baseband chip.
- 1xEV uses 8PSK instead of quadrature PSK as its modulation scheme. This increase is comparable to the higher modulation scheme used by EDGE versus GPRS in which the maximum data rate triples.
- 1xEV-DO uses a separate 1.25 MHz channel. If voice traffic is required, a 1xRTT or IS–95 channel is used.

Unlike the other CDMA2000 phases that we discussed, the 1xEV-DV (data and voice) standard is still being debated. There are two proposed 1xEV-DV standards. Motorola, Philips Semiconductor, Nokia, and Texas Instruments are backing their 1xTREME proposal. At the same time Lucent Technologies, LG Electronics, LSI, Qualcomm, and Samsung support their competing solution. One of the primary differences between the two proposed solutions is the modulation technique used in the RAN. The 1xTREME camp is proposing using 64 quadrature amplitude modulation (QAM), while the other proposed solution uses 16-QAM and MIMO technology.

With QAM, the amplitude and the phase of the signal are modulated to increase throughput at the sacrifice of being less resistant to noise and a higher probability of dropped packets. If you recall our modulation diagrams, just imagine there are 64 dots (64-QAM) or 16 dots (16-QAM). We note that with 64-QAM there are 64 discrete states or 5 bits ($2^5 = 64$). You may also remember that MIMO technology uses multiple antennas at both locations in order to boost data rates, thus a higher modulation scheme may not be required. We favor MIMO technology over increased modulation (always a tough call—pun intended—in a mobile environment).

CDMA2000-3X

- Three 1.25 MHz channels are grouped together in the forward direction to create a 5 MHz super channel.
- Backward compatible with 1xRTT and IS–95.
- Higher voice capacity than 1xRTT.

Given some of the challenges and high costs associated with CDMA2000-3x, carriers may remain with 1xEV-DV and not deploy CDMA2000-3x. Another reason cited by Verizon Wireless is that 3xRTT does not offer any improvements over 1xEV-DV, yet it requires the same amount of spectrum as WCDMA. Thus, Verizon Wireless would more likely deploy WCDMA than 3xRTT, although that scenario is also unlikely. We do point out that the 1xRTT standard incorporates 3xRTT, meaning the 3x standard has been accepted.

CDMA2000 Core Network

A CDMA2000 network is displayed in the *Figure 13*. Chances are the network looks very similar to the UMTS network. For example, both have an MSC, an HLR, a VLR, and some sort of packet node. In fact, the role of the equipment is virtually identical in both networks. Like they say, "looks can be deceiving."

The critical difference between the two networks lies in the signaling software protocols and how information is exchanged around the network.[9] The CDMA and TDMA core networks are based on the ANSI–41 standard, while GSM uses GSM MAP. However, although the GSM MAP and ANSI–41 protocols are not compatible, the SS7 network in both instances is used to transport the signaling information.

Signaling is paramount to the mobile network. It verifies the authenticity of subscribers and gives them access into the network. Signaling is also used to set up calls, keep track of the location of subscribers, send SMS messages, and the list goes on. The same holds true in an IP environment.

CDMA2000 introduces new hardware in order to provide mobile data service in an IP environment. The packet data server node (PDSN) has functions that are similar to those performed by the SGSN. However, the PDSN is purely IP–based networking, whereas the SGSN also handles signaling with the SS7 world.

PDSN is the "liaison" between the mobile device and the mobile data network. It helps the subscriber maintain contact and communicate with the data network as he or she moves throughout the network. In terms of a market potential, a PDSN can support between 12,000 and 15,000 subscribers. However, a decentralized network is also a mitigating factor (subscribers are spread over a large area, which requires more PDSNs). For a nationwide CDMA carrier such as Verizon, we believe it could eventually require as many as 2,000 PDSNs.

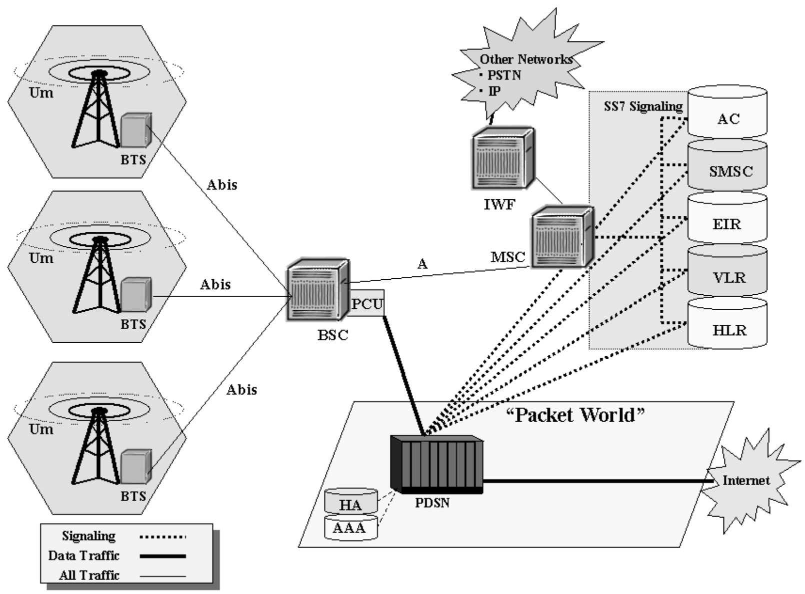
In the 2G world, the Interworking Function (IWF) serves as a "quasi" PDSN by offering 2G CDMA subscribers access to the data world. In some vendors' solutions, the IWF can be migrated to a 3G PDSN through a software upgrade.

In a mobile IP environment, an IP address is assigned to each mobile device. When the device moves through the network, the data side of the network needs to keep track of

FIGURE 13

CDMA Core Network Diagram

Source: DBAB



the subscriber's location in order to send data packets, just as the MSC/HLR/VLR keeps track of the subscriber for 2G voice calls. The following few paragraphs illustrate how IP mobility is maintained in a network.

When a mobile device wishes to transmit data, it sends a signal to the packet control function (PCF), which is located at the BSC. The BSC, in turn, sends this information to the PDSN, and a virtual link is established between the mobile device and the PDSN. Before the network accepts the device, the PDSN acts like a nightclub bouncer and checks out the device's credentials, or user information, with the AAA (authentication, authorization, and accounting) server. The AAA server verifies the subscriber's membership to the club, provides a mobile IP address for the session, and works with the PSDN to keep track of the tab (billing information).

As long as the device remains within the support area of the PDSN, which can be multiple BSCs, everything remains the same. However, things change if the device ventures into another PDSN's domain. If a mobile device enters an area outside of its home area (different PDSN), it still wants to continue to send and receive messages using its original IP address. In order for this to happen, the mobile device goes through the same verification process with the PDSN, in this instance called a foreign agent (FA). The FA (PDSN) passes the request to the AAA server. The AAA server passes this request to the originally assigned PDSN, or home agent (HA), to inform the HA of the devices new location. The AAA and the two PDSNs (HA and FA) then work together to set up a direct link between the two PDSNs. Once this link is set up, the HA (original PDSN) forwards data traffic to the FA (new PDSN), thus creating a true mobile IP environment.

Forget the Higher Data Rates—3G Is All About Added Voice Capacity

Despite all of the excitement over increased data rates, multimedia applications, and other feature-rich services, we believe one of the biggest drivers behind 3G is added voice capacity. Today's networks are reaching, or have already reached, saturation levels. As a result, more calls are being dropped and subscribers are increasingly having difficulty securing an open voice channel to place a mobile telephone call.[10]

Further, with worldwide market penetration at an estimated 14.7 percent by the end of 2001 and more than one-half of the world's population yet to make a phone call, we believe that lower-cost (per call) and higher-capacity mobile networks are perhaps the answer.

In order to determine how much additional capacity is added by next-generation technologies, one needs to take into consideration two facets. First, how many users can an individual RF channel can support. For example, one of the biggest drawbacks of AMPS is that it is an analog technology that does not allow more than one caller to use an RF channel at any given time. The second consideration is frequency reuse, or how often a carrier can reuse a frequency among cell sectors. One of the biggest advantages of WCDMA and CDMA is that they have a frequency reuse factor of one, meaning that the same frequency can be reused at adjacent cell sectors.

We present a chart and table (see *Figures 14* and *15*) that will probably cause more controversy than any other chart or comment we make in this report (trust us, it already has). The table illustrates how voice capacity varies across the different 1G, 2G and 3G technologies. After discussions with several OEMs and operators, we elected to present a range of values for some technologies. We took this approach because there are myriad factors that can swing the actual number in either direction.

With respect to 2G solutions such as GSM and IS–95, new voice codec algorithms can greatly improve voice capacity over initial technologies. For IS–95, this enhancement is deployed today. For GSM, the added capacity feature, called an AMR speech codec, will be available next year. Nokia also pointed out another feature, called dynamic frequency and channel assignment, which they believe can boost GSM capacity even further (by about 40 percent), although it is not being used today, despite its multi-year availability.

From our point of view, capacity claims on paper—be it CDMA, WCDMA, or GSM—do not necessarily equate to capacity improvements in networks. The reason is that operators—or for that matter, subscribers—may not be willing to accept potentially degraded voice quality. In CDMA and WCDMA networks, potential interference problems, both from in-cell callers and adjacent-cell callers, is also a factor.

For example, SK Telecom (using 1xRTT) informed us that it could support 40 voice callers per carrier, but that the operator is limiting the number to 38 callers to maintain good voice quality. At the same time, Nokia believes that 1xRTT will only result in 40 percent improvement over IS–95, which equates to 25 users per 1.25 MHz carrier. We support the higher estimate, although we recognize that other networks may not achieve the same results.

In CDMA–based networks, the best way to increase the number of simultaneous subscribers is to adjust each mobile station's transmitter power so that the signal-to-interference ratio received at the base station is at the minimal acceptable level. Otherwise, subscribers sitting on top of a base station could easily drown out far away subscribers. Thus, one of the main reasons for the increase of subscribers from cdmaOne to CDMA2000 is improved power control. Another mitigating factor is base-station density—a factor that is subject to the whims of the wireless operator.[11] In simple terms, the denser you build a CDMA network, the higher its capacity (densification).[12] This is a key advantage of this technology and is particularly true for high-density population cities such as Beijing or New Delhi.

Factors to consider when trying to interpret *Figure 14* and *15*:

- 1xEV-DO is a separate data-only channel that does not affect voice capacity.
- GPRS and EDGE traffic are data-only. Although more efficient data transfers free up channel capacity, this phenomenon is difficult to measure, and we exclude it from our calculations.
- Comparisons between CDMA 1xRTT and WCDMA are natural to make, but we emphasize that too many variables could influence actual results, thus limiting the value of a side-by-side comparison.
- Recent GSM enhancements meaningfully increase GSM capacity but have yet to be deployed.
- The transition from commercial CDMA IS–95 to CDMA 1xRTT occurs by simply upgrading an existing IS–95 network and has resulted in a capacity increase of 75 percent in a deployed network. Results for other carriers could vary and depend upon several factors, including adjacent cell interference and cell-site deployments.
- We favor the higher estimates for CDMA IS–95 and 1xRTT, although we do recognize that results in other networks could vary.

Carriers deploying WCDMA have to deploy an entirely new network to achieve the cited voice capacity. One artifact of deploying two networks (GSM, WCDMA) is that GSM capacity is additive to the WCDMA capacity, but at a high cost.

FIGURE 14

Voice Capacity per 5 MHz of Spectrum

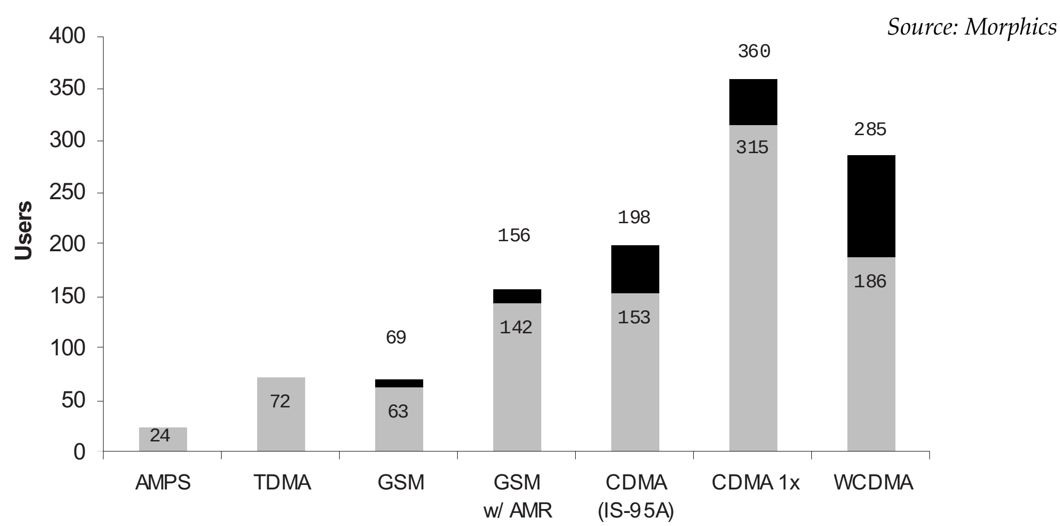


FIGURE 15

Voice-Capacity Assumptions

	AMPS	TDMA	GSM		CDMA (IS-95A)	CDMA 1xRTT	WCDMA
			BCCH[1]	Voice			
BW/Carrier KHz	30	30	200		1,250	1,250	5,000
Users/Carrier	1	3	7	8	17-22	35-40	62-95
Frequency Reuse	7/21	7/21	12	7	1	1	1
Carriers/Sector/5MHz	8	8	1	2	3	3	1
#Users/Sector/5MHz	8	24	21-52[2,3]		51-66 [4]	105-120 [4]	62-95 [5]

Source: DBAB

1) BCCH is a control channel involves using a combination of control and voice voice channels to increase network capacity. We present the assumptions for voice and control channels (e.g., user/carrier, freq reuse, carriers/sector/5MHz).
*2) Lower limit for GSM assumes 21 users per carrier. Upper limit is based upon a frequency reuse factor of 6 which gives 23 voice users versus 21 users (69/3 = 23) and AMR, which is claimed to increase capacity by 125%. (23*2.25 = 52). Available next year.*
3) DCA (not currently used, but talked about for number of years) is claimed by Nokia to increase GSM capacity by 40%. This increase is not reflected in our numbers, but could increase GSM capacity.
4) QCOM, SK Telecom and Nokia provided IS-95A and 1xRTT numbers. QCOM and SKT support the upper limit for IS-95 and 1xRTT. Nokia believes the lower estimates for IS-95A are more realistic and disputes the numbers we quote for 1xRTT. We support the upper limit range for CDMA IS-95A and 1xRTT since they are based upon actual network performance, although results could vary.
5) A more efficient voice codec could increase WCDMA capacity beyond 65 users. QCOM and NOK are not in agreement with the upper limit estimate which was made by Nokia. Given the wide assortment of variables that reflect actual results, a direct comparison with CDMA 1xRTT is difficult.

3G Handset Challenges

DSPs and Microprocessors—Better Eat Your Wheaties

Back in the good old days of first-generation technology, DSPs operated at 5 volts and had to handle only 10 million instructions per second (MIPS),[13] primarily because AMPS is an analog system. Then along came digital technology, and the MIPS requirement quickly jumped by a factor of at least 2x to 4x. As wireless systems move from second-generation voice-centric circuit-switched networks to third-generation voice-and-data, packet-switched networks, the required processing jumps dramatically by as much as 1,000x.

Next-generation phones will need to support multiple bands (e.g., 2000 MHz, 1800 MHz), multiple modes (WCDMA, GSM), multiple modulation techniques (GMSK, QPSK) and handle multiple time slots with GPRS and EDGE in order to increase the data rate. Each of these functions places an additional burden on the DSPs (yes, there is more than one), the microprocessor, plus about 1 million additional application-specific integrated circuit (ASIC) gates for WCDMA processing.[14] Motorola and Nokia both estimate that the radio channel processing requirements alone for WCDMA could reach 200 MIPS and that total MIPS requirements could reach as high as 12,000 MIPS. Although we have not seen any published numbers for MIPS, we believe similar processing power will be required for CDMA2000 (EV/DV).

The processing requirements for 3G phones are distributed across three types of processing: microprocessor (MPU), DSP, and signal-processing accelerators. The MPU supports the user interface, the communication protocol, and the applications made possible by 3G. The DSP must support increasingly complex communications requirements, as well as voice code processing. In a January 2000 IEEE article, Texas Instruments states that only 10 percent of the processing power with 3G can be accomplished on a DSP, whereas with 2G, it is 100 percent.[15] Thus, 3G phones will require additional horsepower that is nearly 10 times beyond what today's DSPs are actually capable of providing. The remaining 90 percent of physical-layer processing requires application-specific processing acceleration. *Figure 16* illustrates the distribution of 3G functionality across processing implementations.

The increased processing complexity poses a significant challenge to power consumption, time to market, and cost. OEMs and chipset vendors are striving to deliver the integration required to keep handset costs low and still maintain long battery life, but the challenges are significant. One of the biggest challenges is in the dedicated hardware accelerators. While ASICs could be used in the past, ASICs lacked flexibility, which is unacceptable in the face of shortened time to market and rapid standards evolution.

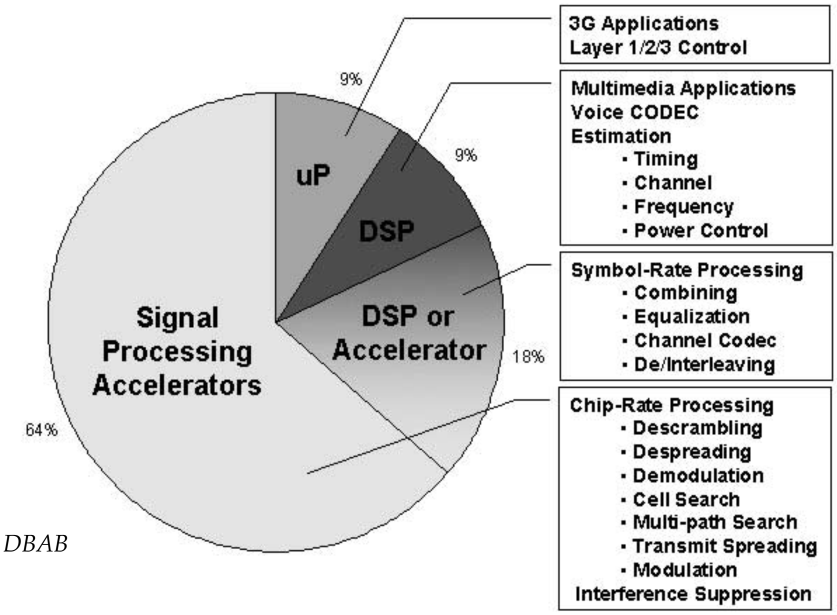
This application layer of a 3G platform is where the general purpose MPU and DSPs must be employed. Unlike voice-only phones, the 3G applications cover a range from simple messaging to real-time video. *Figure 17* from Intel provides a nice illustration of how added functionality increases the need for more MIPS.

Battery Life—Sometimes the Energizer Bunny Cannot Come to the Rescue

In the mid 1990s, Nokia was advertising its 638 phone, which provided two hours of talk time and 26 hours of standby time. An additional extended-life battery increased

FIGURE 16

Distribution of 3G MIPS



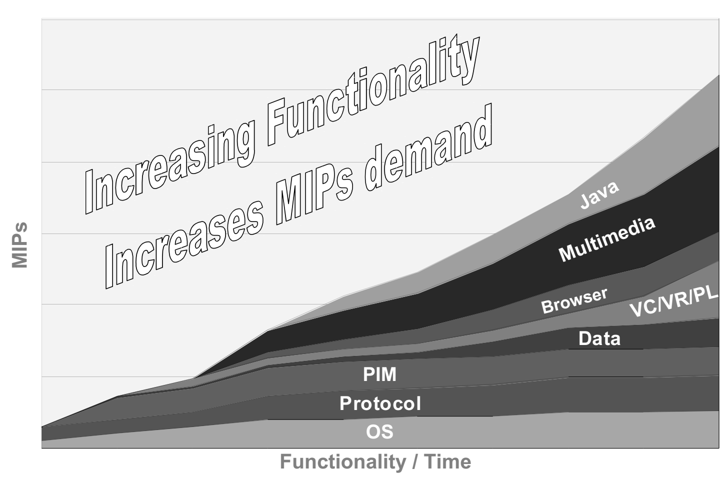
Source: DBAB

talk time to 3 hours, 20 minutes and standby time to 47 hours. Jumping ahead to more modern times, Ericsson claims its R520 phone provides 25 hours of talk time and 715 hours of standby time. To quote Bob Dylan, "the times, they are a-changing."

Battery life, until the next recharging, is determined by its energy capacity, which is expressed as a multiple of watt hours (Wh). If we assume two batteries operate at equal voltages, then the battery with the greater milliamperes per hour (mAh) rating should have a longer battery life. For example, Nokia offers an Ultralife Polymer battery that has 2,300 mAh, although most batteries have a capacity between 600 and 800 mAh. Of course, the other mitigating factor is how efficient that phone consumes power, both in standby and in talk mode. Today's premium phones consume between 2 to 4 mA in standby mode and 100 to 150 mA in talk mode.[16] We did the math, and that means a premium phone that consumes 3 mAh with a 750 mAh battery should have a battery life of 6 hours (750/125 = 6) in talk mode and 250 hours (750/125 = 6) in standby mode. Thus, the increased current required by faster DSPs and microprocessors is an important feature in addition to typical performance attributes such as processor power and memory capacity.

FIGURE 17

Application Drive MIPS



So far we have avoided using a physics equation in our discussion on 3G, but we are going to have to make an exception at this point.

Power = #Gates x Capacitance x Voltage^2 x Frequency

In order to preserve battery life, the handset needs to conserve power, sort of like Californians need to turn off the lights in unoccupied rooms in order to prevent rolling blackouts. All things being equal, a faster running processor/DSP drains the battery more quickly than its predecessor does (the frequency increases). However, the saving grace is the voltage term, which is squared in the preceding equation. If the operating voltage is reduced by a factor of 2, power consumption falls by a factor of 4 ($2^2 = 4$). Perhaps now it is apparent why companies such as Intel stress power and operating voltage requirements in addition to raw processing power.

There have been a number of battery technologies that have evolved over the years. Today, the two dominant technologies are lithium-ion (LiON) and nickel metal-hydrides (NiMh), with LiON rapidly winning the battle due to its ability to maintain its capacity after frequent recharging. It also appears that next-generation batteries will be based around an enhanced lithium technology, such as lithium-polymer, which reduces the size and improves the talk and standby times.

Don't Forget Memory Requirements

In addition to the need for extra horsepower and battery life, memory requirements with 3G also increase. It is estimated that the memory needs of a DSP read-only memory (ROM) for an EDGE handset could increase by a factor of at least five times and that DSP random access memory (RAM) will at least double. These estimates are even worse for WCDMA. The memory requirements for the microprocessor increase as well. It is estimated that Flash memory will have to increase from 16–32 Mbits to 64 Mbits and that SRAM will have to increase from around 2–4 Mbits to as high as 32 Mbits.[17]

Our Handset Market Forecast

Despite all of the challenges that exist, continued push-outs of WCDMA commercial networks and questions regarding customer usage of mobile data, we still believe 3G handsets will eventually come to market, if nothing more than as a means of offloading voice traffic from today's capacity-constrained networks.

Our forecast divides the world into five regions: North America, Europe, Latin America, Asia-Pacific, and Africa/Middle East. For each region, we project on an annual basis the total population and installed mobile subscriber base for each region, which we believe will increase each year as mobile phones permeate our society. We currently forecast a continuous annual growth rate of –9.0% (2001 to 2006), suggesting that growth in the industry will have to come from replacement sales.

Luckily for the industry, handsets are not a durable good and are replaced on a periodic basis. Since the replacement rate varies by technology, region and year, it would be too cumbersome to present a six-year forecast. However, we can summarize our assumptions by stating that we believe replacement handsets will represent 31 percent of the handset market in 2002 and reach 86 percent of the handset market in 2006.

As *Figure 18* illustrates, we currently estimate 389 million unit sales in 2001, 440 million unit sales in 2002, and a CAGR (2001–2006) of 14.0 percent. We also currently believe that WCDMA unit sales will grow from a 0 percent market-share to represent 24.2 percent of the handset market in 2006. We also believe that CDMA unit sales will account for 24.5 percent of the market in 2006, with a majority of these handsets being next-generation handsets.

Our Mobile Infrastructure Market Forecast

We estimate future mobile network capital expenditures (CAPEX), based primarily on new subscriber growth and increased minutes of usage (MOUs), from both voice and data. The increased CAPEX per each additional subscriber varies by region and by technology and should decrease over time. For example, we estimate that a GSM carrier will spend $137 for each new subscriber that it adds to its network in 2001 and that a TDMA carrier will spend $98. We estimate this amount will fall to $120 and $86 in 2002, respectively. The results of our 50,000+ cell Microsoft Excel model are presented in *Figure 19*.

PDC	2,170	1,752	1,200	867	658	422	171	-37.2%
Totals	**46,262**	**41,687**	**42,410**	**44,977**	**50,195**	**55,761**	**58,753**	**7.1%**
Cell site installs	140,064	140,776	159,061	189,723	243,859	310,358	373,570	21.6%
Total # of cell sites	475,095	615,870	774,931	964,654	1,208,514	1,518,871	1,892,441	25.2%
Switch installs	3,602	3,607	4,008	4,557	5,605	6,940	8,191	17.8%
Total # of switches	11,948	15,556	19,564	24,122	29,727	36,667	44,858	23.6%

At first it may appear a bit dismal that the mobile infrastructure spending CAGR (2001–2006) is only 7.1 percent. However, our forecast includes decreased CAPEX for analog (goes to $0 in 2003) and 2G technologies (our CDMA forecast combines 2G and 3G, since it is difficult to separate future CDMA CAPEX between 2G and 3G installations). Since most investors focus on 3G (WCDMA) infrastructure spending, we point out that the CAGR for WCDMA is 124 pecent, growing from only $695 thousand in 2001 to $39.2 billion (66 percent of total annual CAPEX) in 2006.

Conclusions

- We currently estimate handset sales of 389 million in 2001 and 440 million in 2002, with WCDMA handset sales not taking off until late 2002 at the earliest and more likely 2003.
- We currently estimate mobile infrastructure CAPEX spending of $41.7 billion in 2001 and $42.4 billion in 2002. While we forecast a mobile infrastructure CAPEX CAGR of only 7.1 percent (2001–2006), we also forecast WCDMA infrastructure CAPEX growth really taking off in 2003 with a CAGR (2001–2006) of 124.1 percent.
- Based upon discussions with industry experts, we believe that WCDMA will eventually be successful. Currently, the standard is relatively immature and the technology is going through the same growing pains that the CDMA IS-–95 standard went through when it was first deployed.
- We believe 3G infrastructure spending, at least for the near-term, will be driven by the need for additional voice capacity. CDMA2000 and WCDMA technologies both provide the necessary voice capacity that operators so desperately need. The question becomes, when will carriers "cave in" and begin spending CAPEX dollars.

Note: This paper was condensed from a 200-page industry report that was published in September 2001.

Notes

1. In 3G WCDMA networks, the BSC is called a radio network controller (RNC).
2. A T1 line supports 1.544 Mbps, while a T3 line handles 44.7 Mbps. Their European counterparts are the E1 and E3 lines, respectively.
3. As we discuss later in this report, nearly all 3G networks will be based upon a form of CDMA, CDMA2000, or WCDMA.
4. GSM originally stood for Groupe Special Mobile from approximately 1984 to 1992.
5. Verizon and Cingular currently offer similar plans, starting at $2.99 per month for up to 100 messages. Additional messages cost $0.10 each (Verizon only charges $0.02 to receive a message).
6. 3G (UMTS) is comprised of a series of releases, beginning with Release '99.
7. Multiple received signals generally result in poorer reception due to an effect call multi-path. However, a CDMA phone uses a RAKE receiver that can sort through and combine multiple signals, just as a yard rake can group together individual leaves into a larger pile.
8. Comments in this section are based upon discussions with Ericsson and the book *WCDMA for UMTS*, edited by Harri Holma and Antti Toskala of Nokia.
9. In our GSM and WCDMA sections, we introduced a number of interfaces (A, Abis, etc). The ANSI–41 protocols have essentially the same naming scheme and the same non-technical description, so we elected to exclude them from our CDMA (ANSI–41) section.
10. Ironically enough, at the recent Cellular Telecommunications & Internet Association (CTIA) conference in Las Vegas, it was nearly impossible to place a call through our mobile carrier's network.
11. Our IS–95 and 1xRTT estimates are based upon information obtained from vendors and carriers deploying commercial CDMA IS–95 and 1xRTT networks. These estimates could vary in other carrier's networks. WCDMA estimates were taken from the book *WCDMA for UMTS* by Henri Holma and Antti Toskala of Nokia.
12. Densification is a term we invented, but we hope it gets our point across.
13. MIPS is sometimes referred to as Meaningless Indicator of Performance, since it only provides a rough estimate for measuring performance.
14. The primary difference between a DSP and a microprocessor is that a DSP is designed for tasks that require repetition and are numerically intensive (e.g., voice encoding). A microprocessor is more robust and flexible and is designed for control-oriented applications.

Unlock the Value of Convergent Wireless Services: Pricing Models to Achieve Optimal Profitability

James Morehead
Director, Wireless Market Development
Portal Software, Inc.

Introduction: The Wireless Industry in 2001

"Value pricing appears in other contexts. People pay more for orchestra seats than for balcony seats; for Saturday night performances than weekday performances; for the services of more skillful doctors or consultants. … Smart marketers will bundle the product with additional benefits and price the total offering."

Philip Kotler, Kellogg Graduate School of Management, Northwestern University

"The business model based on paid content is simple and transparent—content providers know what they want and what revenues they will get. Users will pay for content that has a high perceived value, that is personalized and delivered in a format that suits their device of choice."

Eden Zoller, Ovum Senior Analyst, August 2001

"Most carriers' billing systems are not advanced enough to split revenue based on customer minutes, and then send revenue back to content providers."

Unstrung, August 2001

"'Content will soon be developed and provided on a usage basis to different market sectors,' predicts Greg Howard, principal analyst and founder of High Tech Resource Consulting Group in San Andreas, California. 'However, a significant hurdle in developing these new business models has been the lack of content usage-based billing solutions.'"

Global Telephony, June 2001

"'We see that there will be traction for content-based billing in two or three years; once … the bandwidth is there with DSL and GPRS,' says Jason Briggs, senior analyst in the Yankee Group's Billing and Payment Applications Strategies division. 'But this is the time where the winners will get the mind share.'"

Billing World, April 2001

"'In most cases operators are still assessing market requirements through service trials, so strategies are still being redefined, but the favored model at present is to charge by the amount of data consumed,' said Yunus. 'Current billing platforms will be inadequate both in the long term and in stimulating demand right now, given the diversity and range of future data applications,' he added."

"Mobile Data Pricing – Will European Consumers Pay a Packet?" Yankee Group, August 2001

"China is also experiencing significant growth in SMS traffic, according to ING Barings, after usage was initially hindered by flat-rate pricing models offered by China Mobile. 'The company later changed the charging method to a per-message basis which started stimulating SMS usage,' says Barings analyst Craig Racine."

Global Mobile, August 2001

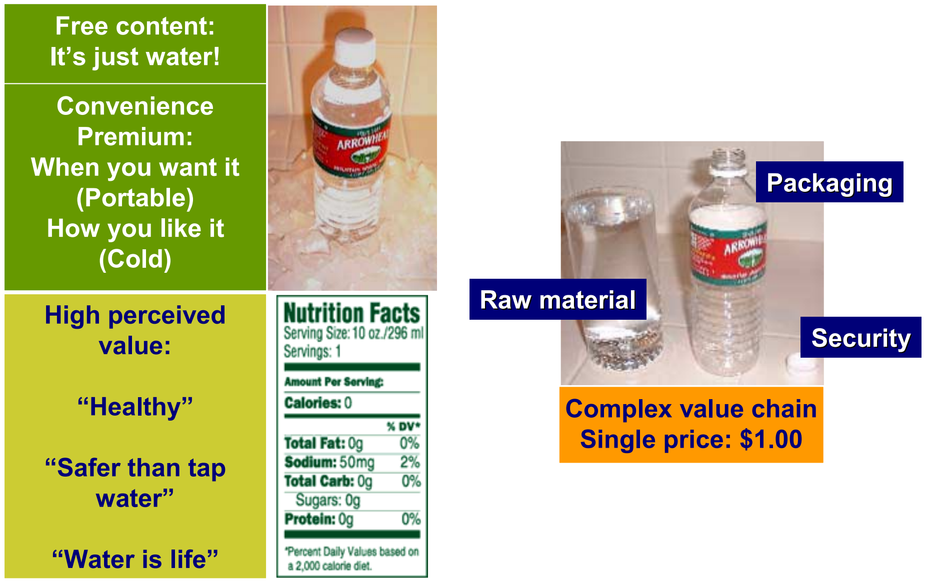
Value-Based Pricing Overview

In the mobile industry, value-based pricing (also referred to as content-based pricing or event-based billing) is being treated as a new way of charging for services. While it is true that most mobile services to date have been charged on a per-minute or subscription basis (voice-mail, calling features), packaged products have long been priced based on value.

Before applying value-based pricing concepts to mobile services, it is useful to consider value-based pricing successes in other markets. The first of several case studies used in this paper is bottled water (refer to *Figure 1*). The content delivered in bottled water is arguably "free" (while in some cases the source it a distant mountain spring, in many cases the content is filtered tap water). There is added value; however, the water is delivered cold and in a portable package—and people are prepared to pay extra for this value—a "convenience premium." There is also perceived value—savvy marketing positions bottled water as "safer" than tap water—and reinforces that water is "healthy" and that "water is life".

FIGURE 1

The Power of Perceived Value



This simple example parallels mobile services—the core value of a mobile phone is its convenience (the "freedom to socialize" with friends and family from any location; the ability to conduct business while on the move). In most countries, there is still a convenience premium paid for mobile phone service over fixed lined service (although this is shrinking over time).

Even more striking is the complex value chain that is required to deliver an ice-cold bottle of water into the hands of a thirsty consumer—elements of the value chain include raw materials, packaging, physical distribution, and even security mechanisms (the tamper-proof cap). Despite the complexity of the value chain, bottled water is sold for a single, simple price—and the price is clearly labeled.

A second example is outlined in *Figure 2*. Here, consumer products are used to compare value-based pricing with "weight-based" pricing. Most consumer products are value-priced—the "weight" of the product is not related to the price, and "raw material" costs are hidden from the purchaser. Even "commodity" products can be branded and their value increased (the bottled water example).

Let's consider for a moment a world where all products are sold based on their weight. In this world, a single price per pound is set for all products (in the example in *Figure 2*, $4.00 per pound). Products such as baby formula with high perceived value are under priced. "Heavy" products such as baking mix benefit. And the cotton ball industry wouldn't have a business case (or, the cotton ball industry would focus on genetically engineering "heavy cotton"). The value chain is encouraged to create "heavy" products and discouraged from creating "light" products.

In summary, people (consumers and business people) accept per-product/per-service pricing and "points of value" as long as the pricing is clear and transparent. Value-based pricing models rewards innovation rather than just "heavy" products.

Fundamentally, why are mobile services any different? This paper argues that mobile services are ultimately no different than the simple examples shown and submits that charging for the value of content and services, not the bytes (raw materials) used to create services, will enable the mobile industry value chain to maximize the profitability of convergent wireless services.

Value-Based Pricing Applied to Convergent Wireless Services

For illustrative purposes, a wireless digital picture sharing service is referred to throughout this paper (such a service is available through both J-Phone and DoCoMo in Japan with multimedia handsets). With this service, users are able to take a picture with a digital camera (integrated into the handset or connected via a cable or Bluetooth), and then send the picture wirelessly to another handset.

The service has value—it is more convenient to send a digital picture directly from a portable device than to synchronize the device to a computer for later transmission. The service is also immediate—for consumers, this makes the service "fun," and, in the case of business applications, provides a competitive edge (e.g., a photo journalist trying to secure a "scoop" at a crime scene).

The service described has substitutes—the end user (for example, a tourist) could take a picture with a digital camera and later upload the pictures to a computer for sending. Or that end user could buy a postcard and stamp (perhaps $0.60 combined). In both cases, the substitute is less convenient and immediate (and in this example, less personal).

FIGURE 2

Decoupling Product Cost from Product Value

Having concluded that the service is of value, how should the service be priced? Three key options are subsequently outlined.

Transport Model (Transport Charge Only)

The simplest pricing model for mobile service providers is just to count the number of bytes transmitted and apply a price per byte. This model scales along with traffic but does not provide any differentiation between the types of services delivered. Low byte volume/high value content generates less revenue than high byte volume/low value content. Just as was the case in the introductory examples (with consumer goods sold by weight), the transport model rewards applications that consume more network capacity and undervalues innovative services that minimize network usage.

Further, the transport model makes "sender pays" pricing models difficult to implement because the type of service is more difficult to determine from a network-level byte stream (it is difficult to "sniff" out services when there are potentially hundreds of content providers). Services such as the digital picture-sharing example will likely be more widely adopted in a "sender pays" model (the wide adoption of core voice service in Europe is partially attributed to "calling party pays" pricing models).

The transport model also makes it difficult to decouple the raw material cost (bytes) from the service value. For example, as compression technology improves, the transport model would automatically pass savings along to the end user, since it is network level activity, not service-/content-level activity that is monitored. The price drop may not be necessary if the compression technology maintains the service quality. With the transport model, it is also difficult to implement content-specific loyalty programs (such as send five digital pictures, get one free).

The transport model is the least intuitive and requires the end user to understand how the service "works" in order to predict the price (e.g., performing a mental calculation: the number of bytes required for the service multiplied by the price per byte). And when the invoice arrives (for a postpaid subscriber), the charges will not be itemized by service but simply shown as a block of bytes. Prepaid users may be afraid to use services under a transport model because they won't be sure how their balance will be impacted.

It is important to note that there are cases where the transport model is appropriate—corporate intranet access, for example, where an enterprise has purchased access in bulk. In general, however, the transport model makes it difficult to align pricing models with service value and to built service-specific remittance agreements with content partners.

Hybrid Model (Content Charge + Transport Charge)

In the hybrid model, there is a charge for both the picture sent and the transport. This requires the mobile service provider to track content events and transport events but not correlate the two. In this model, there is the ability to charge for specific points of value. Because the content charge component is not affected by compression technology improvements, the impact of compression technology on revenues is less severe. The content component enables a partial "sender pays" model so that the receiver is only charged for the transport.

The pricing model, however, is still complex and requires the end user to make two decisions: "Is the content charge good value? What is the additional transport charge?" As with the transport model, the end user will likely not know how to calculate the transport charge, which may delay service adoption. The hybrid model is not favorable to prepaid because of the split charges for a single service.

Content Model (Content Charge Only)

The most intuitive model is charging solely for the content—in this case, the digital picture (e.g., a charge per picture sent). Charging solely for the content simplifies "sender pays" pricing models (since user- and service-specific event information is received from the content server rather than the network). The content model also makes loyalty programs easier to implement (send five digital pictures, get one free).

To simplify the pricing model for the end user, the value chain must absorb complexity. In this example, "absorbing complexity" means not charging for bytes that are correlated to services charged on a content basis, and processing event information received from a third-party content provider.

Table 1 provides a summary of the aforementioned models.

As summarized graphically in *Figure 3*, the impact of compression technology on service revenues and margins is dramatic in the transport model and hybrid model. Only the content model is unaffected by the introduction of compression.

The Advantage of Convergent Services

The digital picture example can be further enhanced when converged with voice services. For example, consider a "Friends and Family Plus" plan where digital pictures sent between friends and family members are coupled with free voice minutes (e.g., two voice minutes per digital picture sent). Voice minutes are used to encourage the use of a higher margin service—sending digital pictures. The example shown in *Figure 4* demonstrates two subscribers in a friends and family group sharing digital pictures, and then making free phone calls to talk about the pictures.

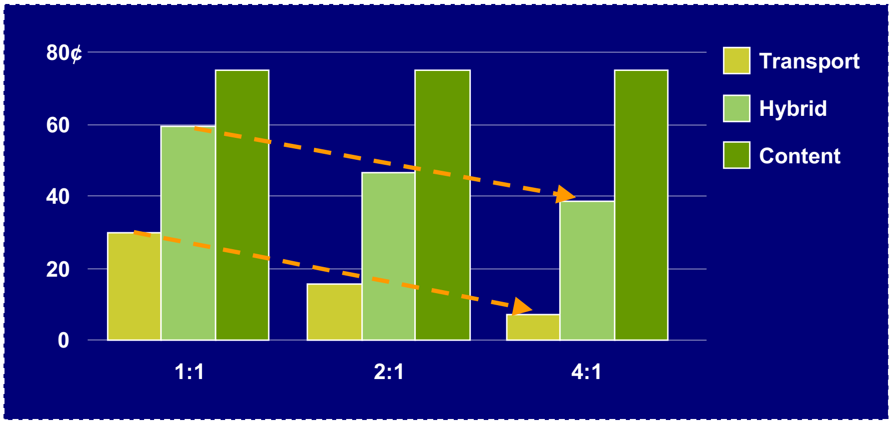
To connect free minutes to services, the hybrid or content model is required. Assuming the content model ($0.75 per digital picture) and two free minutes per picture sent, the resulting revenue is $1.50. The transport cost is four minutes

TABLE 1

Pricing Model	Revenue Generated[1]	Mobile Service Provider View	End-User View
Transport Model ($5.00 per MB)	$0.15 sender – transport charge $0.15 receiver – transport charge	• Revenue decreases with the introduction of compression technology • Loyalty programs difficult to implement • Difficult to differentiate • Difficult to implement "sender pays" models	• Non-intuitive; service may be perceived as more expensive than it really is • Forcing receiver to pay could hamper service adoption • Invoice does not show content-usage detail; repudiation risk (sender and receiver)
Hybrid Model ($0.30 per Digital Picture and $5.00 per MB)	$0.30 sender – content charge $0.15 sender – transport charge $0.15 receiver – transport charge	• Revenue decreases with the introduction of compression technology • Difficult to implement "sender pays" models • Enables loyalty programs and content-specific bundles	• Non-intuitive; service value decision is based on two prices • Forcing receiver to pay could hamper service adoption • Invoice does not show content-usage detail; repudiation risk (receiver) • Separate charges complicates prepaid models
Content Model ($0.75 per Digital Picture)	$0.75 sender – transport charge No charge to the receiver	• Enables loyalty programs and content-specific bundles • Compression does not impact revenues; rather, compression increases profits by reducing transport costs • Well suited to prepaid subscribers	• Intuitive; service and pricing model are matched; pricing is transparent • "Sender pays" model removes barrier for receiving pictures • Invoice is content-specific and reduces repudiation risk • Prepaid and postpaid pricing models can be the same

FIGURE 3

Impact of Compression for Transport, Hybrid, and Content Models



of voice (the free minutes) and a voice minute equivalent of less than two minutes for the data transferred (approximately 120KB)[2]. The convergent offer not only encourages use of a higher-margin service, but also builds loyalty within a friends and family group.

If the value chain cannot capture the full value of content and services, the revenue stream will be insufficient and the value chain collapses. Without an incentive to create interesting content and services, the value chain cannot exist.

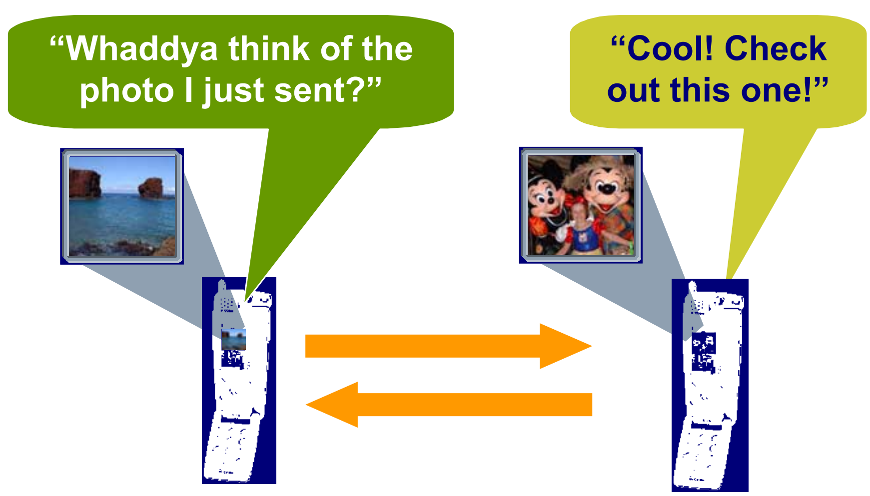
The convergent example discussed here is similar to the strategy used at supermarkets—the milk (a high-volume, commodity-priced or "everyday low price" product) is placed at the back of the store, whereas high-margin products are place along aisles leading to the milk (the "margin gauntlet"). As mobile service providers expand their service and content offerings, there will be increasing opportunities to cross promote, cross discount, and bundle services. Charging for content rather than charging for bytes transmitted greatly increases the options for marketers.

A single example has been examined in detail to draw out the advantages of value-based pricing and convergent services. There will, of course, be a variety of pricing models employed—flat-rate services, usage-based services (metered on content and transport volume), and subscription services. The most successful mobile service providers will build pricing models to match market-driven requirements, not billing system limitations.

The evolution of pricing models in the mobile industry as voice, data, and content converge and competition increases is inevitable—one need only look at other indus-

FIGURE 4

Converging Voice and Data Services



tries to see how pricing evolves in the face of competition (see *Figure 5*).

The key question then is how to implement value-based pricing models effectively. This is addressed in the next section.

Building a Content-Enabling Environment

To enable the digital picture-sharing service described, a new relationship between the mobile service provider and the content provider is required. The content provider will usually be in a better position to specify the detailed nature of a transaction and will hold the copyrights for branded content. In addition to providing the transport, the mobile service provider will usually be in a better position to obtain payment from the end user (the *only* way in the case of a prepaid subscriber that does not want multiple balances with multiple parties). The mobile service provider is also an excellent source of location information to enhance content and services.

Consider the digital picture example. The mobile service provider is able to detect the bytes going across its network, but unless it has chosen to host the service, the mobile service provider may not be able to track the number of digital pictures sent and to whom they are sent (and if the digital pictures are encrypted for privacy, tracking transactions at the network level will be virtually impossible). The content provider is able to track the number of digital pictures sent—even if encrypted—and provide detailed information regarding both the sender and receiver but may not be able to entice the end user to set up a separate account for billing (or a separate prepaid balance).

Further, if the content provider chooses to bypass the mobile service provider, the end user will pay the transport directly, resulting in the hybrid model. As discussed earlier, this is a less intuitive pricing model that may impact the rate of service adoption. When the mobile service provider is bypassed, the benefits of convergence are lost (cross-product discounting, bundles, and convergent loyalty programs), which hurts both parties.

In the digital picture example, if the mobile service provider and content provider work together, the full value of the service is "unlocked." The content provider provides usage details about the digital picture service, and the mobile service provider bills the end user (or impacts the prepaid balance). The mobile service provider and content provider then settle the revenue received. Just like buying bottled water, the end user is shielded from the complexity of the value chain. An interconnected value chain maximizes value to the end user—and as a result maximizes revenue to the value chain. There are strong motivators for the mobile service provider and content provider to work together and form a profit maximizing value chain—it is the natural evolution of the mobile industry.

The mobile service provides a "content-enabling environment" and extends its value well beyond a simple "pipe" for bytes. The content provider, by working with the mobile service provider, ensures full value for its services and enjoys the economies of scale of the mobile service provider's convergent billing environment.

This relationship is shown in *Figure 6*.

Creating New Value Chains

Next-generation billing platforms enable links between voice and data network technologies, content partners, and payment methods. Innovation will occur in the network as

FIGURE 5

The Evolution of Pricing in Competitive Markets

	Initial Pricing Options	Pricing Options in the Face of Increased Competition	

Automotive	• One price, one model, one color (Model T)	• By model

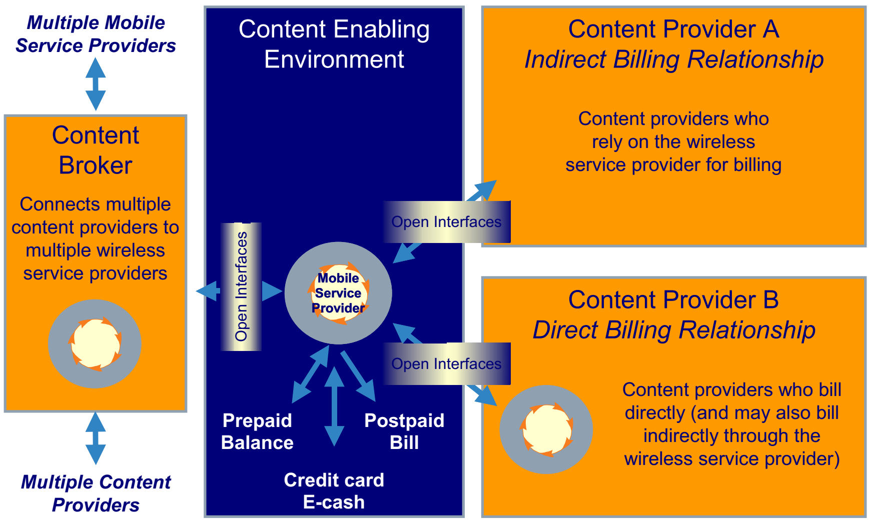
FIGURE 6

A New Relationship between Mobile Service Providers and Content Providers



new technology enablers are deployed and outside the network as new services are created. As highlighted in *Figure 7*, traditional billing systems were custom built to interface with network and mediation elements for batch processing of voice call detail records (CDRs). Next-generation billing platforms support both batch interfaces for high-performance processing of voice CDRs and transactional real-time interfaces for prepaid services, advice-of-charge, and other applications requiring real-time processing.

The explosion of content providers outside the mobile service provider's network requires billing platforms to support open interfaces. Going forward, it will not be practical for a custom integration to be built between each of hundreds of content providers and the mobile service provider.

Customized closed systems were not designed or intended to rapidly adapt to such a constantly changing environment. The total cost of ownership (TCO) for custom-built systems increases rapidly as the number of content providers increases. In a highly competitive marketplace, a delay of even one month can have a significant impact on the profitability of a new service.

FIGURE 7

Multiple Sources of Information in a Mobile Network

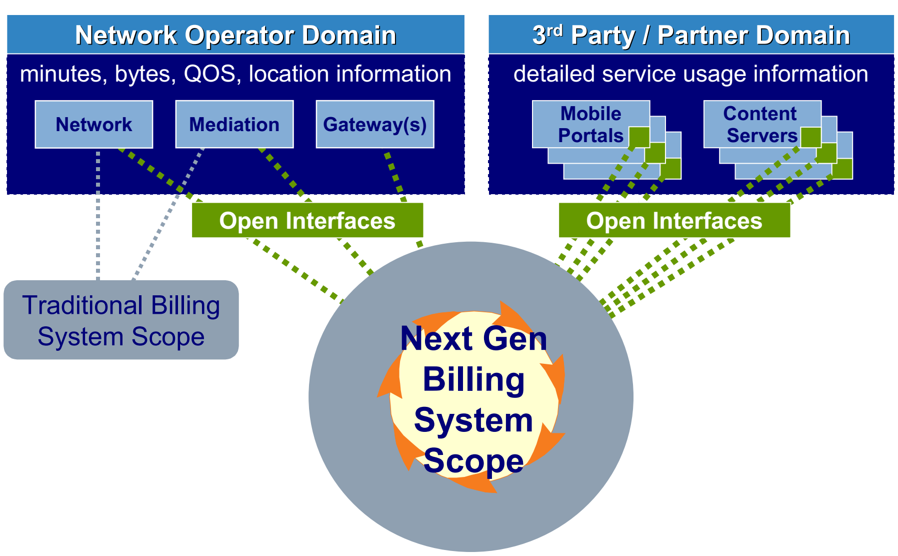


Figure 8 demonstrates the flexibility of a next-generation billing platform using the digital picture example. While the network and mediation layers provide information on the volume of bytes consumed using the mapping service, and possibly the universal resource locator (URL) of the service, the mobile portal and/or content service have very rich detail on the service consumed. This richer detail enables innovative pricing models, sponsorship, loyalty programs, and remittances, *but only if the information can be effectively delivered to the rating and billing platform.*

Conclusions

There is growing consensus in the mobile industry that value-based pricing models are required to maximize the profitability of enormous investments in 2G, 2.5G, and 3G mobile networks. Next-generation billing platforms will enable mobile service providers to match service innovation with pricing innovation. Events for rating and billing are no longer limited to network-centric sources. Rather, a next-generation billing platform enables a customer-centric approach—using sources of information that are closer to the service and the customer—enabling pricing models that are intuitive, competitive, interactive, service-specific, and, most importantly, profit-maximizing.

Notes

1. The revenue generated is based on a 30KB transfer (including overhead). In the transport model, the price is based on 30KB transmitted at $5.00 per MB. In the hybrid model, the sender pays for content and transport ($0.30 for the digital picture and $0.15 for the transport). In the content model, only the sender pays, since there is no transport charge (network activity to the content provider is "non-chargeable" but may be tracked for service profitability analysis).
2. This assumes 14.4 kbps packet data, which translates into 90KB/minute in circuit-switched terms, or less than two minutes of "voice equivalent" network capacity. 120KB represents two pictures sent, 60KB for each (30KB to send and 30KB to receive).

Advanced Hyper Satellite Designs for the Next Decade

Joseph N. Pelton
Professor, Institute for Applied Space Research
George Washington University

Ivan Bekey
President
Bekey Design Concepts, Inc.

Abstract

For communications satellite systems to remain relevant a decade hence, new technology and new design architectures may well be necessary. In this article, a brief description is given to four "dramatically different" designs of future "hyper satellites" that could be deployed in the 2010 to 2015 time period. These totally new types of satellites architectures, once deployed, could delivery services at extremely high rates—i.e., in the terabits/second range and at transmission costs that might be as low as $0.0l per 2 gigabits of information transmitted.[1] If the designers of satellite systems do not seriously consider breakthrough designs with new types of systems architectures within the next few years, then satellite networks could lose rather than capture new market-share in future years. This would be unfortunate, because broadband Internet, interactive entertainment, mobile Internet protocol (IP) services, and other opportunities are now open to the satellite industry.

Hyper Satellite Design Concepts

For more than 35 years, the dominant trend in satellite communications has been to develop higher-capacity and higher-throughput satellites by designing larger power systems and higher-gain antennas (and thus larger-aperture antennas). This trend has also produced a corollary assumption. This is the dominant systems paradigm where moving to larger-aperture and higher-gain satellite antennas (accompanied by higher-wattage power systems) has also meant that we had to move to much higher-mass satellites that would be more expensive to launch and also bring other problems related to reliability, etc. The antennas that are planned for the next Telesat system, as well as those designed and launched on the Asian Cellular Satellite System (ACeS) and Thuraya represent this trend toward bigger, more massive, and certainly more expensive satellites (i.e., both to build and launch).

Figure 1 shows this type of extrapolation toward larger and massive satellites with higher throughput capabilities. This same graphic also includes a very important new idea. This idea is that if there were better designs with better and lower materials then in a decade or so more productive and cost-efficient satellite systems could be developed.

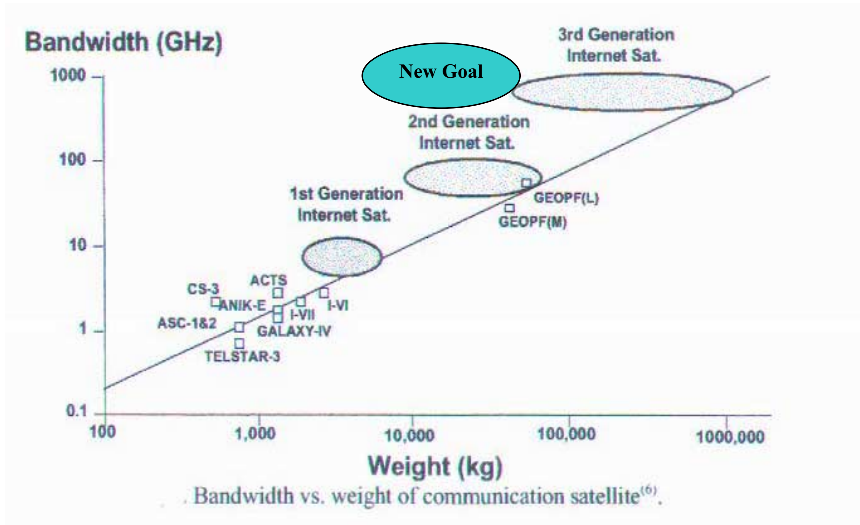
There are, in fact, a large number of potential new architectures that could allow the design of new satellite systems that could be at least an order of magnitude more cost-effective than "conventional satellite communications" technology, as represented by an Intelsat 9, an ACeS or a DirecTV 4S satellite. One of the more promising approaches developed by researchers in the field is the design of satellite communications antenna systems that use remarkable lightweight materials as well as advanced and highly efficient power systems so that the throughput/kilogram is 10 times less that today's conventional designs. Also, the power levels derived from the very highly focused satellite beams would provide flux densities sufficient to support tiny micro-terminals (including the possibility of wearable mobile antenna systems).

In studies currently being conducted by George Washington University's Institute for Applied Space Research (IASR), there are three different types of advanced designs under consideration. These designs (that might be called "hyper satellite designs") all achieve very high capacities (or digital throughput) while minimizing mass and systems costs and also increasing usable lifetimes. These are briefly described as follows:

- *Hyper Satellite Option One:* Implement a constellation with a number of very lightweight antennas placed far apart in space and fed by a central unit. The location of the antennas in this constellation would be maintained principally by passive means, most likely achieved by a rotating tethered system.
- *Hyper Satellite Option Two:* Implement one or, at the most, a few very large filled aperture antennas using advanced phased array antenna technologies and little or no structure, such that one to two orders of magnitude of weight and cost reduction are obtained compared to conventional antennas. One of the principal keys to this design is that the feeds to the antennas would be phased array elements or multiple illuminators that would create many narrow beams.
- *Hyper Satellite "Swarm" Option Three:* This design would implement an extremely large sparse array antenna with a large swarm of tiny elements acting in concert to form a coherent phased array without any structure. The dimensions of the antenna would be principally maintained by passive (i.e., gravitational) means.

FIGURE 1

Past Trends in the Size and Mass of Satellites and a View of the Potential of a New Type of Satellite Architecture



Such designs are currently being evaluated against such factors as cost, reliability, technical feasibility, complexity of deployment and operation, need for new material development and new research and development (R&D), space environment/space debris concerns, human health and safety issues, and legal or regulatory constraints.

All of these designs would also include new highly efficient "rainbow" solar cells with a very high level of "junctions" so that a much higher percentage of the power contained in infrared light and ultraviolet radiant energy would be captured and thus convert more than 50 percent of the sun's energy. Such totally new designs are not likely to be developed prior to 2010 and would not become operational until 2015. Unless key development work is carried out now, however, these highly efficient systems may not be accomplished even by those dates. Important technologies needed to support such advanced satellite platforms include those listed in *Figure 2*.

FIGURE 2

KEY TECHNOLOGIES FOR GEO PLATFORM SYSTEMS

- Advanced phased array antenna concepts
- Polyimide materials (less that one kg/square meters, including electronic components)
- Advanced fullerene-based (e.g., "Bucky ball") and other advanced tether structures for antenna deployment
  Tether structural design for forming passive constellations
- Adaptive electron-beam shaped piezoelectric membranes
- Liquid metal solid-state field effect electric propulsion units
- Broadband time-delay microcircuits that are capable of modulation
- Large phase shift capability microcircuits that can be modulated
- 10–12 bit digital samplers at gigahertz frequencies
- Integrated self-contained silicon-based picosatellites that can be deployed in swarms
- Highly efficient photovoltaic thin films (e.g., rainbow solar cells)
- Piezoelectric bimorph membranes resistant to the space environment
- High-temperature superconducting long wires
- Precision optical sensing of surface figures
- Precision metrology for position control in formation flying
- Integrated multifunction components

To illustrate what these concepts might look like in actual operational satellite systems, the following graphics are provided as a preliminary visualization of these types of advanced communications satellite systems. Concepts 1, 2, and 3 as presented in *Figures 3*, *4*, and 5 would represent increasingly more demanding new technology.

Beyond these three new rather radical "hyper satellite" design concepts, there is yet another way to devise telecommunications concepts for the future that are more than an order of magnitude more cost-effective than conventional satellite technology. This is merger optical laser technology that is being developed for intersatellite links with so-call stratospheric platforms or high-altitude platform systems (HAPSs).

High-Altitude Platform Systems Including Hybrid Satellite and Stratospheric Platform Systems

Thus, the other "new idea" is to have space communications service to HAPSs via optical links and then using radio frequency (RF) service (probably in the Ka-bands or above) to

FIGURE 3

Hyper Satellite Concept 1

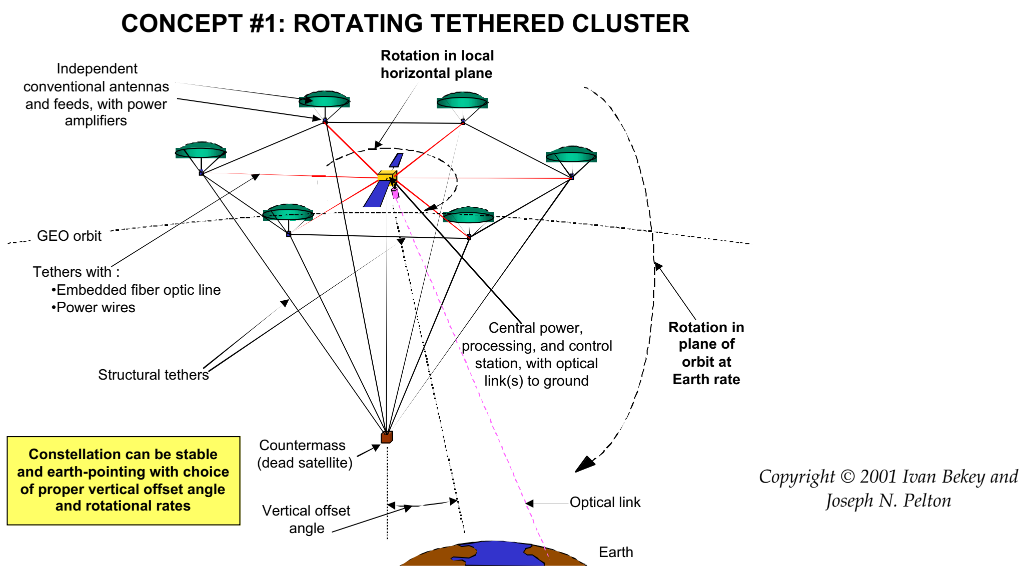


FIGURE 4

Hyper Satellite Concept 2

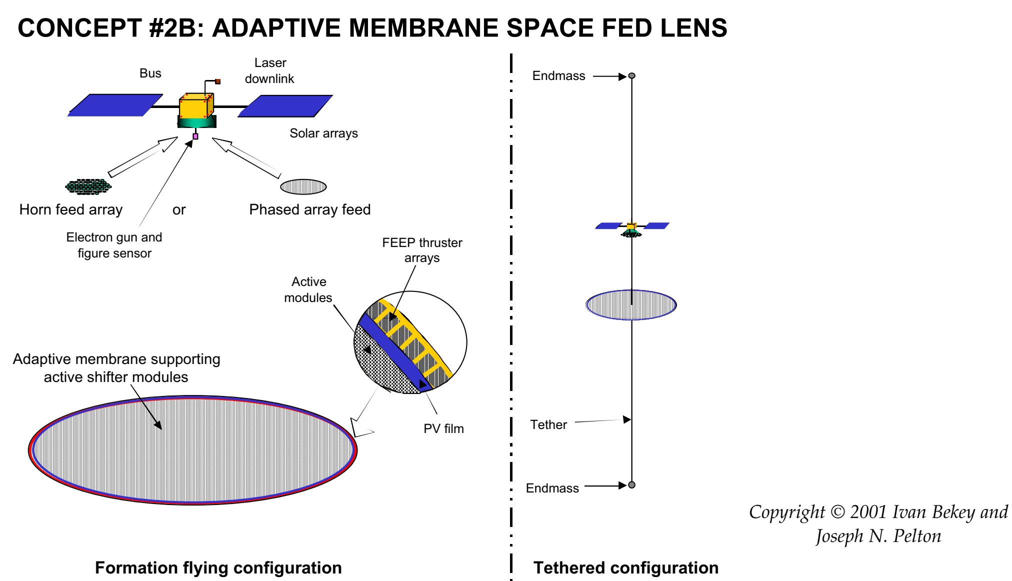

FIGURE 5

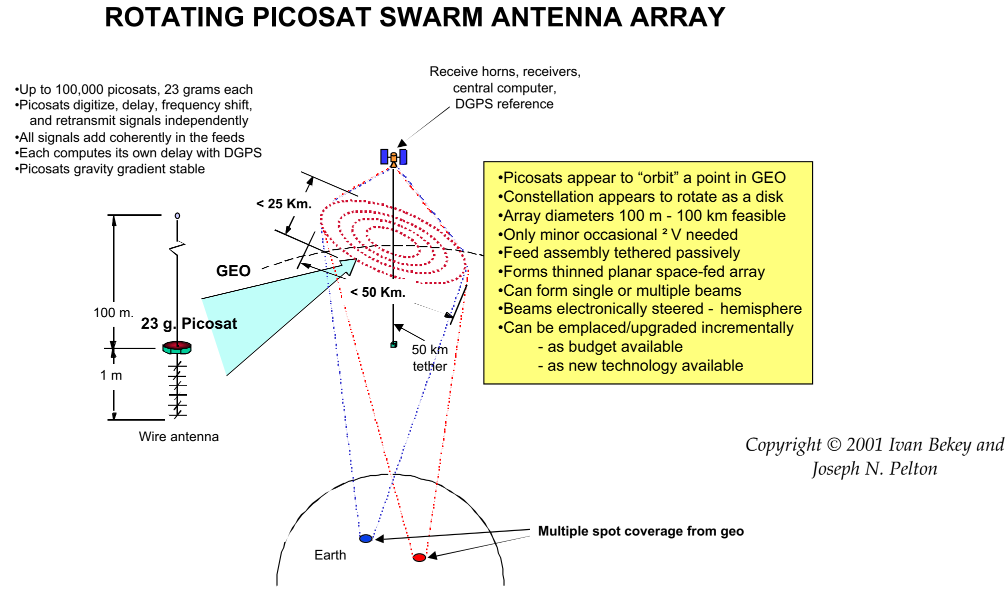
Hyper Satellite Concept 3

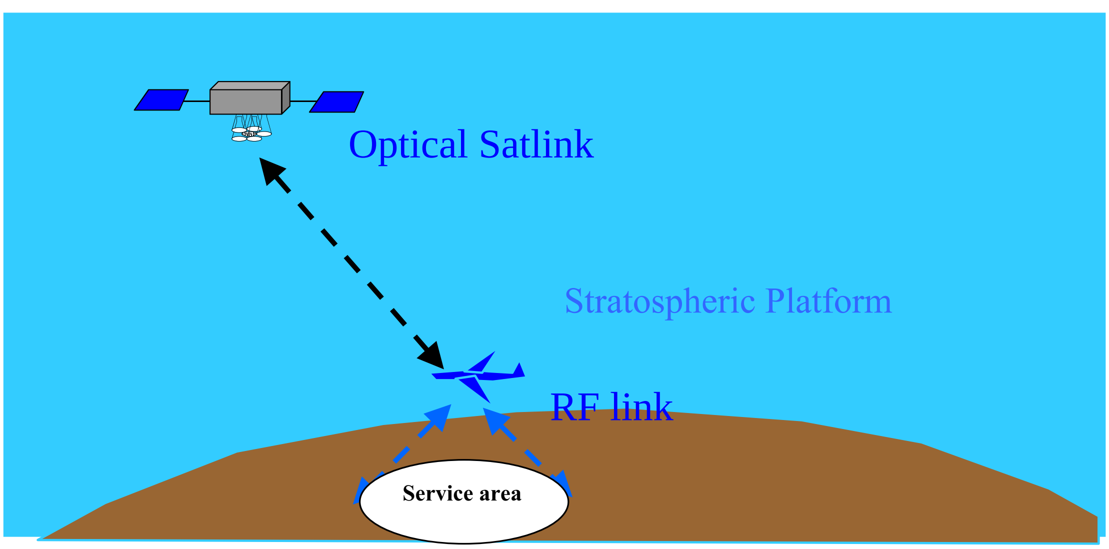


provide broadband services to cities. Such systems would be capable of very high system capacities with high cost-efficiency and with a highly desirable feature of low transmission latency. This concept is shown in *Figure 6*.

Only a network of a dozen or so optical satellites equipped with intersatellite links as well as optical links to a system of hundreds of HAPSs could provide mobile and broadcast services to create a global information network capability. If the HAPSs could be deployed at altitudes as high as 32 kilometers (or 20 miles), then they would be well above the atmospheric disturbance and rain attenuation that makes space-to-Earth communications difficult.

Further, the HAPSs would be equipped with enough on-board power to operate at very broadband, extremely high frequencies (EHFs) effectively. This is particularly true since the look angle would be highly favorable and the path-loss considerations minimal for the high gain, multi-beam phased array antennas that could be deployed on-board

FIGURE 6



HAPSs by 2015. The detailed engineering of such a system is beyond the scope of this study, but a preliminary review of such a hybrid system is presented in *Figure 7*.

The overall consideration is that while the hybrid satellite/HAPS network would likely be cost-effective and address the latency problem for many applications and services, it is not certain that such a network would have sufficient capacity to address the rapidly growing demand for broadband mobile services. In short, such a hybrid system might be needed in addition to terrestrial mobile wireless systems in the 60 GHz and above bands as well as geosynchronous–Earth orbit (GEO) platforms.

In all of the aforementioned advanced architectural concepts, very broadband communications, including broadband mobile communications to portable (and even wearable) micro-terminals, would be technically (and likely economically) feasible.

Summary and Conclusions

The field of satellite communications has grown tremendously in terms of new technology and service capabilities over a span of nearly 35 years. The increase in capability from Intelsat 1 to Intelsat 9, for instance, represents a gain of well over a thousand-fold, but for satellites to maintain their economic and technical relevance in the 21st century, dramatic new gains are needed. The total new architectures discussed in this article show that "technical breakthroughs" are possible to create new hyper satellite systems a decade into the future. These system could produce not only major increases in throughput, but also breakthroughs in cost-efficiency, so that 2 gigabits of information could be delivered at a transmission cost of about $0.01.[1]

FIGURE 7

KEY OBSERVATIONS ON A HYBRID HAPS/GEO SATELLITE NETWORK

- Such a hybrid system largely overcomes problems of latency for regional and intra-city communications, but interregional and international communications would still experience some 250 milliseconds of delay.
- HAPs would function as optical/RF transformers. (Thus, an optical signal can be sent to and from a geosynchronous satellite from a stratospheric platform.)
- HAPSs, in comparison to geosynchronous satellites, substantially reduce the problem of rain fade in Ka-band and above because of high power, favorable look angle, and reduced path loss (e.g., 35 kilometers maximum versus 35,800 kilometer altitude).
- Optical communications satellites can be deployed in multiple locations for space diversity, and thus direct space-to-Earth and Earth-to-space links would be available as an emergency "fail over" system.
- High levels of frequency reuse can be achieved by HAPSs (with well over 1,000 beams and up to 300-fold frequency reuse) for such applications as broadband mobile communications. Simpler systems could be deployed for entertainment and broadcasting applications
- HAPSs could serve localized needs, and optical communications satellites could serve inter-regional needs.
- High-altitude aircraft have now been developed and prototypes are in operational testing, and thus represent a higher state of R&D and feasibility testing than most geoplatform concepts.

3G in Latin America: Building the Network

Willy Schotte
Senior Director
Bechtel Telecommunication

Third-generation (3G) wireless systems promise advanced services and revenues for the operators. Nevertheless, questions remain. Is your customer base and market ready for the new services? What 3G standard is best for you and your market? Should you wait for Internet protocol (IP)–based systems? Is an interim technology such as general packet radio service (GPRS) a good solution for now? Whatever your analysis, the switch from second generation (2G) to 3G is a major technological challenge; you will soon need major changes to your systems and organization.

Wireless companies in Latin America, including countries such as Brazil, began the cellular race late. They started late and faced the challenge of constructing networks and systems in less than half the time of typical U.S. companies. However, they have performed well and continue to build out and introduce new technologies. Cellular phones are becoming essential to conducting business and are very much a part of life. For the most part, carriers have built their networks and now are changing the business focus from providing coverage to providing capacity and features as quickly as possible. Now, the focus is on marketing and the introduction of new services and applications. The challenge is how to get and keep customers while maintaining profitability.

Today, the world is talking about 3G (third-generation mobile systems), and operators cannot sit back and watch their competitors take the lead. Operators need to say READY, SET, GO—and begin the race to implement the new 3G networks. The world is ready for high-speed data, music, and video on portable devices. Some believe we will still talk on portable phones in the future. The hype about 3G reminds me of the hype about integrated service digital networks (ISDNs). I really hope that 3G exceeds the market success of ISDN. Today, around the world, carriers are taking a sober look at the 3G revenue potential and are carefully analyzing the cost to implement it.

What Is the Best Approach for Carriers in Latin America?

One can correctly conclude that every flavor of technology, frequency, and service provided is present in every country, with very little roaming possible with advanced services. Can an operator remain with short message service (SMS) only, or is a combination voice and cellular digital packet data (CDPD) necessary? Several options in a dual-mode/dual-band handset are available. Eventually, if we wish to have full transparent roaming, we must align with the most common technology and with the most universal and open standard. That may be some version of 3G. Today, many carriers are taking the interim approach to network evolution and are moving towards 2.5G and GPRS. In several countries, the operators concluded that data rates around 40K are sufficient to meet the demand of the market for the next few years. They plan the move to GPRS and will use GPRS as a training ground for the new data world to which their operations have to adjust. The move to 3G may be less painful with 2.5G operation experience. However, the capital cost for 2.5G may not be recovered before the next change-out to 3G is required!

READY, SET, GO—Building the Network

While considering the move to the next generation, carriers are underestimating the efforts involved in moving to the new technology. The following are some points that could help operators avoid mistakes when building the next step in their network.

The variety of vendors, frequencies, and services does not allow me to be very specific on the issues; hopefully, there is sufficient information to trigger "opportunities" in your system. The new technologies are universal in the way in which they can be implemented. Any installed digital service can migrate to 3G. Any frequency band can be used for 3G. What a system!

This implementation could be easy—if one has a new license and if ample bandwidth is available. It is not so easy if the new service has to be implemented in the current operating system and has to reside within the current allocated spectrum. If major changes to the frequency plan are required, and spectrum clearing is necessary, engineers can expect serious challenges. The complexity and cost of spectrum clearing is directly related to the bandwidth to be cleared. Additional construction of cell sites may be required to protect the service during the installation phase of the new service. If the regulatory agencies have allocated new spectrum where current microwave systems are operational, spectrum clearing may add additional cost to the implementation, especially if the new user is forced to relocate the current systems.

Many alternatives can be considered if additional spectrum is assigned. One alternative is pre-seeding of the market with dual-mode/dual-band phones. Be warned, several operators have reported that in some areas, even though the voice quality is acceptable, the data-transfer quality is not. This is not the end of the challenge. The installation of additional equipment in cell sites requires additional floor space. Those upgrading to GPRS should consider looking at the requirements for migrating through to 3G. The GPRS implementations for some vendors are simple and do not require major equipment changes; however, major additions may be required for the next step to 3G. Developing current, correct site documentation will save you money in the long run.

The additional demands for alternating current (AC)/direct current (DC) power and the increase in air-conditioning requirements add to the complexity. On most rooftop sites, space is limited, and, in some cases, expansion of the systems has maximized the rooftop loading. This may require a review of the structural parameters. Grounding also needs to be reviewed. Cell-site equipment most likely runs on DC power and is well screened from outside influence by the AC/DC power systems. Now several vendors are introducing direct-powered AC equipment sites, such as data routers and hubs located next to the DC equipment, and are introducing equipment that is not typical. Several violations of grounding rules have been observed that expose the site to possible damage by power fluctuations and lightning strikes.

Site acquisition becomes very difficult in cities. Most rooftop prime locations are taken, and if not, we find a radio frequency (RF) nightmare on the rooftops. Safety for personnel becomes an issue, and interference is present. When a tower is feasible, co-location may be the only option; here, structural loading is again of concern. Additionally, the rooftop and tower owners know the value of the roof or tower!

If site acquisition is successful, we then have to deal with increased complexities in the zoning rules and permits required for construction and changes to structures. Moratoriums on towers and antennas are present in several jurisdictions. Even a minor change in the dimensions or visual change of an existing antenna requires weeks of waiting for zoning approval. The co-location of antennas on rooftops or towers becomes a major issue, considering the additions of new frequencies and transmission of high-density data signals. Inter-modulation to your current systems and to the other co-locators should be analyzed.

New equipment such as the diplexer is introduced to the RF path of working systems. This will change the losses in the RF path and the characteristics of the site. Coverage and quality may be affected. The introduction of wideband signals with high data rates requires a complete review of the RF path. Several devices in the current systems—such as filters, combiners, lightning protection, and test systems—may have bandwidth restrictions, and change-out would be required. Several of these devices cannot meet the specifications required for the high-speed data.

If the 3G signals are added to the existing RF path, the power specification of the equipment in the chain has to be reviewed. In some cases, equipment from different vendors may be used. The interaction between this equipment must be carefully analyzed.

Today's transport networks are mostly built on channel-based T1 or E1. The system tolerates minor impairments without major impacts to the service. Compression, drop, and insert are used frequently. Most existing wiring is below standard for the new applications. The microwave spectrum is open, and the local carrier can meet the T1 or E1 demand. The move to wideband signals and high-speed data demands major changes to the network. T1 or E1 cannot be channelized. Several products cannot meet this requirement. Drop and insert is not possible. Wiring must be upgraded considerably; this may be a challenge to the service provider. If the system depends on a microwave system, a review of the specifications for non-channelized high-speed data is recommended.

Remember that under the 2G technologies, most mobiles are dormant and observe the control channels for activity. They use minimal bandwidth while in the idle mode. The 3G equipment could be very active receiving data while at rest on your desk and be perceived to be idle.

In a system with high data density, the quality of the network becomes important. Poor bit-error rate (BER) performance and the resulting retransmission of data packets may decrease the useful capacity of the system and bring unacceptable quality of service (QoS). The measurement of "lost packets" is also essential. The traffic-engineering rules being tested for the new systems are complex. To guarantee QoS, it might be that meeting the objectives on voice quality and dropped calls may not be sufficient indicators for good service. Can you see the impact of missing packets in critical applications?

How Can We Minimize the Opportunities for Problems?

The following are of equal importance:

- Clear market and marketing objectives
- A good entry plan
- Pre-construction surveys and site inventory
- Review of structural loading
- Well-developed RF plan
- Well-developed network plans (for voice and for data)
- Program management and logistics for large builds
- Integration and cutover plans
- Operations support system (OSS) adapted for the voice/data systems

For those of you that plan to build systems and then later consider upgrading to 3G, I recommend that you manage this move as a new system build. Most of the problems that you solved in your first build will return, and then some. The need for experience is key. Training your staff on the new specifications and system requirements is essential. Training should also focus on data systems. Technicians at your cell sites will now need to be skilled in information technology (IT). Carefully select your OSS. Don't forget you manage data—not channels, circuits, or voice.

The change from 2G to 3G is a major technology change. It requires major adjustments of your people and support systems. It is like a new language—you have to learn it!

My final comment is that you should not forget to watch the market and be prepared to make prompt adjustments in your course. Building a network is a big challenge. We are building the network to offer services to our clients and to anticipate their needs and their willingness to pay for the service. The latter may be the biggest challenge of all.

Mapping Mobile Commerce to Network Support Systems Requirements: An Overview

Nicholas C. Stanley
Principal
Lecoma International, Ltd.

Summary

The mobile telecommunications industry is now making a vast bet on the future: that there exist compelling reasons for customers to use next-generation mobile networks in ways that will produce revenue streams well above those for voice. While revenue in and of itself is good, the carriers also look to next-generation services to decrease churn by making users more dependent on the carrier's services above and beyond generic voice. Reducing churn and pushing more content through the system's infrastructure are both vital to the bottom line.

While early indications for 2.5G and 3G are mostly a product of speculation in the trade press, less attention has been directed to the task of "monetizing" customer behavior—that is, the means to translate consumer use of services to cash flow.

This paper[1] will attempt to model various consumer behavior and identify what business support system (BSS) needs could be deduced from the payment models. There appears to be a strong business case for continued use of third parties in the payment and settlement process, much as there are in conventional retail services. Indeed, mobile commerce may show many parallel elements to conventional commercial structures, which leads to the conclusion that the dominant industry players in consumer retail payment collection and settlement may have significant influence upon the fate of the wireless industry—a new force has entered the arena.

Contemporary Projections and Conventional Wisdom

As this paper is written in the winter of 2001–2002, both the popular and trade press are frequently populated by articles on next-generation services: Some are optimistic to the point of hype, while others forecast financial meltdown.

The future is unknown. Certainly the most optimistic models are based on wishful thinking but do have a basis in fact: Mobile services have historically vastly exceeded expectations (in the early days of cellular radio, the total number of cellular phones in the United States was expected to be less than one million). The cynics can point to massive failures of business models still shaking the industry (Excite@home being one).

Nonetheless, a few facts put things in perspective.

- *Consumers find ways to do new things.* Witness short message service (SMS)—originally almost an afterthought in the Global System for Mobile Communications (GSM) model. Estimates are that more than 200 billion SMS messages will be sent this year[2]. If the carriers capture just U.S.$0.01 (or even €0,01) for each message, that equals U.S.$2 billion or just under that in euros. Quite a nice bit of cash.
- *Things unique to mobiles become lifestyle component*. Ring tones, which can use either existing SMS–type technology or new 2.5/3G systems, are expected to bring in about U.S.$300 million in Europe in 2002[3] and at about U.S.$1.00/€1,00 each—that's a lot of beeps and burps.
- *New services start in one segment and move outward*. One doesn't have to repeat here the success story of i-Mode in Japan, where DoCoMo is reaping the benefits of the attraction of mobile content to demographics far beyond the original teenage early adopters.
- *The fixed Internet provides a guide, but perhaps not a roadmap.* Mobile content as a whole (which includes ring tones, multimedia alerts, electronic greeting cards, etc.) is predicted to catch on as SMS has done and, using projections from the Internet use of "push" and "pull" technologies, may reach significant levels as next-generation services are rolled out.

Many, many other examples can be pulled from the media. The purpose here is not to establish the credibility of the argument that new services will mean new revenue streams—that much is given. What is not so clear, however, is how much of that cash flow is going to be applied to the amortization of the capital investment in the infrastructure that makes the revenue possible. It's not beyond the realm of possibility that the carriers could find that their BSSs are unable to cope with rapidly emerging services. Those services, by definition, are in high demand by consumers, and somebody will find a way to deliver them. If the carrier's BSS cannot capture some part of the value for particular transactions, the remaining cash flows from other services must pick up the load on the marginal costs involved.

The old paradigm was "If you can't bill it, kill it." The implication was that the carrier had a choice in the matter. No longer. The carrier may not have that luxury.

End-User Models

The need for carrier's BSSs to evolve and develop in concert with the next generation of services is hardly news. Industry experts have been producing analyses and proposing solutions for some time. One thing that is given scant attention in these articles is the actual segmentation of the consumer market. This is natural, as most experts come from the billing-systems industry, where the "consumer" is actually a "subscriber" and as such is a fairly homogeneous class. All cellular subscribers act pretty much in the same manner: They talk;, they roam; they use a few vertical services. Up to this point, most billing companies were concerned with how to gather information on events, rate those events according to a set of rules, and then produce a bill for the services and perhaps a settlement report for outside partners.

Now, the challenge for the carriers is to find a means to evolve their billing systems in such a way as to capture as much revenue as possible from the flow of next-generation services and content delivery. Sophisticated and complex models for partnership settlement, revenue sharing, and so forth are spun out. Complex software tools are being developed and intensively marketed.

While certainly far from trivial, such a picture misses the point. Consumers are becoming heterogeneous, and no matter how comprehensive the BSS becomes, it is fated to be only one component of several. The diversification of the consumer base brings with it a strong need for the carrier to support the personalization of service offerings. Every customer will have a slightly different selection to fit his/her preferences. While the aggregate choices may be fairly uniform with a customer segment, carriers must take it as a given that no "one-size-fits-all" billing model can exist.

We postulate here that in the next generation of mobile services, consumers will decide for themselves how they wish to pay. Just as they do now in a store, they will demand flexibility, and the degree will depend on the value of the transaction relative to the relationship that the consumer has with the carrier. We have, somewhat simplistically, divided consumers into four segments:

- *Lifestyle Consumers:* The prototype is the Gen-X young consumer using a mobile as an integral part of a fashionable lifestyle. Voice, images, ring tones, "texting"—whatever is new and innovative, they try it. As new ways of communicating are found, the carriers and service providers may find themselves being led, not leading. How do they pay for all of this? Whatever it is, it has to be simple. And affordable.
- *Convenience Consumers:* This group uses mobile services that provide a function or a feature to them that just makes life easier. The soccer mom getting directions to a new school for a meet, the business traveler checking for flight information in the taxi, maybe getting the occasional alert from a stockbroker. The dominant theme is using the unique capability of mobile access to information, but on a demand basis. Spend a bit more? Sure, it's worth it.
- *Deliberate Consumers:* A more intense blend of the lifestyle and convenience consumer segment. The deliberate consumer has built mobility into his or her profession. Examples abound. The road warrior with regular access to his e-mail and voice-mail via integrated messaging. The real-estate broker who is also an active day trader, so she requires real-time quotation and access to trading. The deliberate consumer makes conscious, rationale choices on what services he or she needs and how much to pay—and how to take the money from their pockets.
- *Enterprise Consumers:* This class has received remarkably little attention in the trade press regarding their impact on 2.5G and 3G networks, perhaps because it's far less glamorous. But it's far more lucrative. An enterprise consumer is an individual that uses mobile services but has no personal connection to the payment process, although they may be aware of the costs. Examples here are employees using mobile services under a company account for voice, access to enterprise information (either via a mobile portal or the Internet), and specialized information services. An enterprise customer can also be a deliberate, or even convenience, customer. For example, getting road directions while on a sales call. Personal use outside of business is almost a given and would be hard to prevent, and thus the implications are many.

Consumer Payment Model: Money Makes the Map

We now come to the exercise of mapping the consumers onto payment models. Note that we have not mentioned the type of network used—2.5G, 3G, i-Mode, wireless local-area network (WLAN). The underlying network infrastructure is, at this point, almost irrelevant. The driving choices here are as follows: Is the consumer aware of the cost of the services, and, if so, what are their likely choices for settling their bills? And, given those choices, which ones are likely to dominate? Given these choices, the implications for the BSSs within the carriers are starting to take shape.

Likely Choices

Figure 1 shows a projected range of payment models. Note that we have not assigned any particular customer segment to the choices. The figure is presented in the form of a decision tree, with the branches determined by what choices the customer would have to make. The endpoints of each branch are the possible payment models. Each model has certain implications for the carrier BSS, and some overlap as indicated.

The payment choices defined in *Figure 1* are somewhat arbitrary for the sake of simplicity. While it is ultimately true that each and every transaction must find its way to the end of a decision tree, we'll stick to the most obvious choices.

- Enterprise charging is a direct billing of services from a carrier to an enterprise, which in turn allows members to use the carrier's services under some type of contractual, negotiated term. An enterprise can be a company, a nonprofit, a government entity, etc.
- The Inclusive/Package payment branch is similar to existing "bucket" plans in which consumers can buy voice minutes. In this case, perhaps a bucket of voice minutes comes with 200 SMS messages and five ring tones a month. Anything over that goes down the next path.
- The Carrier Billed/IN Wallet path is for transaction payment where the carrier's own systems handle the financial settlements, either by adding a line item to a recurring bill for a subscription or by decrementing a store of value within the carrier's network. Prepaid services fall into this category if the prepaid services can be charged at a discretionary level by the consumer specifically for transactions, not just voice.
- If the carrier has arranged with a third-party clearing or financial-settlement house to charge consumers for the services via an external mechanism, typically a credit card in the United States or bank debit in Europe, then the transaction takes the next branch. Here, we differentiate between a third-party system in which each and every transaction is billed and one in which charges are aggregated then billed to the external payment system at some period (every month) or at some value (every $25).

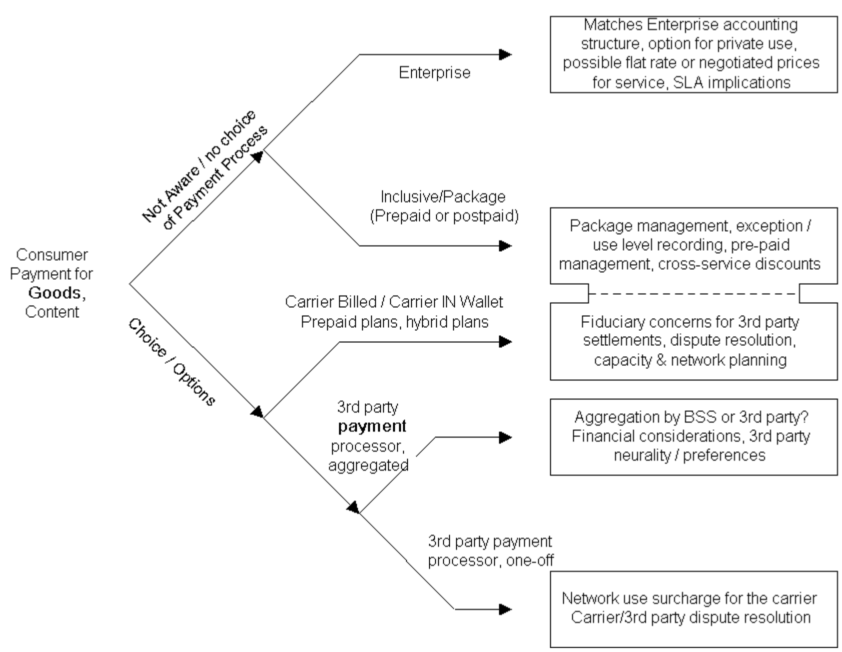
Figure 1 can be read as follows, reading left to right, top to bottom.

- *Branch #1:* If a consumer is not aware of the payment/settlement for the services, then either those services are included as part of a package (e.g., 100 free SMS a month, hard limited; access to a carrier's location service is part of a premium package) or the consumer is an enterprise customer, and the bill is settled by their employer.
- *Branch #2:* Here the consumer does have a choice. The two fundamental choices are 1) to have the carrier do the billing via a subscription (charges appear on the monthly bill) or via some type of stored value in the network (this would apply also to prepaid), or 2) to have a third-party payment system.
- *Branch #2, Sub-Branch.* If a third party is involved, they may be either for single, one-off transactions of presumably higher value or may be an aggregator that collects a number of smaller monetary charges and then takes payment from the consumer at some future time based on a commercial scheme (monthly or when the collected charges hit a set amount.).

The key point for *Figure 1* is simple: *Every consumer/customer for a carrier will follow a decision tree of similar format.* The decision points will be determined by their personal preferences and may change over time. Also, the flow down the decision tree may be different for different individual transactions. For example, a subscriber may have text SMS subscribed but pays via a consolidated third-party for stock quotes. However, it's likely that a given segment will show a strong affinity for certain choices. *Therefore, the implications on BSSs can be driven from consumer-segment behavior.*

FIGURE 1

Payment Models for the Consumer



The implications on the carrier's BSS are shown in the boxes on the right in *Figure 1*. These are hardly inclusive, and each box could be deconstructed in a complete analysis far beyond the limits of this paper. The concept, however, remains. The cash flows from each endpoint are distributed amongst multiple entities. The sum of the cash flows for the carrier are what will drive the carrier's revenue for content and services and thus are the only source of amortization for the infrastructure investments.

Limitations and Boundaries

Implicit in the model is that some limits will exist on consumer behavior. These limits can be soft, in the sense that consumer behavior for wireless services will match that for any other discretionary purchase. Other limits maybe hard, in the sense that a carrier may choose to set financial or monetary restrictions based on its own business models.

An example of some of these limits are (in no particular order) as follows:

- A carrier may choose to limit the amount of external services (e.g., directions, stock quotes, ring tones) from external suppliers to no more that $XX per month if those services are to be direct billed.
- External content providers that are paid using a subscriber's credit card may not accept transactions lower than a certain amount, demanding that the network or a third-party consolidation of disparate charges take place.
- Carriers may offer a stored value service ("wallet") but, for fiduciary or risk reasons, may limit the amount that may be deposited.
- Taxation for out-of-jurisdiction transactions may force certain events to a given payment model.
- Individuals will choose logically to set their own choices. This is shown in the next section.

There are many other factors. These may make the decision tree more complex, but in the end, all consumers must travel down one route or the other.

Mapping Models to Use

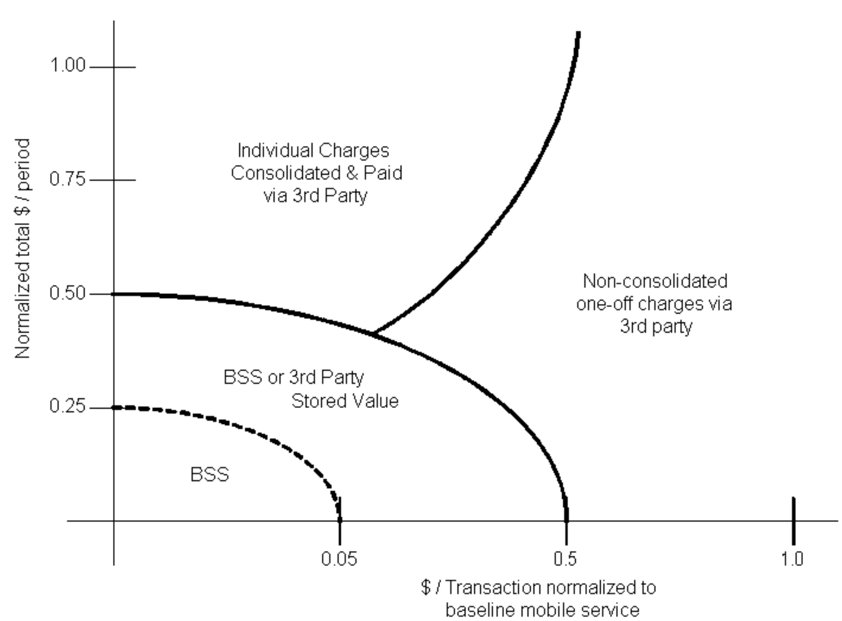
Figure 2 is an attempt to map the various simplistic models in *Figure 1* onto revenue. It's difficult to predict the amount of money associated with these future services. Instead, we have used a normalization process.

The horizontal axis in *Figure 2* relates the value of each individual transaction to the basic wireless service charge. The rationale is that the consumer will treat an incidental or casual use of a service differently depending upon its relative size to their actual recurring or baseline charge. For example, a fifty-cent ring tone bought once in a great while is readily accepted to be billed on their U.S.$50.00 monthly subscription under "miscellaneous" (normalized value = 0.01), while the booking a payment of a U.S.$75.00 train ticket (normalized value = 1.5) is something else. The normalization takes into account that high-value customers (say, U.S.$500.00 a month) would have a different view than the youth customer trying to keep things at less than U.S.$40.00 a month because that is all his father allows.

The vertical axis in *Figure 2* is again normalized, this time taking the ratio of the total monthly consumption of mobile-commerce services, whatever the payment method, to the baseline subscription. A ratio of 1.0 indicates that the total amount of discretionary content and services is equal to the baseline subscription charge. The period can be the billing period (for post-paid) or the consumer's own budget period

FIGURE 2

Payment Models As a Function of Monetary Value Related to Wireless Service Value



for prepaid, however informal. The rationale is parallel to the first. Namely, a customer that has mobile commerce transactions, however many, that are still a small part of the bill will prefer certain payment methods to another with the same set of transactions but instead are very significant compared to the "normal" bill. We have arbitrarily taken some breakpoints at 25 percent and 50 percent for illustrative purposes.

Figure 2 presumes that there are certain boundaries to types of payment models.

- "BSS" refers to the routine billing or charging of things within the core BSS of the carrier, post-paid or prepaid. The boundaries are dotted, as this area is probably the least defined.
- As the discretionary use of mobile-commerce services increases, the carrier may choose to enforce a wallet or stored value to control post-paid risk and for handling prepaid subscribers who may wish to segregate payment for discretionary purchases from basic communications. The intercept points on the axis are highly debatable, but the basic shape is probably similar—the implication is that the internal BSSs of the carrier will be handling only a subset of all possible transactions. The carriers are also keenly aware that there are fiduciary implications for them as the amount of stored value increases. For nationwide carriers, even a few tens of dollars in millions of accounts represents a significant figure. Also, they must take care how those funds are used and stay away from any services that begin to look like banking (such as transfer of funds to another person or entity independent of a purchase transaction).
- Outside the area of the BSSs, we see two distinct areas. One, in the upper portion, bounded by the y-axis, is the area where third parties consolidate multiple smaller transactions into reasonable units. There may be many such providers, servicing different segments or different services—ring-tone portals, travel sites, telematic services, etc. The other area is where there is a significant monetary purchase that is conducted over the wireless infrastructure but has a single discrete payment and settlement process. The obvious is an e-commerce purchase over the Internet that just happens to use a wireless connection: buying an airline ticket, a book, a CD, etc.

Payment Models and Customer Segments

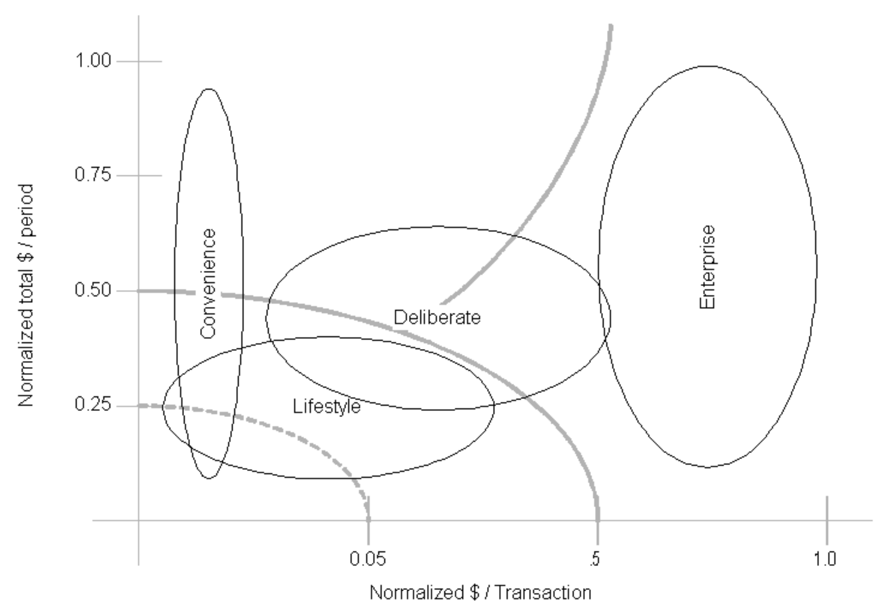
The last step is to map the customer segments discussed earlier onto the payment map. This is shown in *Figure 3*. It is obviously very much a subjective process, given that little data is available and that what is known is a carefully guarded secret of the carriers.

There are two key points in *Figure 3*. First, each consumer segment must fall into at least one area of the payment space. Thus, the total customer base can be mapped onto one or more payment mechanisms, and this mapping is determined by consumer behavior. Second, the relative value to the carrier will be determined by the marginal revenue obtained from each customer as well as the marginal cost to produce that revenue.

The second point is an interesting one to consider. A model which attempts to push the boundaries of the BSS outwards, on the theory that the more revenue captured the better, runs up against consumer behavior as well as the increasing cost to produce that revenue. Expansion of a carriers' BSS to encompass aggregation and collection may

FIGURE 3

Consumer Segments Mapped on Payment Models



be best left to those who are best at doing such things. The key is how much of that segment is left in the BSS and what falls elsewhere.

Conclusions: Implications for BSS in Carriers

The impact on the carrier's BSSs can only be covered at a very high level, given the level of detail in this paper. *Figure 1* presented a very concise set, which may be readily expanded from the basic ideas presented. Clearly, a payment method involving an enterprise customer must match the internal accounting structure of the customer. An intelligent network (IN) wallet of stored value within the carrier network creates a fiduciary responsibility on the carrier to properly manage and secure that value. Use of a third party is essentially an outsourcing operation with some of the characteristics of factoring. It has no direct counterpart to the retail environment, where every transaction stands alone, but it is also not a subscription relationship between the consumer and the carrier, either.

The primary difference in this analysis versus many in the media is that it has attempted to link customer segments to operations support system (OSS)/BSS implications and, in doing so, provides a rough model on how such an analysis could be undertaken with more rigor. Certainly it is not the only model and may, indeed, be only a means to provide a reality-check on other planning and business models.

Fundamental aspects relating to BSSs relate to consumer behavior, in particular behavior that relates to a changing view of mobile services. For the lifestyle consumer, mobile services are a locus of communications and exciting, different ways to interact socially. For the deliberate consumer, services become an enabling part of their professional lives. For the enterprise consumer, it becomes one more tool on the job.

Individuals charged with BSS and OSS planning have to consider the needs of multiple "customers" for their complex systems: the external customer (the one who pays the bills!), of course, but also internal customers (network planning, marketing, finance, sales) and partners (content providers, third-party payment houses).

The planners will have to wrestle with questions such as the following:

- *Granularity versus Cost:* At what point must an individual charge be maintained within the BSS? Example: A what point does internal aggregation of cheap services become mandated? Does the BSS have to track millions of transactions a month if they are worth only pennies each?
- *Customer-Relationship Management (CRM) Implications:* If a convenience consumer buys a movie ticket on their cell bill and later wants a refund, how is the settlement made?
- *Fiduciary:* If an IN wallet for payment of external partners resides in the network, what is the liability for record keeping/audit of the use of those funds? How much overhead does the accounting function take relative to the income gained?
- *Neutrality:* Will there be regulatory restrictions on the use of "in-house" aggregators by the carriers if doing so places third-party clearing companies at a disadvantage? For example, where the net effect is to favor the carrier's preferred suppliers who can clear payments via the in-house system while other content providers must pay a third-party handling fee. This may not be a concern for the lifestyle consumer, but you can be sure that the deliberate consumer will have something to say about it. The customer segmentation allows for a better handle on the pros and cons of each choice.

Predictions

Always a risky proposition, but we believe certain trends are taking shape that are consistent with our viewpoint.

Prediction #1: Big billing systems will stay, but will not longer be the only systems that touch the money. The carrier's BSSs and OSSs will have to migrate away from a single, monolithic system to a "best-of-breed" approach. The primary reason is simple flexibility—no one knows for certain what revenue model and consumer model will dominate. We suggest looking outside the telecommunications industry to world-class consumer-oriented providers, where best-of-breed CRM, enterprise resource planning (ERP), and financial systems are the dominant players.

Likewise, the process of aggregation, as discussed earlier, could be done by the billing system or by an external third party. Carriers must choose internal complexity over control.

Prediction #2: There's room for more players and for innovation in payment systems. There is a role for external third-party payment and settlement processors now and in the future. If for no other reason, carriers want to be carriers and not financial clearinghouses. They cannot match the sophistication of the credit-card networks nor do they have the capital reserves and transactional integrity of the banking system. Nevertheless, the interaction between the external parties and the carriers will have to be through the BSSs. We predict a tighter integration of BSS functions and external third-party payment systems. The ones that do the best job will see lower costs of implementation and a cost advantage in the marketplace. In a marketplace with multiple carriers and a vast array of services and content, this price/convenience advantage could be critical.

Prediction #3: Content will stay content. We present in the Appendix a very simple flow model for content. Over time, the economies of scale and the need to reach the particular segments of the mobile consumer market will re-establish some (if not all) of the distribution (middleman) elements shown. Content, in the widest sense, will migrate to a business model with the least amount of economic friction between the consumer and the source. While seemingly complex and inefficient, we posit that in fact the marketplace has shown them to be highly efficient; after all, in a capitalistic open economy, inefficiencies in distribution are a fruitful area for innovation. Therefore, whatever the model, the producers of content will be disconnected from the underlying carrier infrastructure and its BSS/OSS if they are not there already.

The entire area of the impact of next-generation mobile commerce on the carrier's infrastructure is extraordinarily complex, with enormous ramifications for the ultimate profitability of the carriers. Certainly they will survive, but at what level of profitability is unknown. Consumer behavior, and the understanding of it, is the place to start.

Appendix: A Content-Delivery Model

Figure A-1 represents an idealized picture of how content flows from talent to consumer. It's simplistic in that it may show functions that are not always present, nor does it take into account new business models unique to the Internet and mobile commerce.

Nevertheless, this model has existed in one way or the other for hundreds of years and survives because each element of the chain provides some type of defensible value or has been mandated by regulation/law.

Where new business models allow that value to be moved up (or down) the value chain, or bypasses regulatory-defined structures, that function can and does go away. In the special case of legal or governmental involvement, some business models may be restricted or declared illegal (e.g., Napster).

The model in *Figure A-1* can be read from left to right. Each content piece (in the leftmost box) relates to the downstream (toward the consumer) piece by reading across at the same level. Hence, it's Movies – Artist – Studio – etc. (with apologies to the independent film industry).

The diagram can be used to determine where the value chain relating to the delivery of mobile content becomes specific to the mobile environment or access network for the end consumer. For example, a ring tone may not be mobile specific until it is bundled by a media company. Granted, a ring tone is useless unless it's in a mobile handset, but as a item, it's just bits until it is on the market and offered to consumers.

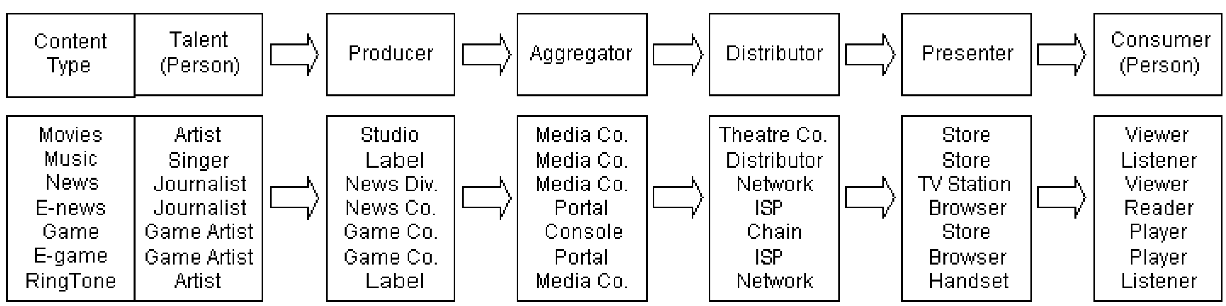
Content Value Chain



The UMTS Marathon: Maneuvers for the Long Haul

Patrick Tao
Vice President, Marketing
Tesaria, Inc.

The Global System for Mobile Communications (GSM), general packet radio service (GPRS), and Universal Mobile Telecommunications System (UMTS) equipment industry has changed. For brevity, I will use the term GSM equipment to mean equipment in the GSM, GPRS, and UMTS family. Where once an expanding market made room for many competitors to grow their business and sustain a break neck pace of research and development (R&D) investment in new products and new technologies, the economic downturn of 2001 and the contracting GSM equipment market is forcing all competitors to put spending under a microscope. This lesson is not limited to the GSM equipment market but applies to all telecom equipment markets. I will focus on the GSM equipment market to illustrate my thoughts.

The late 1990s were good years for the wireless equipment business. The industry grew 20 percent to 25 percent each year, with equipment revenues peaking in 2000 at roughly $56 billion. Long-range forecasts for the wireless equipment market still call for substantial growth once the economy recovers and wireless operators begin to invest in network expansion again. The picture in the next year or so is not so rosy.

GSM operators around the world have announced year-over-year reduction in capital expenditure (CAPEX) plans. From these announcements, many analysts have concluded that revenues in 2002 for GSM equipment suppliers will be flat or down by as much as 10 percent from revenues in 2001. In response, major GSM equipment suppliers (original equipment manufacturers [OEMs]) have been forced to shed product lines and cut staff to get their financial house in order.

The race between OEMs to bring new products to market has become a marathon where once it was an all out sprint to the finish line. Companies with the financial endurance to last through the downturn and into the eventual third-generation (3G) networks build-out will be the ultimate winners. Companies can no longer speculate on technology roulette. R&D budgets are being trimmed to support only those projects with solid, tangible, near-term, financial business cases.

Many observers expect a rationalization of the GSM equipment industry and the larger wireless equipment industry to which it belongs. The assumption is that at the end of this transition period, there will be fewer competitors for the GSM equipment market than today.

In this paper, I propose another business model to achieve a rational industry structure. The system specialist model is one that consolidates the horizontal supply chain so that current OEM suppliers can achieve the economies of scale necessary to compete; the industry achieves greater efficiency in the use of engineering and technical resources; and the industry sustains the product and service innovation needed to spur overall industry growth.

Wasted Product Development

The GSM equipment development business has been wasteful and inefficient. Each GSM equipment supplier today devotes hundreds of people and many millions of dollars to the development of GPRS and UMTS equipment. Most of these people are working on products with capabilities defined by the industry's standards. There are literally thousands of pages of standards specifications that have been produced during the past few years defining the functionality that every GSM equipment supplier must provide just to achieve the basic operation of the system. This mountain of technology specifications continues to grow faster than the ability of GSM equipment suppliers to actually implement those specifications.

In a thriving market, the duplicated efforts between these companies are buried under the overall positive results and are seldom questioned or dealt with. To stay competitive in a declining market, companies cannot afford this duplication. If the competitors in the GSM market had comparable revenue streams, the inefficiencies would affect all competitors evenly, but, in fact, the competitors in this market have widely different market-share and revenues. This gives the largest competitors a distinct cash-flow advantage for outspending and outlasting their smaller competitors.

Today, OEM companies are focused on cleaning up their balance sheets and generating immediate, positive cash flow. Gone are the days of long-term, "strategic" investments in products. The industry has returned to R&D spending guidelines such as "each product must be capable of generating revenues 10 times the development cost" and "at least $1 million in revenue per employee." Under these operating constraints, if broad competition among OEM companies is to remain, the smaller competitors must find new, cost-efficient ways to deliver products.

When we look at other industries with many sustaining competitors, we find examples of supply chains where product suppliers source their common technologies from companies that specialize in those technologies. In the GSM equipment supply chain, many companies have established successful businesses supplying technology components in this manner to the OEM suppliers; but we must go further.

Hardware platform suppliers have emerged in the last few years as the OEMs realized that they could use volume manufactured hardware to save time and money. There are now many choices of hardware suppliers for systems based on compact peripheral component interconnect (PCI) technology. On the software side, companies such as Wind River, Hughes Software Systems, and Trillium have provided common software protocols and functions to the OEMs that provide savings in software development.

The availability of technology components changed the way in which OEMs develop products. The OEM developer's job has become the integration of hardware and software from the component suppliers and the development of control logic to orchestrate the components into full working systems. These two jobs are where the duplication of effort exists today, and this is where the opportunity to fulfill the role of a system specialist supplier emerges.

When the OEM sources technologies from traditional components suppliers, the onus is on the OEM to develop the control logic for the components, to make the system perform, and to develop value-added functionality that differentiates one OEM's product from another. Unfortunately, with the complexity of network products today, the first two tasks consume so much effort that the task of adding value to the product is the last to get tackled. In the past, there has been, in a technical sense, a close coupling between all of these tasks that made the control-logic and system-performance tasks difficult to separate from the value-added functionality. New software technologies change all that.

Architecture for System Specialist Business Model

Distributed software technologies from the information technology (IT) world have wrestled with the problems of integrating independently developed applications running over diverse hardware and software platforms. Technologies such as interface definition languages (IDLs), code generation, object request brokers (ORBs), Java, extensible markup language (XML), and enterprise application integration (EAI) software frameworks emerged during the last few years to allow software applications to share data, share functionality, and bind stovepipe applications together into integrated business systems.

Companies such as Tesaria have begun to apply the same distributed software technology to the network equipment development world. At Tesaria, we realized that we would achieve greater developer productivity with this software bus architecture but that, more importantly, this software architecture supported the system specialist business model between Tesaria and our OEM partners.

In the system specialist business model, the system specialist produces fully integrated, network equipment compliant with the relevant standards. The OEM may further enhance the product with their own technology, but the product that ships from the system specialist may be used directly in operator networks.

Following the system specialist model, the Tesaria XGSN is a fully implemented GPRS support node (GSN). At the same time, we expose our internal, fine-grained, software-control functionality through our IDL so that our OEM partners can implement value-added functionality that supports their unique customer value proposition.

Let's look at how this works in practice. One of our partners plans to use content-transcoding capability to give end users faster perceived data throughput. The end users will be given individual control over the accelerator algorithms to suit their individual user tastes and preferences. This gives the OEM a key differentiator for their GPRS GSN product.

Tesaria supplies the GSN platform and enables the OEM to use internally developed, proprietary, content-transcoding technology where the OEM has a competitive advantage. By exchanging control messages between the Tesaria GSN core and the OEM's content-transcoding module, the OEM is able to deliver unique differentiation to its customers.

This is not a joint development project. Co-development on a single product-development project has a poor track record, as development teams and company management get in each other's way during the development. Tesaria has total control over the GSN core implementation, and the OEM partner has total control over the content-transcoding implementation. This is made possible by the software bus architecture and the IDL–defined programmatic interfaces between the two software systems.

The OEM controls the priority, timing, and effort involved in delivering their differentiating features. Concerns over sharing proprietary technology and trade secrets disappear because the OEM maintains full control throughout the development process.

How does this benefit the industry? All sectors of the GSM industry gain from this business model. GSM operators benefit from competition between OEMs, as the OEMs vie for operator contracts with product innovation and price incentives. Industry rationalization that results in OEMs exiting the business will leave higher prices and fewer product enhancements.

OEMs realize that if they exit the GSM equipment today, they would be foregoing a lucrative and strategic GSM equipment business that awaits them beyond the next year or so. Working with system specialist suppliers to manage their finances during this slowdown in network spending preserves their customer base and market position for a day when growth returns to this sector.

The system specialist business model sustains a competitive industry structure even as the OEMs share common overhead costs over a broader revenue base. Eliminating the wasted development of GSM standards-defined functionality allows the OEM suppliers to concentrate on creating value-added capabilities. The capabilities will give more services for GSM operators to sell to their customers and more reasons for the customers to subscribe to next-generation services.

Winning the Marathon

Competitors who know how to last the entire race win marathons. They know when to conserve energy, when to make a break for the finish line, and when to make strategy adjustments. The GSM equipment industry is clearly in transition. No one knows what the landscape will look like in three years' time, but it is safe to say that the industry will be more efficient than it is today. As the major equipment suppliers focus on their core business and find ways to cut R&D spending without losing competitive position, system specialist suppliers provide a means for the OEM suppliers to focus on product differentiation and to manage their bottom lines back to health.

Wireless Generations: Past and Future

Andrew J. Viterbi
President
The Viterbi Group LLC

The Standard Nomenclature and Its Misleading Implications

It has become commonplace to categorize advancements in wireless technologies by a generational label. Thus, the first analog phones of the early 1980s, constrained to a bandwidth of 30 kilohertz (kHz) or less, are designated as first-generation (1G). The actual breakthrough, though, was not in the means of transmission, which were simply the evolution of decades of frequency modulation (FM) technology, but in the cellular concept that, by assigning multiple base stations to the population of users, increases system capacity many-fold while reducing power requirements for the user terminals. Digital handsets, designed primarily for voice and standardized in the late 1980s and early 1990s, are called second-generation (2G). Lastly, advanced digital terminals, designed for both data and voice and standardized in the late 1990s, are designated third-generation (3G).

These simple distinctions may appear perfectly logical on the surface, but they do not reflect the marked difference between the two categories of 2G technologies: those based on relatively narrowband time division multiple access (TDMA) and those based on wideband spread spectrum or code division multiple access (CDMA). Even within the TDMA category, there are three varieties: on the one hand, digital advanced mobile phones system (D–AMPS) and personal digital communication (PDC), which preserve the bandwidth of analog technologies, and, on the other hand, Global System for Mobile Communications (GSM), which occupies a wider bandwidth and time-shares among a larger number of users. The relative success of the three TDMA varieties has been drastically different. While the more narrowband versions have reached their limits at only tens of millions of users and will gradually begin to be phased out, as has already largely happened with analog phones, GSM has proceeded to gain hundreds of millions of users, representing more than 80 percent of the total market. The latter's success was partly the result of early entry, though it owes more to European industrial policy, which froze out competitors but, by enabling universal roaming throughout the European Union, proved so desirable that it was extended to many other parts of the world. CDMA is a distant second among 2G technologies, with about 70 million users, mostly in North America, northern Asia, and parts of Latin America.

Yet the many demonstrated advantages of CDMA have become so widely recognized that it is the overwhelming choice for 3G, which is projected to handle equally both voice and data, the latter at speeds in the hundreds of kilobits per second (kbps) and, in some instances, as high as 2 megabits per second (Mbps). Even here, however, two rival approaches have been standardized—one championed by the current CDMA service providers and manufacturers, and the other by current TDMA entities. The former is called CDMA2000, while the latter is referred to as wideband CDMA (WCDMA), among several other designators for both. The differences between the two 3G CDMA standards are relatively minor, mostly small discrepancies in parameter choices, with one exception: the issue of whether or not to synchronize base stations or let them operate asynchronously. In the latter case, as proposed in the WCDMA standard, terminals must be resynchronized to the most recently encountered base station. The principal argument raised for asynchronous base-station operation is to avoid the current dependence on global positioning systems (GPSs) for synchronization. This seems strange for two reasons: first GPSs are not the only means to achieve this; other approaches to network synchronization have been successfully demonstrated. More importantly, a predominance of handsets, at least in North America, may soon incorporate GPS chips for emergency location purposes, making the issue of incorporating GPSs in the far smaller number of base sations of minor significance.

But the considerable difference between the two approaches to 3G lies not in the aforementioned details, but rather in the approach to the transition—designated as "2.5G technology." For the systems that currently employ 2G CDMA, the nomenclature is fitting as a way to describe the evolution from current low-speed data capabilities to the much higher rates anticipated by 3G applications. The required improvements are implemented mostly at baseband in signal processing chips, with virtually no changes in radio frequency (RF) front ends or antennas. They include more efficient modulation and demodulation of the current (direct sequence) spread-spectrum waveform, improved power-control techniques, and advanced error-correction codes suited to the less stringent delay restrictions of data. These are evolutionary modifications, which over time will lead to the full capabilities of 3G without major base-station refurbishment and with complete backward compatibility with 2G and 2.5G CDMA handsets. On the other hand, what is being referred to as the 2.5G transition for GSM (and possibly other TDMA formats) is really only an extension of GSM to handle higher data speeds. Known as general packet radio service (GPRS), it provides for multi-time-slot transmission of data, thus nominally reaching 64 kbps speeds, a minor milestone on the way to 3G requirements. More important, in no way does this represent a step toward implementing any form of CDMA. The goal of the GSM–standard group to implement WCDMA will require a complete refurbishment (or new construction) of base stations, at far greater cost and delayed time to market. Hence, the wide divergence in 2.5G approaches and the misleading implications of the term when applied to GSM.

Future Technologies

What newer technologies can we expect after the currently occurring transition to 3G is completed? The several candidates that present themselves all capitalize on one or both of the two primary characteristics of spread-spectrum technologies:

1. Universal wideband occupancy in each cell by many users, with advantages through frequency diversity, multipath resolution, and combining and interference management
2. Tight signal parameter control by exploiting the bidirectional nature of the communication channel and thus adapting both signal modulation and demodulation to the instantaneous channel conditions
3. Not mutually exclusive, multiple access technologies are potential contenders for what is already being called fourth generation (4G). These are as follows, in order of decreasing likelihood:
   - i. Multiple-input/multiple-output processing antennas, also described as spatial processing, space-time coding and "smart" antennas. It has for some time been recognized that spatial processing of multi-element antennas provides an added dimension for improvement beyond what is achieved by temporal processing. Some rudimentary forms of antenna-element processing are already present in some current generations. Rapid and accurate channel measurements achieved through spread-spectrum and bidirectional signaling, as mentioned, will benefit spatial as much as it does temporal processing.
   - ii. Orthogonal frequency division multiplexing and multiple access—a modified spread-spectrum approach that may provide for simplified processing and more rapid adaptation to channel conditions. In the forward direction (multiplexing), it substitutes orthogonal sinewaves for the Walsh functions of CDMA. In the reverse direction (multiple access), it has characteristics of both frequency division multiple access (FDMA) and spread spectrum.
   - iii. Ultra wideband (UWB) radios, which by transmitting subnanosecond pulses, somewhat randomized, effectively spread the spectrum over a bandwidth exceeding 1 Gigahertz (GHz). Because regulatory authorities do not award such wide swaths of bandwidth to any carrier or user, UWB proponents request that, due to the extremely low spectral density of such signals, they be allowed to coexist with present occupants, thus effectively rendering much of the presently allocated spectrum unlicensed—at least for UWB implementers. While the federal Communications Commission's (FCC's) action to initiate an inquiry on UWB technologies has represented a breakaway from existing mindsets, the outcome and wide adoption remains questionable. Also to be demonstrated are cost-effective terminal implementations. While time and major advances in enabling technologies may well overcome the physical uncertainties, the departure from established practice remains the greater hurdle.

Though measurable activity is occurring in each of the aforementioned, the types of compelling market needs and driving forces as had previously induced the overwhelming acceptance of 1G and 2G technologies have not yet appeared .

Section VI:

Operations and Quality Control

Centralized Network-Performance Monitoring

Gary Barton

Senior Market Manager, Mobile, Global Market Management

Agilent Technologies

Introduction

Providers can view performance monitoring in two ways: from the drive-test side and from the network side. This paper provides an overview of performance management from the network side.

First, it will explore why performance management is needed. Once the need for this is clearly established, issues of what performance management involves can be discussed. The two major monitoring techniques, real-time thresholding and historical reporting, will be introduced; and wireline, wireless, and Internet protocol (IP) performance metrics will be considered briefly. Finally, given that performance management is important for quality of service (QoS), and given the techniques, performance metrics, and architectures available for monitoring the network, this paper will look at how performance management can be implemented and integrated with the rest of the network-management tools.

The Need for Performance Management

Questions to Help Guide Providers

Service providers do not necessarily always know that they need performance management. What they more generally know is that they simply have certain problems that they need to address. Providers, then, face a number of questions, including the following:

- What is the perceived quality of the network?
- Is the network keeping pace with growth?
- Where should investment occur, and how much should be invested?
- How can more revenue be generated with the existing system?
- How can operating costs be reduced?
- How can a problem be identified as a simple abnormality or an indicator of something more serious?
- How can churn be reduced?
- How can future capital expenditures be predicted?
- How can system usage information be used to improve marketing and sales?

Along with these issues, recently introduced legislation has raised another concern. This legislation would require the Federal Communications Commission (FCC) to publish information on the number of complaints against a telecommunications provider and the nature of the problems. Under this legislation, the FCC would be charged with identifying responsible carriers. Thus, with the FCC reporting the number of complaints received about telecommunications networks, providers will also have to ask if they will be the next newspaper headline.

Definition of Performance Management

Performance management can provide the information necessary to answer all these questions. Performance management—defined as the collection, analysis, and presentation of network-performance data for use in evaluating the quality and efficiency of the telecommunications network—basically monitors the health of the overall network. It asks not only if the network is providing high-quality voice service but also if it is using all resources to their highest efficiency.

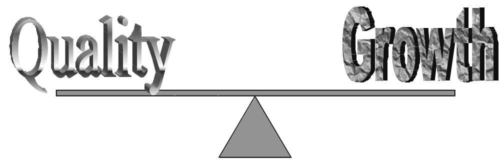
The service provider faces the challenge of striking a complex and delicate balance between quality at one end of the spectrum and growth at the other (see *Figure 1*). Providers will always look to add more subscribers, which, without a corresponding increase in the amount of network equipment, can result in increased utilization and degraded network quality. Adding more equipment will improve the quality of the network by reducing congestion, but overprovisioning a network increases the overall costs of a network. The goal for the provider, then, is to maintain the level of quality required to be competitive in the market without spending too much money in the infrastructure.

The Customer's Perception of the Network

Thus, a customer-centered point of view is critical to carrier success, and performance management provides that customer's perception of the network. Customer perception is especially important in two areas: purchase and retention. Among purchase considerations, price is the foremost in people's minds. Customers invariably will want to know how much they will have to pay for the phone and for service. The second-most important consumer-purchase consideration is coverage—the general geographical coverage area where good reception occurs. Services, such as voice mail,

FIGURE 1

Network Balancing Act



call waiting, and the like, make up the other area of customer concern. Customers are also highly concerned about availability—that is, the likelihood of finding a phone in stock at a store and walking out the door with it programmed and ready to use.

Customer-retention considerations add additional concerns to these purchasing considerations. Call quality, which includes voice quality as well as drops and blocks, are the most important for retention. Roaming service and customer service also have an impact upon retention decisions.

When data transmission is considered as well, more concerns emerge. The two major determinants of customer satisfaction in this case are the content of services (does a service provide value to the customer?) and the quality of the service (QoS). Quality of data services is based upon the provider's speed (which is essentially determined by the available bandwidth), jitter, and delay. The provider, for instance, must determine if there is sufficient bandwidth for Internet browsing, or if voice over IP (VoIP) or global positioning system (GPS) would experience too much delay and jitter within the system for customer satisfaction.

Figure 2 shows the results of a J.D. Powers survey concerning customer satisfaction. The survey found that after the consumer has purchased a phone and arranged for service, the most important factor for customer satisfaction becomes call quality. In this light, it should be noted that voice quality is only one piece of the overall call-quality perception; drops, blocks, and other call problems are the other parts that compose this perception.

Performance management, which can focus on these quality issues, then, has clear value in promoting favorable customer perception.

Components of Performance Management

Performance management is composed of two basic elements: real-time thresholding and historical reporting. A third area involves controls—the call gaps, filtering, and the like that manage the calls coming in once a problem is identified to manage overload in the network.

The first activity of a performance-management system is collection: each wireless network region involves gigabytes of data, making collection a nightmare. Storage is the next activity: once the data is collected, it must be stored in a database as quickly as possible. Next, the data must be managed: this process involves summarizing, as it would be impossible to query against just the raw data—there is simply too much of it. The data must then be analyzed to provide some meaning to the raw information collected. Finally, it must be presented in a format that is usable: reports (such as spreadsheets), graphs, or geographical displays. Many different kinds of users need to see the data collected in different ways, and the system must be able to supply what they need.

Real-Time Thresholding

Real-time thresholding is a technique for analyzing and presenting the data available from performance-management systems. *Figure 3* shows a scalable architecture for the real-time thresholding component. It involves multiple collection gateways that can serve the huge amount of data coming into the system. As the data is collected, the system applies a threshold to determine which data will be stored for analysis and which data will be discarded. In this way, data needed for specific purposes is maintained, whereas data that is not pertinent is discarded to avoid the need to store, summarize, and analyze it.

FIGURE 2

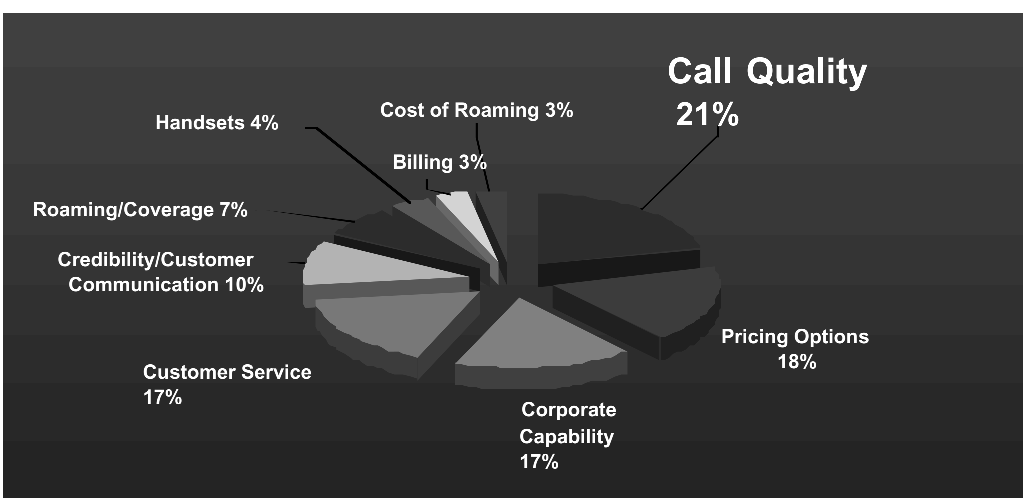


FIGURE 3

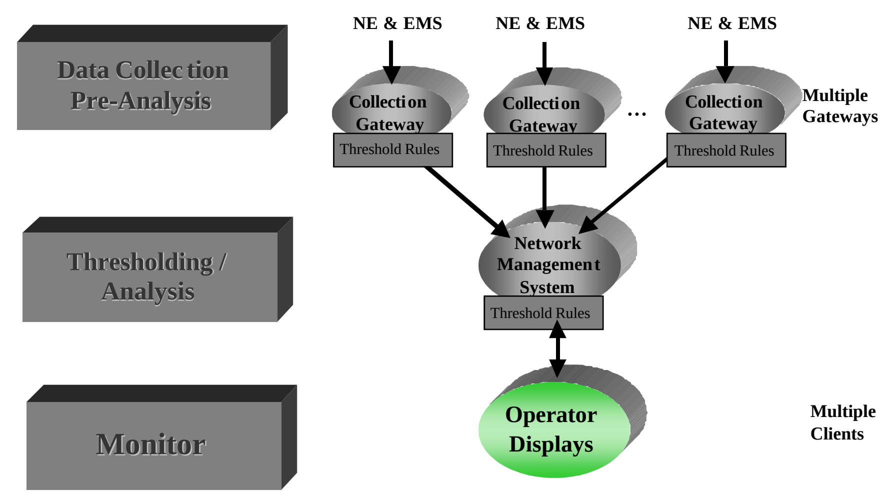
Real-Time Scalable Architecture

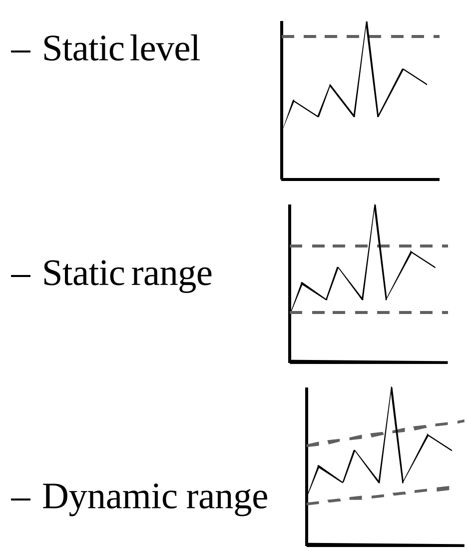


Performance Metrics

There are several ways to set the threshold or performance metrics of the performance-management system (see *Figure 4*). One method is to determine a static level, for example, to tell the system to issue an alert if a certain level is exceeded. Filters on the alert displays can then ensure that the proper person sees the alert. A static threshold is established by pre-establishing a specific value that the performance data is compared against. Two static thresholds can be established to form a range in which the data should stay within. Providers can set up groups of cell sites so that any new cell site in the group inherits the thresholding metric.

FIGURE 4

Real-Time Thresholding—Performance Threshold Metrics



The advantage of using a dynamic range, on the other hand, is that the provider does not have to preassign the range that will generate alerts. New cells do not have to be told what their thresholds are; instead they learn them over time.

The performance metrics involve another important network task: normalizing the data. Networks today involve multiple vendors, multiple types of technology, and multiple versions of the same technology. To normalize data over this variety of components, generic metrics with vendor-specific, technology-specific, and version-specific formulas can be utilized. This approach allows the comparison of information from different types of networks (such as analog and code division multiple access [CDMA]) and different versions of the same software.

Historical Reporting

The historical-reporting aspect of performance management determines which data will be maintained for a longer time period. *Figure 5* shows a scalable architecture for this component.

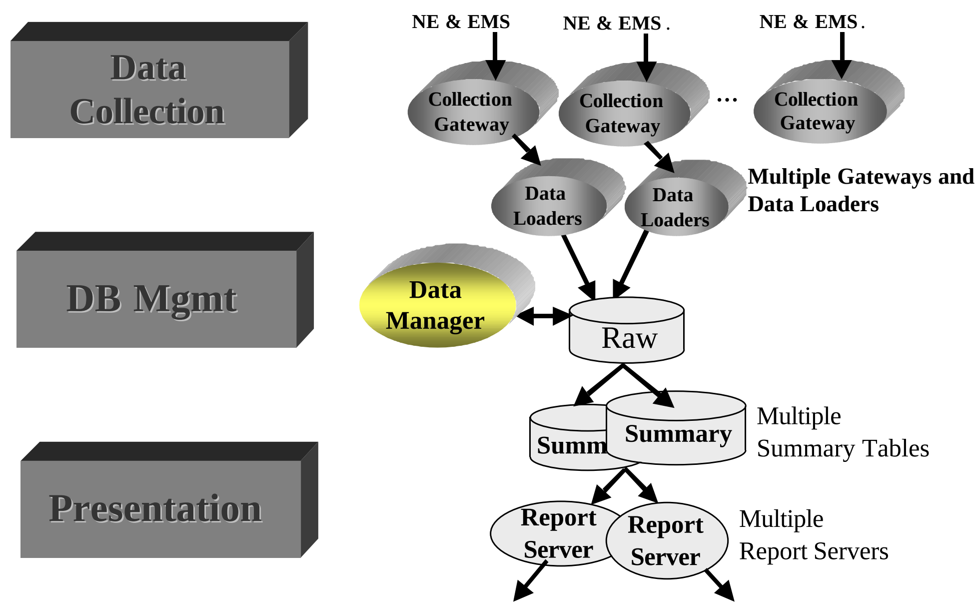
As data is collected through the collection gateways (the average network will have multiple data loaders with multiple databases), it is stored in the database. The data manager reviews the data to determine if any data is missing. If so, data can be interpolated to fill the holes. From the raw data, summary tables are then developed (see *Figure 6*) to save space and decrease query time.

Network sizing is an important consideration at this juncture. The network must have sufficient bandwidth to pull data from far-reaching regions. Alternatively, the data can be collected and summarized at the regional level, then sent to a central collection point. Network sizing usually involves busy-hour considerations.

Historical reporting also is made up of several components (see *Figure 7*). The interactive report definition determines what reports will be issued, then saves the reports so they

FIGURE 5

Historical Scalable Architecture



can be run again and again. Report scheduling specifies when reports will be run. For example, a provider may want to run a report every night to make it available to employees when they arrive at work in the morning. Historical reporting provides information about which reports are supposed to be run and when, and where the reports are stored after they are run. It can also handle interactive queries, ad hoc reports that are not required regularly. Engineers, for instance, may need to compare equipment functions over different time periods. Scheduled reports, on the other hand, automatically generate a spreadsheet or graphical display.

FIGURE 6

Summaries

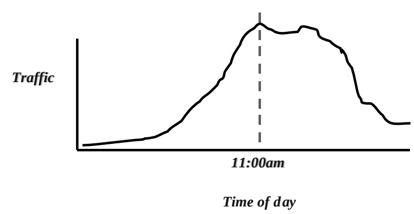
- Used in network sizing
  - Time-consistent busy hour
  - Bouncing busy hour
  - 3-day or 5-day average



Performance-Management Implementation

Networks involve a wide range of users. At the top is the executive who makes decisions for the entire corporation. The executive typically looks for a simple number that can give some indication of how well the network is performing. On the other end are the engineers who are looking for answers to specific questions about the cause of specific problems. The performance-management system, then, must offer a reporting system that provides answers to the types of questions posed by the entire range of users.

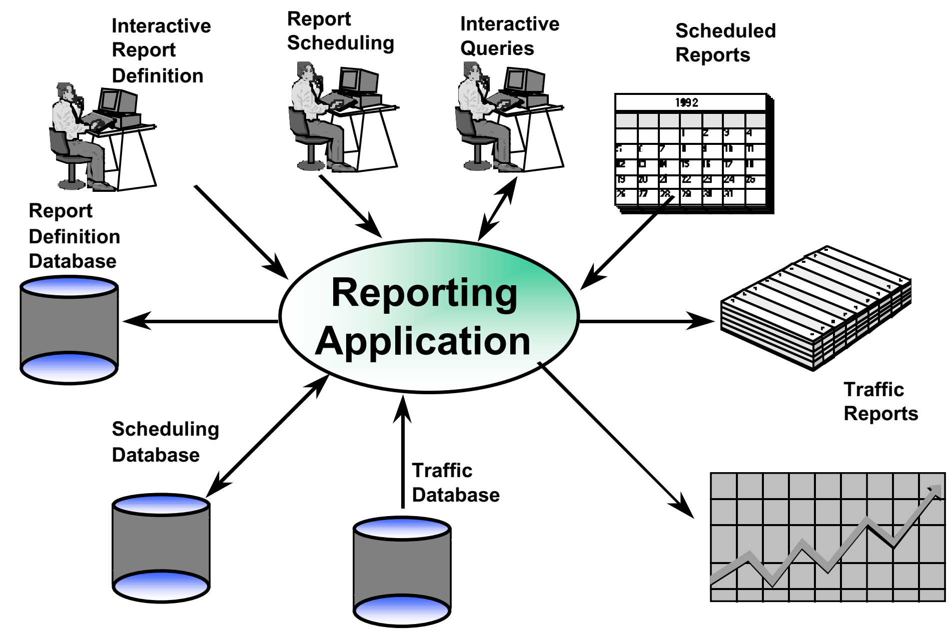
Performance Reporting

The first requirement of such a system is a common reporting tool. The system should not have to build a whole new reporting infrastructure for each different user. The query tool should enable extensive reports, scheduling, and ad hoc queries across the company. Scheduling is another important aspect of the performance-management system, because it is much more efficient to set up the system to generate certain reports regularly than to request them each time. Web-browser access is critical for enabling anyone to access information from the system. Reports must be easy to modify so that information that engineers require to solve problems can be provided. Using a standard query language enables the company to hire people from the outside who can utilize the reporting system immediately.

From the historical reporting side, the system will ideally produce spreadsheets with a higher layer of summary report. This arrangement allows a user to see a problem, click on that area, and get additional information about it. This approach is much easier than having to run a series of reports (which requires an extended time period) to access the information needed. A graphical presentation is easier to use as well.

FIGURE 7

Historical Reporting



Historical reports are important in forecasting, especially for capacity planning. Exhaustion reports, which indicate when the system will run out of capacity, are one type of report used in this area. The other is a utilization report, which forecasts usage at a particular date in the future. This report can be used to plan purchases of equipment. A visualization display, including graphical or geographical (map-based) displays, indicates where failures or critical alerts are occurring and can also be used for fault management or trouble ticketing.

These performance reports are designed to monitor both grade of service and QoS. A grade of service is a predefined value that the network is engineered to: for example, a wireless network typically allows a specified level of blockage or overflow or a specified number of drops. QoS, on the other hand, is more subjective. It represents the customer's perception of service.

Wireless Metrics

Performance-management system metrics must monitor several areas. The most important of these is drops. This is a critical area because customers respond very negatively to being dropped from the network. Another version of a drop is a handover failure from one network to another. A handover failure appears to customers the same as a drop: that is, a customer was on the phone, then the connection was lost. Blocks, a situation in which the customer cannot access the network at all, would be the next most critical type of failure.

Capacity utilization must also be monitored to enable forecasting and equipment utilization. If the provider knows that equipment in one area is underutilized, it can be redeployed to another area where equipment is overutilized. This type of metric can also be used to identify cells that are "sleeping," or not carrying any traffic at all. These cells will not generate alarms, of course, because there is nothing to indicate that something is wrong with them. But when the provider finds no usage, a check may show that some problem has actually occurred, such as an antenna being blown over.

Wireline Metrics

Wireline metrics typically measure physical things, such as trunks and lines. These metrics can discern utilization of capacity. Overflows, or too much usage, may require rerouting traffic. Wireline metrics can also measure the total number of calls going through the network—information that can be very useful for forecasting and planning.

IP Metrics

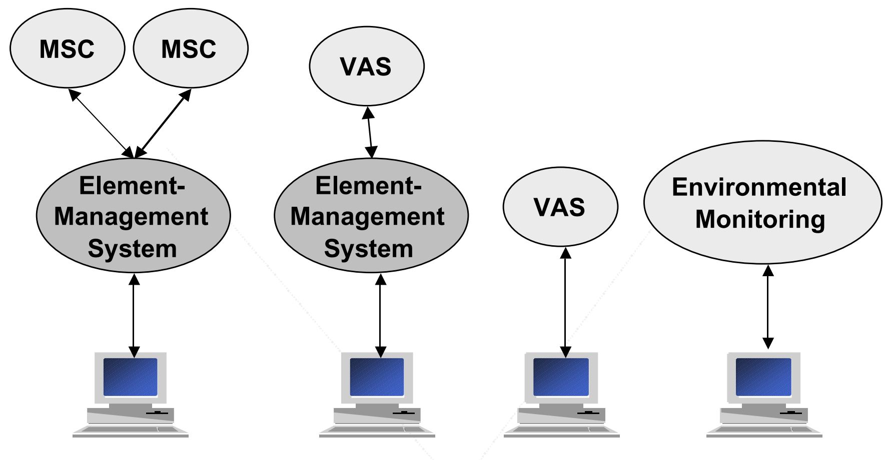
IP metrics can present information about latency, which describes the delay in packets across the network; jitter, which involves packets reaching their destination out of order; and errors and lost packets. Lost packets require retransmissions, which consume additional bandwidth. And someone whose call was dropped will have to redial, thereby using up more network capacity. So savings can occur through performance management in these areas as well.

Centralizing Management

Performance-management metrics can fit into different types of management architectures: fully distributed, where each region is autonomous; fully centralized, where network responsibility is centrally located; or distributed with central monitoring, which has become most common today. Initially, local network management may involve a monitoring system for each of the different elements (see *Figure 8*). These element-monitoring systems feed information to a single network-management system. Alternatively, each different region may have its own local network-management system.

FIGURE 8

Local Network Management



For security purposes, each region should be able to take over for the other regions in case of emergency. A central network-management system that can see all regions and take over management when necessary or when scheduled (for maintenance, for instance) may be the answer (see *Figure 9*).

Central network management, then (see *Figure 10*), looks at overall system performance across the entire network. In addition, it is responsible for identifying serious traffic problems, performing after-hours monitoring, and allocating resources networkwide.

Centralized management has several advantages. It supports a network-management strategy. Once the decision is made to utilize certain tools and maintain a certain level of quality, it implements that strategy across the entire network. Centralized management provides a common view across regions so that comparisons can be made. It allows consistent, standard alarm presentation to correlate activity across regions. A common platform integrated with common components expedites trouble ticketing. Common systems, interfaces, and practices reduce duplicate development.

In addition to offering advantages, however, centralized management also pose some challenges to providers. One such challenge comes when operating across multiple time zones (see *Figure 11*). Certain questions arise with this: What busy hour should be used? What time-stamp location should take precedence? Another challenge to operating across time zones is that equipment and operations are highly distributed: an operator can see equipment on a screen but cannot actually reach it physically. Low-bandwidth communication channels going across country can

FIGURE 9

Local Network Management—Centralized

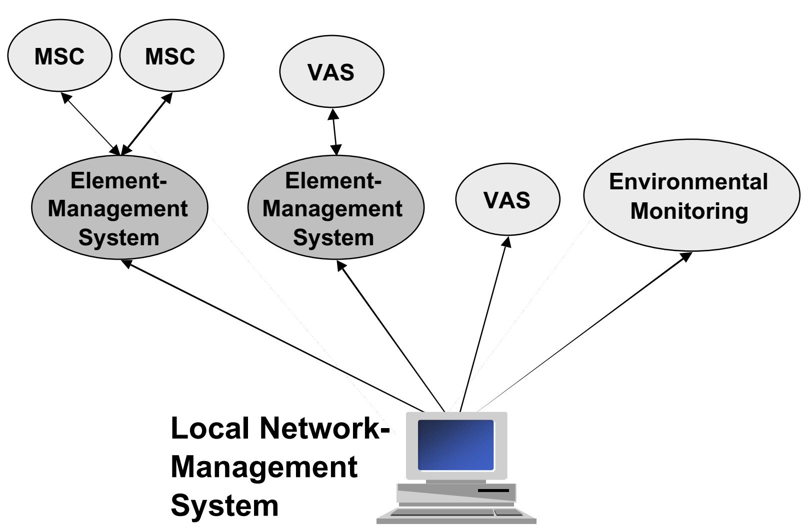


FIGURE 10

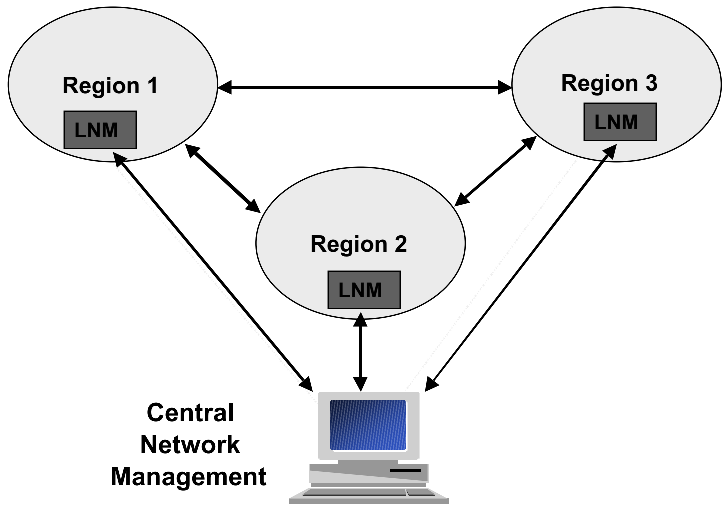
Central Network Management



have an impact on company e-mail and performance data that must be transmitted from one coast to the other. When a national network is centralized, the network provider may find multiple versions of equipment and software as well. Getting everyone using the same version can be a daunting task. Finally, regions often want to maintain control themselves. They do not want "Big Brother" watching over them.

Integrating Performance Management

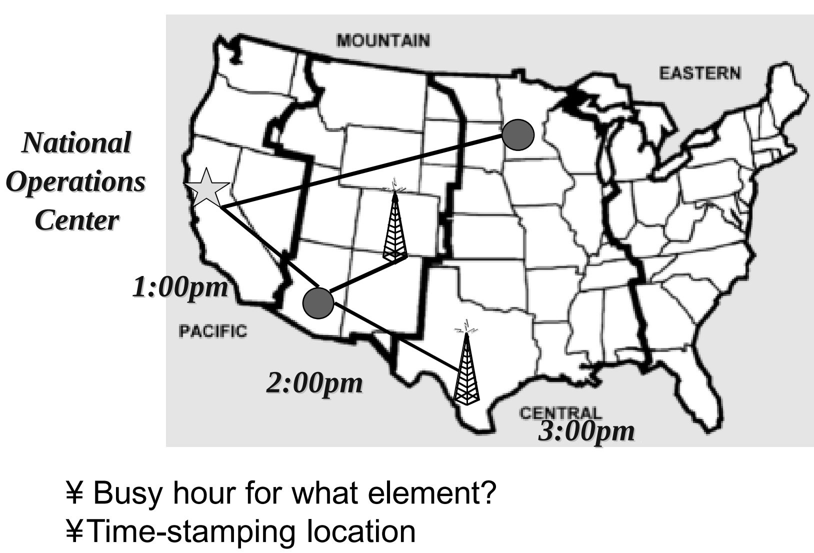
One of the most difficult aspects of any performance-management system may be integrating it into the company culture. Performance management, however, cannot be a stand-alone solution. It affects all the different areas of the organization. Performance management can function as a communication tool across the company, connecting such diverse areas as repair, facilities ordering, and marketing and sales. It can provide information about when repairs are necessary, when more equipment must be added, and where problems exist that cause customer complaints.

Conclusions

Performance management is critical to optimizing a network and reducing costs. It can ensure network health, enhance network utilization, support forecasting, aid in planning, and increase network availability through

FIGURE 11

Operating across Multiple Time Zones



proactive management. Moreover, performance management can provide a view of the customer's experience with the network.

A good performance-management system must be implemented according to individual business needs, however. It must be determined, for instance, whether the business requires centralized monitoring, or if regions can be left to work on their own. Internally, the system must meet specific needs as well. It must consider all the different users and the kind of reports they need to do their jobs effectively. Finally, the performance-management system must be fluidly integrated within the organization: the data such a system provides is very valuable, and it should be available to and used by everyone in the company.

The OSS Architecture Crossroads

Silo-Based OSS Architecture Has Led the Industry up a Blind Alley—a Truly Integrated Approach Is Now Required

Peter Briscoe

Principal Consultant

Cramer Systems

A system that automatically provisions new telecom services is a holy grail for all operators. Faced with increasingly complex networks and a worldwide shortage of skilled provisioning engineers, ever more powerful provisioning software is the only hope that telcos have of cutting service-delivery times and improving network utilization.

Yet this goal may never be realized unless operations support system (OSS) vendors and telcos abandon the piecemeal approach that has characterized the development of their OSS systems. This has led to the so-called stovepipe or silo-architectured OSS suite in near universal use today.

Silo-based architectures have been the quick fixes for each new technology that has come along. The downside for telcos is that their network information has, as a result, been scattered across several applications, saddling them with a fragmented picture of their network resources.

The way forward is to adopt a more centralized OSS architecture, which holds network information in a central repository and makes it available to all OSS applications that can be used to obtain a detailed overview of network infrastructure.

What Is Silo Architecture?

In a stovepipe or silo-architectured OSS suite, provisioning for different technologies is supported by dedicated, standalone applications, and each is optimized for that function alone.

For example, a provisioning engineer might use one application to allocate capacity on a synchronous optical network (SONET)/synchronous digital hierarchy (SDH) high-speed ring and a second application to configure an Internet protocol (IP) or asynchronous transfer mode (ATM) layer in order to set up a new circuit for a customer. Separately, each has access to the telco's order capture software and to the network activation layer.

The OSS architecture typically comprises a series of provisioning stacks connecting the customer order-capture layer with the network—a structure that is suggestive of a grain silo or factory stacks, hence the name. These provisioning applications are generally standalone, but communications between applications can be a serious problem.

How did this situation arise? Until fairly recently, switched voice services accounted for most of the telecom market. The provisioning systems that supported them were developed internally and were tailored to suit each company's process and needs.

However, explosive growth in data traffic in the 1980s, underpinned by a succession of new technologies such as SONET, ATM, transmission control protocol (TCP)/IP, and integrated services digital network (ISDN), was beyond the scope of most in-house OSS teams to support. Instead, telcos turned to external vendors of provisioning software and bought dedicated OSS applications supporting a specific technology.

These systems were bolted onto the telco's existing OSS applications suite without any major reworking of the system, thus minimizing software-development costs. Although they were designed for the job and worked well, there was little integration between the new application modules and the core OSS software. In particular, there was no inherent mechanism to exchange data. This proved to be a major problem.

Changes to the OSS software were often matched by organizational changes. Many telcos set up a new network provisioning team to support each new service. This, in turn, encouraged a fragmented view of the network and stored up trouble for the future.

Consolidation across the telecom sector has, ironically, further exacerbated the OSS problems for some telcos. Takeover of one telco by another often meant that an OSS support team was left with a legacy of two incompatible OSS systems. More often than not, the merged company chose to keep both systems running in parallel rather than migrate network information to one system. This decision usually prevented the telco from realizing the full benefits of consolidation and network rationalization.

The Communications Bus

One fundamental problem with a silo-based architecture is that it presents a fragmented view of the network and fails to take account of the inter-relationship between individual provisioning operations, such as network routing and checking quality of service (QoS) levels when planning a new end-to-end connection. Each activity is generally handled by separate applications. For example, there are usually dedicated silo stacks for provisioning asymmetric DSL (ADSL) connections, IP routers, SONET optical fiber buses, and dense wavelength division multiplexing (DWDM) connections.

In-house OSS support departments have attempted to solve these communications problems by building links between applications. But such was the complexity associated with many point-to-point connections that it soon became clear that a formal method for exchanging distributed information between modules would be needed. The enterprise application interface (EAI), such as TIBCO Software, has offered one attractive solution.

Several companies tried to apply this new EAI technology with the next stovepipe solution to be added to their OSS suite, but it soon became obvious that all the system components would need to be modified. Each would need an EAI communications adapter for the exchange information via a common EAI information bus.

As a result, this proved a far bigger problem to solve than originally envisaged. With no prospect of an immediate financial payback, the idea of adding an EAI information bus across the entire OSS suite was often shelved. Many telcos have since recognized the crucial strategic role played by OSS in network profitability and customer service and are revisiting the case for a major re-engineering of their OSSs.

Toward a Centralized Data Model

In a silo-based OSS architecture, network information is fragmented between applications. To make this information available to other applications, the industry is moving toward the adoption of a complex messaging technology. But a better solution would be to centralize network information in a common database model of the network.

Some equipment vendors and system integrators have adopted technologies such as lightweight directory access protocol (LDAP) and the common information model (CIM) (sponsored by the Object Management Group) to provide a common framework for the sharing of network information. But these central store network models used a broad-based generic description of network components to ensure that all the systems involved with the OSS could use it.

Databases built on this model are complex and difficult to use, so systems integrators developing centralized OSSs have, as a first step, arranged for the network model to be updated periodically by uploading data from the OSS applications on a batch basis.

These centralized data models provide greater visibility of the network and can be used by provisioning engineers to guide their routing decisions. But the network information provided is read-only and does not allow provisioning engineers to interact with the network model in order to allocate network resources. Consequently, it fails to address the main problem with silo-based systems—the lack of end-to-end control over the provisioning process.

This is because the task of allocating network capacity is divided between several provisioning engineers, each of whom is responsible for provisioning a specific network layer or technology (see *Figure 1*). Individual provisioning engineers can only see their network layer and cannot examine the impact of their provisioning requests on other network layers. These requests are passed on to their colleagues to handle. With the addition of each new system stack, the production line just gets longer and the provisioning problem gets bigger.

Case for Network Overview

For a provisioning engineer to do his job well, he should have access to an end-to-end view of the network showing where capacity has been allocated and where there is capacity to spare. To illustrate the problems that can arise, a good example would be the task of adding a new virtual private network (VPN) customer to an existing network.

The first step is to locate the nearest access points to the customer's sites. Once you have checked that capacity is available, a path is routed across the access network to a point-of-presence (POP). This will provide access to the telco's backbone network that may typically be a combination of ATM and optical technologies.

Selection of the nearest access point is a simple matter. The provisioning engineer has only to check the status of the nearest access point to see what ports and slots are free. But this check says nothing about the connection between the access point and the POP or across the backbone. This information is normally held in the IP, ATM, and optical applications.

An optimal route may be found to the major POP, but there is no way of knowing that the connection into the network over the next layer has capacity. *Figure 1* illustrates the problem.

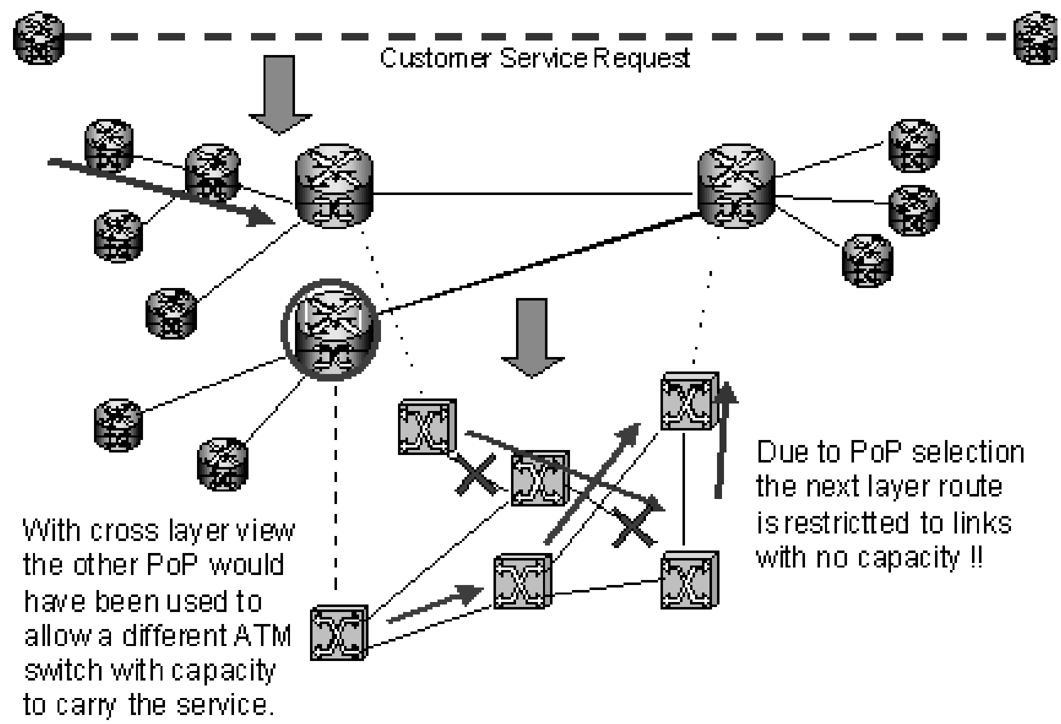
A customer request for a new service is mapped on to the IP layer first and then onto the adjoining ATM layer. Separate engineering teams for the IP and ATM layers might typically handle this process. *Figure 1* shows that the IP POP maps directly to the underlying ATM switches. The selected POP has capacity, but the ATM links from the switch are full. So the ATM planner either has to reject the request for a link and hand the routing task back to the IP planning group or must arrange to add capacity on the requested path.

A cross-technology view of the network avoids this problem by presenting the provisioning engineer with a view of network capacity across technology layers. This means he can explore alternative routes and get the routing problem right the first time. For example, when a route through the first POP and ATM backbone could not be found, the engineer could have selected a second POP and used the available ATM backbone links.

By contrast, in a silo system, the routing operation has to be repeated until a free route though the ATM layer can be found. This presents a fundamental barrier to the further automation of the provisioning process. After all, what is the point of automating a process that may have to be repeated several times?

FIGURE 1

A Silo-Based OSS Architecture



Central View Importance

An OSS, which presents a single view of the network at a physical and logical level, is fundamental to any hope of automating the network-provisioning task.

But implementing a central view can still be a challenge, because its effectiveness will depend on the accuracy of the data making up the network model. This information can be dispersed throughout an organization. It may be held in different data formats; some of it may even be paper-based. The task of collating data and loading key parameters can be crucial to the success of any project of this sort.

Unlike a central data view, the structure of the data is tailored to the functions that must be supported by the OSS, but access to this data must be provided in an open and easy fashion for read-only and reference purposes, otherwise it will revert back to a closed system approach.

The goal for many service providers is to balance the transfer of functionality from the existing systems to the new central view, as the new view provides a significant business benefit. For example, move the planning of ATM to the central view when the view also allows the mapping of passive devices and SDH/SONET usage.

The move to a central system is not simple, but it is a necessary step to allow today's operators to enhance their ability to speed the delivery of new services and ensure the fastest time to market—the keys to good market growth.

OSS Integration Approaches

Lee Chow
Senior Analyst, Telecom OS
RHK, Inc.

Introduction

This paper addresses the various operations support system (OSS) integration and deployment approaches that are being taken in the telecommunications industry today. It will examine OSS interoperability needs and deployment approaches, including management suites, interface integration, and systems integration of commercial off-the-shelf (COTS) components. Also under consideration are industry trends that may affect each of these approaches and may preclude or enable the future proliferation of some of these approaches.

OSS Interoperability Needs

Figure 1 describes the framework of a typical service provider's business processes. One or more of these processes are instantiated and supported in OSSs, including billing, customer-care, service-provisioning, and service-activation platforms. These OSSs support the service providers' business processes and, when deployed, are tightly integrated. The fundamental reason to integrate the processes is to ensure process flow-through and, as a consequence, enable automation. Service providers are looking for automation to derive profitability and also to eliminate manual processes that are cost-prohibitive. An example of process flow-through is service fulfillment, where the order of handling, service-provisioning, network-provisioning, and element-provisioning processes are tightly integrated.

Management Suites

OSSs today are deployed essentially using one of three approaches. The first approach is via management suites. Two examples of the suites being offered today are shown in *Figure 2*. Offered by a single vendor, management suites are pre-integrated, shrink-wrapped solutions. These solutions span horizontally across the fulfillment, assurance, and billing space and also vertically across the telecommunications management network (TMN) layers. These management suites will have applications in the element-management layer (EMS), network-management layer (NML), service-management layer (SML), business-management layer (BML), and also in the fulfillment, assurance, and billing space.

The components of the management suites are tightly integrated, most likely through proprietary interfaces. For example, with Lucent One Vision, there is a billing component, a service-activation component, and a trouble-ticketing component, all tightly integrated through a proprietary Lucent interface. Because of the nature of the proprietary interface, it does not lend itself well to a multivendor OSS. For example, if the billing component of a management suite is offered by another vendor, integration between the multivendor components will present a challenge, primarily due to the proprietary interface. Mulitvendor integration will more likely occur at the OSS–to–network element (NE) layer and also the OSS–to–element-management system (EMS) layer.

OSS Integration through Management Interfaces

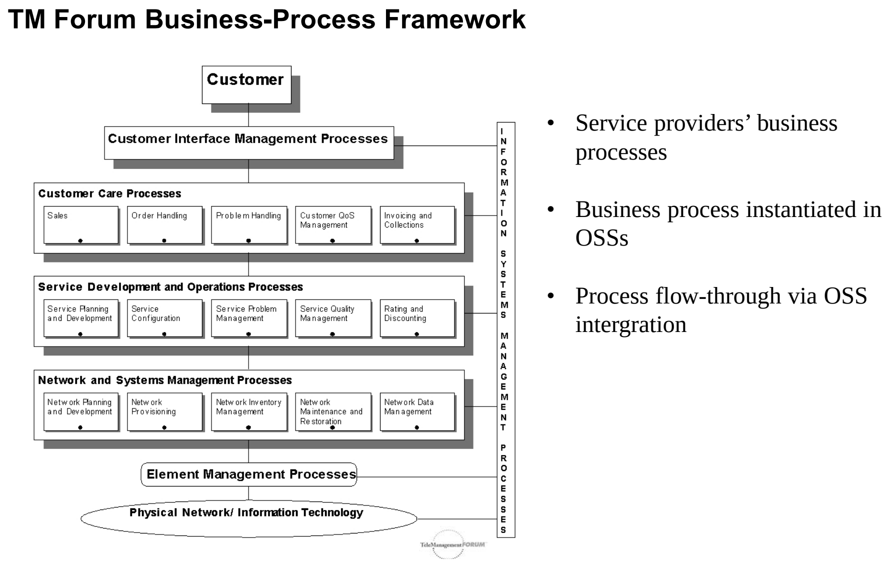
The second deployment approach is through OSS interfaces (see *Figure 3*). OSS interfaces can be applied to several reference points. The requirements, approaches, and solutions vary depending on the reference point. For the interfaces between EMSs and NEs, there are many NE view models and protocol-specific implementations that exist today, including simple network management protocol (SNMP) and transaction language–1 (TL1).

Standard information models and interfaces exist today but apply only to technology-specific domains. The standards include the recommendations from the Asynchronous Transfer Mode Forum (ATMF) and the Synchronous Optical Network Interoperability Forum (SIF). The majority of the interfaces between the EMS and NE are proprietary, driven by the fact that many of the equipment vendors who provide NEs also provide EMSs. When the vendor's bundled NE and EMS are deployed in a service-provider environment, that NE–EMS interface is transparent to the service provider. Therefore, the proprietary nature of the NE–EMS interface does not present an issue for service providers. Also, EMSs typically have a single-vendor focus and do not normally apply to multivendor network elements

At the reference point between the EMS and network-management system (NMS), there are many network view models that exist as well as many different types of interfaces, such as TL1, SNMP, common object request broker architecture (CORBA), extensible markup language (XML). Some of these solutions are recommended by the International Telecommunication Union (ITU). Also noted are T1M1 submissions to ITU, the ATMFM4 interface, and

FIGURE 1

OSS Interoperability Needs



the SIF interface. Work within the TeleManagement Forum (TMF) has produced the TMF 509 interface, which is a CORBA–based interface applicable to SONET, synchronous digital hierarchy (SDH), dense wavelength division multiplexing (DWDM), and ATM.

Proprietary interfaces are used between the service-management and network-management layers. Work in this area, also in the TMF, is underway under the TMF508 initiatives.

The approaches in multivendor OSS integration are accomplished today through proprietary interfaces, standard recommendations, or through de facto standard interfaces. De facto standard interfaces are interfaces that are not formally or fully recognized and yet have enough momentum from the vendor community that they proliferate through the industry.

The interfaces used for OSS integration are segmented into several different components. Functional requirements and use cases are delineated from the information and data model and are further differentiated from the technology-specific implementation interface. The motivation for the segmentation is to drive the preservation of

FIGURE 2

Management Suites

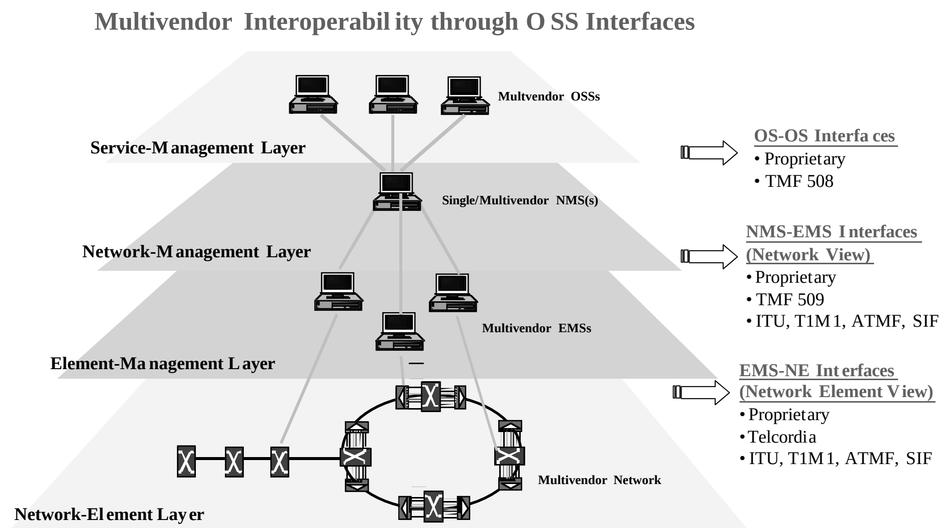
Source: Telcordia

FIGURE 3

OSS Interface Integration



the data modeling effort, separate from the technology-specific implementation.

Within the interface-integration approach, vendor product compliance does not ensure multivendor interoperability. Multivendor interoperability is insured only after there is some level of interoperability test. Although vendors' products may comply to interface recommendations, there is still some room for interpretation. The onus of validating interoperability is, thus, left to the service providers, who will actually perform the interoperability tests.

Systems Integration of COTS Components

Systems integration of COTS components represents the most recent approach in OSS integration. The fundamental principle behind this third approach is a distributed architecture composed of interchangeable plug and play (PnP) components and integrated via a common communications bus. The multivendor PnP components interface and communicate through a common communication bus and reference data through a common information model. A workflow engine is used to coordinate the flow of the service provider's business processes.

An important aspect of this third approach is that interoperability is tested and ensured by third-party systems integrators (SI). The total solution is pre-integrated by the SIs and delivered to the service provider. Unlike the previous OSS integration approach, the integration interoperability testing is done not by a service provider but by the SI.

Figure 4 illustrates this particular approach, using the TMF Broadband-Cable Catalyst Project as an example. The PnP components include an order-management component from Metasolv; a billing component from Portal; a service-level agreement (SLA) management piece from Trendium; a performance management (PM) part from TSCI; a fault management (FM) component from Micromuse; and a service-activation piece from Syndesis. Each of the multivendor PnP components communicate through a common communication bus. If a common information model is not implemented, a data-transformation application is used to normalize the data representation. Finally, a workflow engine is used to enforce the service provider's business flows.

OSS Deployment Approaches

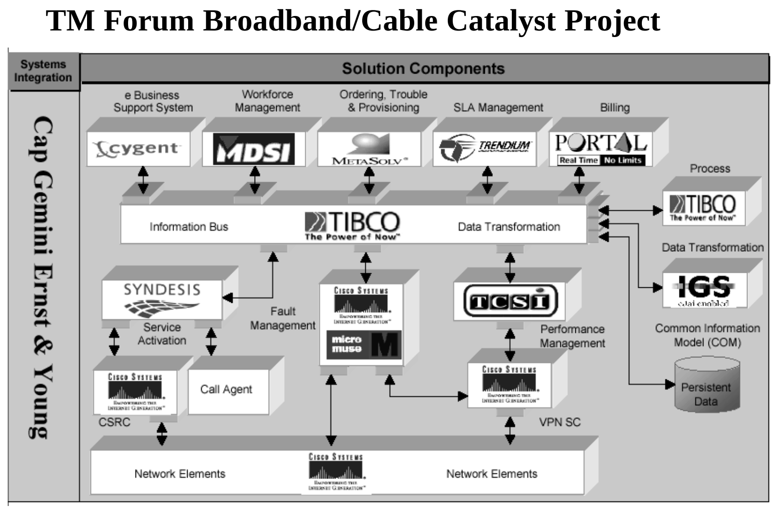
In examining the three approaches, two common factors of each approach become critical for service providers: time-to-deploy and the level of multivendor interoperability (see *Figure 5*). The management suites, because they are pre-integrated and are shrink-wrapped, will have a shorter deployment span. On the other side of the spectrum is integration through OSS interfaces, where there is a comparably higher time to deployment. In between is the systems-integration approach. In terms of multivendor support, management suites are very single-vendor focused. On the other hand, the systems-integration approach fosters a multivendor environment.

Industry Trends

The OSS integration and deployment approaches are greatly affected by emerging industry trends. One trend that is having an impact upon the systems-integration approach is being fueled by the greenfield carriers. Greenfield carriers are emerging carriers, typically without legacy OSSs in place with stringent time-to-market requirements. OSS deployment cycles are of primary importance to these service providers. Many do not have the resources to support in-house development, interoperability testing, and integration. As a result, these service providers will lean on an SI to do some of that work. The systems-integration approach is much more appealing to greenfield carriers.

FIGURE 4

Systems Integration of COTS Components



Source: TM Forum

Another important trend to note is the tremendous consolidation that has occurred in the OSS industry. Examples of such consolidation include ADC's acquisition of CommTech, Orchestream's takeover of CrossKeys, Agilent's purchase of OSI, Spirent's acquisition of Hekimian, and Nortel's acquisition of Architel. The trends toward consolidation may lead to the monolithic management suite approach. Prior to an acquisition, an OSS vendor's product may address a particular area, such as PM; after a complimentary acquisition, however, that product offering will likely expand from PM to FM to SLA management.

Conclusion

This paper examined three different OSS deployment approaches: management suites, systems integration of COTS components, and OSS interface integration. The management suites that exist today are single-vendor focused, shrink-wrapped and pre-integrated. OSS integration through interfaces utilizes three types of interfaces: proprietary, de facto, and standard recommendations with proprietary extensions. Finally, the last approach follows the fundamental principles of a distributed architecture, PnP components and integration through a common communications bus and data model.

QoS Routing Hierarchy in ATM Networks

Motorola

Abstract

Quality of service (QoS) routing enables network service providers (NSPs) to guarantee a certain level of network performance to user applications while optimizing the network resources utilization. In this paper, we present the state-of-the-art of the process of constructing asynchronous transfer mode (ATM) private network-to-network interface (PNNI) hierarchy that enables the QoS routing. A new concept of inner metric to the PNNI logical group node has been introduced that enables clustering algorithms that recursively partition a network into peer groups and that improves algorithms to transform a generic peer group into a Complex Node Representation with minimal error. The ATM PNNI hierarchy created with these improvements will enable the network connection admission control (CAC) to build QoS routes and guarantee end-to-end performance requirements of user applications.

Introduction

In recent years, the Internet has created a huge impact on people's lives. It demonstrated the power of information sharing and the potentials that may bring. However, as the nature of the Internet protocol, namely transmission control protocol (TCP)/Internet protocol (IP), is best effort, when the information carried in packets are routed through different paths to reach a destination, there is no performance guarantee from NSPs. As a result, a broad range of network applications is failed by the current TCP/IP technology. This class of applications ranges from real-time audio/video and teleconferencing to bandwidth on demand, etc., and can be identified as applications with QoS requirements.

QoS is in general measured by a set of parameters characterizing connection performance. The most important QoS parameters are usually in terms of network resources and connection quality, such as central processing unit (CPU) time, delay (transmission and queueing), link bandwidth, and loss ratio, etc. A QoS guarantee is a performance contract between a user application and network, which is often in terms of end-to-end measurement. Asynchronous transfer mode (ATM) technology has been deployed to support this class of QoS–sensitive communication applications.

ATM is a connection-oriented technology. The use of fixed-size packet (called cell) enables the switching technology to route data packets at extremely high speed. It has already been deployed by the current Internet to provide *flat* Internet backbone networks. With its routing hierarchy built to the ATM PNNI standard, it provides an efficient routing protocol with excellent scalability and security for large networks

QoS routing along with other network-management functions, such as CAC, enables NSPs to provide QoS guarantees to QoS–sensitive applications. It uses connection-oriented techniques to make resource reservations at the connection-admission phase and guarantees its performance commitment. The data transmission of such connections will not affect or be affected by traffic dynamics of other connections sharing the common links. Before the reservation is done, the routing function must select a path with the best chance to satisfy the resource requirement of the new QoS connection request. Admission control determines whether a connection request should be accepted or rejected based on the required QoS and routing hierarchy it maintains. Once the request is accepted, the required resources must be guaranteed.

ATM PNNI Routing

PNNI is a routing hierarchy that partitions a network into a hierarchy of sub-networks, called peer groups, and aggregates network-topology state information. As a source routing protocol, each switching node needs to maintain a complete up-to-date network-topology and link-state information. Because of the size of the Internet, it becomes necessary for the network-state information to be summarized and distributed efficiently to minimize the memory and speed requirements on network switching nodes and to reduce network-management complexity and its overhead consumption of the network capacity.

A peer group can hide the details of its internal structure from the outside world by advertising a summarized view of the internal structure, hence providing excellent scalability and security measures. In the PNNI standard, each peer group is represented by a logical group node as an abstraction in the next-higher routing hierarchical level. The logical group node is represented by the PNNI Complex Node

Rrpresentation that retains the most important link-state and topology information of the peer group. In each peer group, a leader aggregates and distributes information for maintaining the PNNI hierarchy. The PNNI routing hierarchy also allows asymmetry in the sense that, for a given lower-level peer group, its parent peer group can be a grandparent or great-grandparent peer group to some other same lower-level peer group at the same time. An example of a complete PNNI hierarchically configured network is shown in *Figure 1*.

Routing collects and maintains network-state information and searches state information for a feasible path. The search for feasible QoS paths greatly depends on how the state information is collected and where the information is stored. The ATM PNNI routing hierarchy provides a standard structure to collect, aggregate, and store such state information. It can be viewed as a recursive process to generate peer groups. In the process of this abstraction, information about a child peer group of a logical group node is aggregated and summarized into a logical group node, which in turn is represented by the Complex Node Representation.

The PNNI is a QoS–sensitive source routing protocol. When a new connection request comes to a network-entering switch, the switch is responsible to find a connection path to reach its destination while satisfying its QoS requirements. The CAC function used by this originating switch will select a route with the link-state information of the whole network in its local topology database. If a path can satisfy the QoS requirements with the information maintained in the local link-state database, the path is encoded in a designated transit list (DTL). Then a message is sent out to set up the new connection and make necessary network resources reservations along the path. If, at a certain point, the connection's QoS requirements cannot be satisfied, a crankback occurs to partially release a connection set-up and comes back to the node that created the DTL to perform alternate routing. This probing process continues until either a path is found satisfying the QoS requirements or the connection request is rejected. After a successful attempt, a new virtual connection is set up; the source may start communicating with the destination; and the network guarantees its resource commitment to the QoS requirements for the lifetime of the connection. In a network, there may be several paths between two border nodes. The path chosen is always the one with the minimum end-to-end delay.

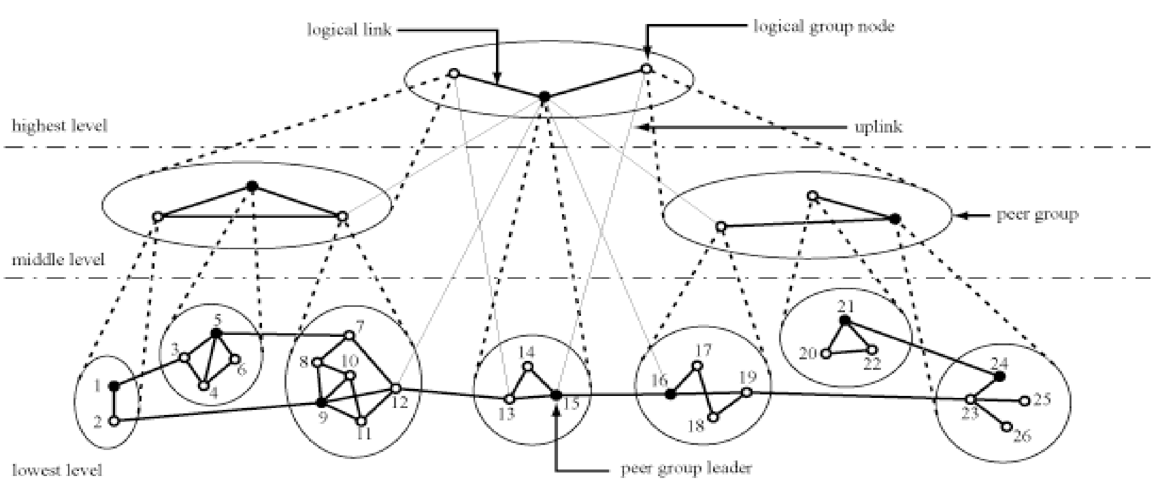
The PNNI uses flooding as its advertising mechanism. It ensures that every node in a peer group has an identical topology database. Furthermore, the flooding flows downward into and through the child peer groups. The PNNI routing hierarchy can be naturally viewed as a recursive generation of peer groups. At the lowest level of this PNNI hierarchy, clusters of the physical switches are grouped into peer groups. Then the detailed nodal and link-state information of each peer group is aggregated into one logical group node to a higher level in the hierarchy. This grouping and aggregation process is repeatedly applied to the higher levels of the logical group nodes in the PNNI hierarchy until the whole network is aggregated into one peer group.

PNNI Complex Node Representation

To be able to make effective QoS routing decisions, the most important topology-state information of a peer group needs to be retained in its logical group node. The complex node representation was proposed to represent the aggregated state parameters of the peer group in a logical group node. A node identifier identifies a logical group node. The complex node representation aggregates a peer-group topology into a star topology whose center serves as the interior reference point of the logical node and is called the virtual nucleus of the complex node [1]. The links connect the nucleus only to the border nodes of the peer group. This Complex Node Representation reduces the overall complexity and hides the topology internals of the peer groups. The logical connectivity between the nucleus and a border node is referred to as a *spoke*. The concatenation of two spokes represents a traversal of the peer group. This process of

FIGURE 1

A PNNI Hierarchical Network



aggregation and summarization is called topology aggregation. As peer groups are usually not symmetric, exceptions are used to represent particular ports whose connectivity to the nucleus is significantly different from that of the default, or between two ports, i.e., a bypass that is significantly better than traversing the nucleus.

Many efforts for constructing effective PNNI Complex Node Representation with respect to various QoS requirements are discussed in various literature [3, 4, 7, 8]. In a typical aggregation model, a PNNI peer group is represented by a graph G. Let G = (V, E, B), where V is the set of switching nodes, $B \subseteq V$ is the set of border nodes, and E is a set of bidirectional links among the nodes in V whose values represent the corresponding link costs. This model can be applied to the networks where the majority of data traffic is balanced, as those in voice or video telephone conversations, etc., where the traffic volumes in both directions are about the same. A border node is a logical node that has at least one link across the peer-group boundary that it is in.

An N x N matrix is used to represent the cost metric between border nodes of a peer group, where $N = |B|$, which is the size of the border node set. Many aggregation techniques in the literature [2, 3, 4, 8, 10, 16] extensively use matrices to hold the topology metrics of concern. In [16], a new concept of intra-nodal metric is introduced that uses the main diagonal of the metric matrix $a_{i,i}$ to hold the intra-nodal costs, i.e., the default spoke value of the PNNI Complex Node Representation for the logical group node. Note that, at the lowest level of the PNNI hierarchy, logical nodes are real physical switches in the network. We initialize this intra-nodal cost metric to zero for the lowest-level nodes for the negligible network costs, such as delay, inside a physical switch. But at all other levels, this intra-nodal metric is obtained by the default spoke of the logical group node, and it is always a non-negative number. This internal metric enables us to construct a PNNI complex node for any peer groups with minimal error, which significantly improves the quality of peer-group aggregations and minimizes the discrepancy between the PNNI Complex Node Representation and the peer group it represents. The links in E are physical links at the lowest level of the PNNI hierarchy and logical links at all other levels. Without loss of generality, we denote the link weight as the link-delay metric, and use link delay as the focus metric of our algorithm.

Topology-Clustering Algorithm

The network-clustering algorithm is used to partition the network into a hierarchy of sub-domains and to construct peer groups. The recursive nature of the PNNI hierarchy dictates the algorithms to use recursion to partition the network into levels of peer groups in a bottom-up fashion, in which process peer groups are abstracted into logical group nodes.

It usually starts with a delay matrix at the lowest PNNI level, i.e., the physical switches and links as the nodes and edges in the graph G (V, E, Ø) with total of N nodes. Because this matrix covers the entire network, there are no border nodes to have links to the outside of the network. Matrix elements are initialized as $c_{ii} := 0$ and $c_{ij} := d_{ij}$ where $i \neq j$ and $0 \leq i, j \leq N$, and d_{ij} is the direct link-delay between nodes i and j. If there is not any direct link between node i and j, set $c_{ii} := \infty$.

$$C^0 = \begin{pmatrix} 0 & c_{1,2} \ldots & c_{1,j} & \ldots & c_{1,n} \\ c_{2,1} & 0 \ldots & c_{2,j} & \ldots & c_{2,n} \\ \cdot & & & & \cdot \\ \cdot & & & & \cdot \\ c_{i,1} & c_{i,2} \ldots & 0 & \ldots & c_{i,n} \\ \cdot & & & & \cdot \\ \cdot & & & & \cdot \\ c_{n,1} & c_{n,2} \ldots & c_{n,j} & \ldots & 0 \end{pmatrix} \Rightarrow C^1 = \begin{pmatrix} pg^1_1 & c^1_{1,2} \ldots & c^1_{1,j} & \ldots & c^1_{1,m} \\ c^1_{2,1} & pg^1_2 \ldots & c^1_{2,j} & \ldots & c^1_{2,m} \\ \cdot & & & & \cdot \\ \cdot & & & & \cdot \\ c^1_{i,1} & c^1_{i,2} \ldots & c^1_{i,j} & \ldots & c^1_{i,m} \\ \cdot & & & & \cdot \\ \cdot & & & & \cdot \\ c^1_{m,1} & c^1_{m,2} \ldots & c^1_{m,j} & \ldots & pg^1_m \end{pmatrix}$$

Next, an affinity function is defined, usually a function of hierarchical levels, that cluster logical nodes together into peer groups. The affinity criterion can be a number to limit the maximum number of logical nodes in a peer group, or it can be a function of the QoS parameter of concern. We will use link delay in our case. The link can be either physical or logical. A modified version of the Kruskal Minimum Spanning Tree has been used to construct a PNNI hierarchy of peer groups, i.e., a minimum spanning-tree forest as a collection of peer groups. Once the partitioning is done at one hierarchical level, the PNNI complex node transformation algorithm is invoked to convert the peer groups into the PNNI Complex Node Representation. Then we can replace the matrix blocks—entries of the same peer group—with a single delay element, as the post-aggregation matrix C^1 shows. Generally, for peer group i in C^1, entry c^1_{ii} will be the default spoke value of the PNNI Complex Node Representation of pg^1_i, and c^1_{ij}, the delay between peer group i and peer group j at the same PNNI hierarchy levels. For the nodes not belonging to any of the spanning trees, we can leave them to be included in peer groups of a higher PNNI hierarchical level later. This clustering process continues to recursively aggregate and build higher-level delay matrices C^2, C^3, …, until the whole network is contained in one peer group, the highest level C^D.

Based on the affinity criterion used in the partitioning process, link delays among nodes of higher-level groups are greater than those among of lower-level group nodes. In other words, at a certain hierarchical level, peer groups X, Y, and Z are viewed as delay matrix blocks, and delay matrix block A, i.e., a higher-level peer group, $a_{ij} \geq \max\{x_{mn}, y_{pq}, z_{rs}\}$, where $a_{ij} \in A$, $1 \leq i, j \leq |A|$, $x_{mn} \in X$, $1 \leq m, n \leq |X|$, $y_{pq} \in Y$, $1 \leq p, q \leq |Y|$, $z_{rs} \in Z$, and $1 \leq r, s \leq |Z|$, $|A|$, $|X|$, $|Y|$, and $|Z|$ are the sizes for the matrix blocks A, X, Y, and Z, respectively. Also, the sum of the intra-group bypasses is less than the inter-group cost, i.e., $\max\{b_{mn} \mid \forall\, m, n \in X\} < a_{mk}$, where $e(m, k) \in E$ is a valid link, $k \in A$, but $k \notin X$ and $m, n \in X$. In case this assumption does not hold at a certain level inside the hierarchy, make one group with larger b_{mn} into higher levels directly, i.e., a PNNI induced uplink, until the affinity function returns true for the new level or into the highest level of the hierarchy, where inter-group delay will no longer be of concern.

When we start the partition-conversion process, the inter-peer-group links are aggregated so that there is only up to one link between any two peer groups at a higher level. This is generally applied to any inside levels of the hierarchy. The only exception to this occurs at the lowest level, i.e., the physical level, where multiple links may exist among different peer groups as no aggregation is done.

The PNNI complex node transformation algorithm in the next section has been used to convert peer groups into PNNI Complex Node Representations. The algorithm recursively works on the delay matrix obtained from the aforementioned PNNI partitioning algorithm. It recursively partitions the matrix into disjoint sub-matrix blocks, aggregates each block into one logical node, and generate summarized matrices.

Due to the overlaps of the links aggregated, the delays of the spokes cannot represent the true minimum delay parameters from border nodes to the virtual nucleus. Bypass links are introduced to handle these exception linkages. Define an internal delay variable, equivalent to intra-node transit delay or internal queueing, so that a shortest path or minimum link delay can be used between two peer groups. Besides considering the cumulating of inter-group delay on the path, intra-group delays need to be included by each group on the path and to add to the path's delay when path is being built up.

$$d_{ij} = pg_i + d_{ij} + pg_j$$
$$d_{ii} = pg_i$$

With the topology-state database, an ATM CAC can quickly admit or reject a new network connection request based on the end-to-end delay QoS requirement of the new connection request and path delay information in the local topology database. The other QoS metrics can replace link delays previously used to enable other end-to-end QoS requirements of new connections.

Topology Aggregation

In the following sections, we present a new approach for finding the logical links of the star networks [2]. This involves the algorithms that aggregate a graph G = (V, E, B) into a star network with bypasses, where V is the set of nodes, $B \subseteq V$ is the set of border nodes, and E is a set of bidirectional links among the nodes in V.

Different aggregation schemes have been proposed for the ATM Forum's PNNI hierarchy, such as star, minimum spanning tree, and random spanning tree. Based on the simulation study, the star-based aggregation schemes have consistently performed better than schemes based on minimum spanning tree and random spanning tree [7].

The first step is based on Dijkstra's shortest path algorithm. It has positive edge weights and calculates the shortest paths among border nodes in an undirected graph. For a given peer-group representation in a graph G represented with adjacent lists, the purpose of this first step is to find the shortest paths from each border node to all the other border nodes. First, transform the given graph into a complete mesh, then search for the shortest path for each border node as follows: From each source border node, initialize a weight function of each node to infinity, which records the running delay from the single source to other nodes. Then relaxation technique is applied to obtain the shortest paths. These minimum delay results are stored in a delay matrix. At the end of the step, the delay matrix will hold the minimum end-to-end delays among all border nodes.

The next step is to transform the delay matrix into the PNNI Complex Node Representation—i.e., a star representation with bypasses—and store it in an enhanced delay matrix. Due to the overlaps of the links aggregated, the delays of the spokes usually cannot represent the true minimum delay parameters from border nodes to the virtual nucleus. Bypass links are introduced to handle these exception linkages. The following steps will generate the bypasses to make exception linkages available to the routing algorithms.

The process starts with a node set with one border node, then repeat the follow step until all border nodes are in the set: Find the longest delay link that connects nodes inside the set and outside. If the link delay is less than the existing spoke of the inside node times two, reassign this spoke to the half of the cross-link delay and add the outside node into the set. After the spoke is calculated, validate all exception bypasses into the enhanced matrix; if there is a link between two border nodes having a delay significantly less than the traversal delay through the nucleus, add this link as a bypass to the matrix positioned by the node IDs of the two nodes.

At the end of these processes, we have successfully aggregated the peer group with arbitrary topology into the ATM PNNI Complex Node Representation.

Conclusion

With these clustering and transformation algorithms, network-topology–state information can be aggregated efficiently to build the ATM PNNI hierarchy. With the routing tables built with these aggregated QoS parameters, an ATM connection admission control can quickly admit or reject new network connection requests based on the end-to-end QoS requirement of the new requests by simply performing some routing-table look-ups.

Service Quality in Large-Scale DSL Deployments

Didier Cop
Vice President, Marketing
Amplify.net

Service Quality and Assurance

What are today's requirements for the digital subscriber line (DSL) infrastructure to deliver service quality and assurance? This article will discuss this question, as well as technology requirements for the access network.

Service-level agreements (SLA) receive a great deal of attention in this industry. But SLAs are a myth. They are a myth because they only work if there are teeth in them, a fact that that really applies to the corporate marketplace, with huge contracts and true SLAs. DSL is a residential/small-business play, and has so far been a best-effort service offering. As we will see, if implemented correctly, service quality is a good substitute for SLAs.

Quality of Service

So what should really be service quality? Taken from a global perspective, an SLA is mostly understood as a written contract wherein particular performance criteria are set out. But when considering the current DSL market, talking about an SLA really means being concerned with meeting the satisfaction of the subscriber and the users at this subscriber. A distinction can be made between the two. The subscriber is the decision maker in any particular household, while users are the people using the service and can be very influential on the subscriber. Many subscribers and users have been recently disconnected, initially because of a failing Internet service provider (ISP) or a failing data local-exchange carrier (DLEC). It is increasingly important that DSL users be happy with the quality of the service they receive. They will then spread positive messages, rather than negative ones.

Quality of service also means meeting the internal metrics as specified by the service provider. For example, if a subscriber might have signed up for a 640 kilobit (k) service, the internal service-provider specifications could be that the user should never be below 128k but get 1 megabit per second (Mbps) at off-peak times. This is an informal SLA, wherein the marketing folks decide what the service quality should be; it is not on a contractual commitment, but it is one way to define the service level.

DSL is a service crossing several boundaries, from the end customer to the final destination on the Internet. It goes through several networks such as the access network or the metro network, and real SLAs here are required. We are talking about bigger monies and bigger contracts. The ISP is actually offering service through an open-access environment and shares the same access infrastructure with several other ISPs. ISPs are dependant on the services metro providers offer.

Subscriber Satisfaction

Does the subscriber get what he or she pays for? For standard Internet access, what is the phenomenon observed by the subscriber or the user when the contract is not delivered? In most cases, he or she will not notice unless a software performance tool is used because the service is data, not real-time. The same goes for services around security. The only time when the user will feel the contract is being breached is if an intrusion occurs, and while the risk is there, the event is infrequent.

Today's new communication value-added services—like voice and video—are being introduced among well-established metrics of quality such as toll-voice and broadcast television and DVD. Here the SLA contract is very simple—will the user get the quality experience he or she expects every time? That's what quality of service is about. In these instances, because of the user's well-established quality expectations, it is possible for him or her to feel immediately that the service contract is broken.

Service-Provider Specifications

For these real-time services, service providers should provide a high level of service quality—or no service at all. Historically, it is what customers have come to expect from regular phone service or the DVDs they rent. Sub-quality service will not be good enough to keep the customer. Following are a few example guidelines for service specifications:

- Bronze customers should never get less than 20 percent of the service level they expect (i.e., 640k to 128k)
- Silver customers should never get less than 40 percent of the service level they expect (i.e., 640k to 256k)

- Voice should be 64k for business (worst case), 32k for residential, and denied if not possible
- Video on demand should be a DVD–like experience

Infrastructure Requirements for Paying Value-Added Services

The first infrastructure requirement must be the ability to guarantee that the actual level of quality is being delivered for each of the services, each time. The second is maintaining the quality end-to-end—from the end-node at the subscriber to its destination, which can be the ISP or a video server or a voice gateway, which is not controlled by the ISP, but rather is controlled by the access provider or another partner. Access providers have a further challenge as they are serving or will shortly serve several ISPs and application service providers (ASP) through the same infrastructure. They will have to deliver SLAs to each that enable them to differentiate and compete in the market.

Technology Considerations

Quality of Service in the Access Network

In *Figure 1* a distinction is made between the last mile, which is everything from the customer to the access device in the central office or in a digital loop carrier (DLC), and the metro or long haul, which links all the subscribers to various ISPs.

Figure 2 shows quality-of-service technologies, used in asynchronous transfer mode (ATM) or Internet protocol (IP) networks, such as multiprotocol label switching (MPLS) or resource reservation protocol (RSVP). None of them have been engineered for the last mile, where bandwidth challenges dominate. It is rather easy to scale the metro network, but it is very difficult to progressively add bandwidth in the last mile.

Last-Mile Aggregation: Internet Access

Historically, broadband has simply been Internet access, with a very simple playing field—users were connected through modems to a digital subscriber line access multiplexer (DSLAM) before reaching the metro network. Now we have to face adding multiple real-time services serving multiple ISPs. For DSL, while it is now dominantly self-serving to the incumbent local exchange carriers' (ILEC) own Internet entity, ISPs still have a lot going for them and have an integral part to play in marketing, selling, and delivering services to the end customer. Open access is also emerging in the cable environment, where multiple ISPs are starting to gain access to the cable infrastructure owned by the cable companies (see *Figure 3*).

Multiservice Open Access

Access providers must be prepared to aggregate traffic between multiple points to and from the same subscriber. It will not be long before a subscriber will want to access several service providers for several types of services. Different users at the subscriber home or business will have different inclinations from the same PC and will want to use a plethora of services that all require different behaviors, all behind the same IP address.

This poses a formidable challenge to access providers wherein the first location just after the customer premises becomes the only real service aggregation point before it gets distributed to different destinations. This point that requires a lot of granularity in terms of quality of service. When an access provider is serving multiple ISPs, it will need to enable service differentiation and meet different service models and different quality-of-service requirements. *Figure 4* shows a multiservice open access environment with subscribers using multiple services.

FIGURE 1

End-To-End

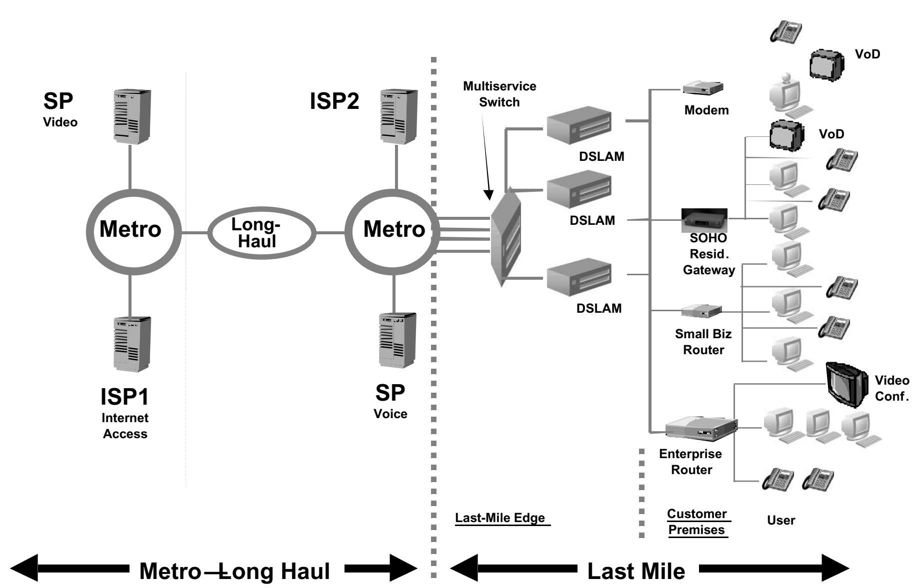

FIGURE 2

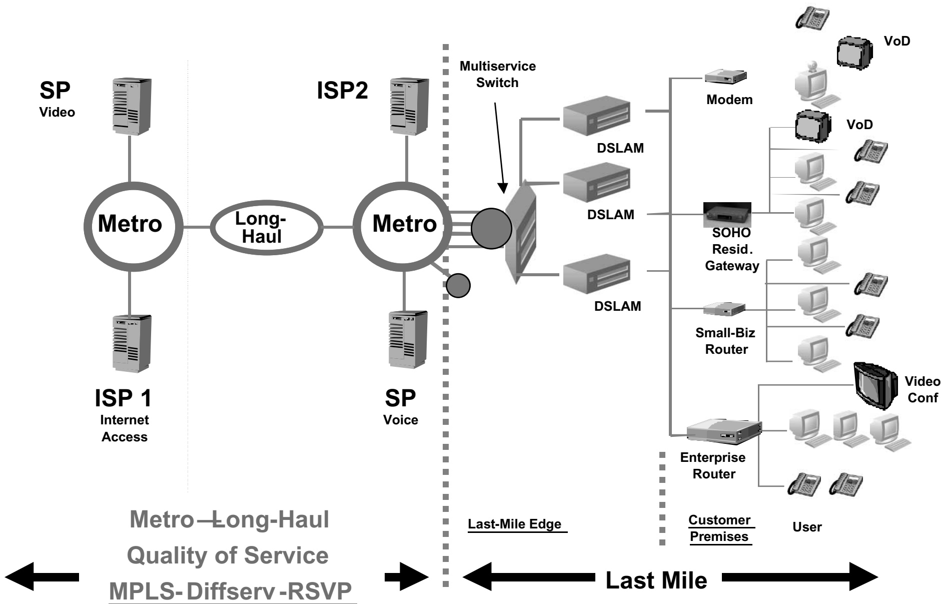
End-To-End Service Quality



Each of the DSLAMs before aggregation to the multiservice switch is a potential physical congestion point (see *Figure 5*). Because the access infrastructure is going to be serving several ISPs, there will be a number of virtual congestion points, such as the total bandwidth allocated to each ISP and the classes of services that each ISP has established. It is likely that each ISP will have its own strategy of what a silver service should be and how much over-subscription it wants to implement.

When examined from the user's PC perspective—that is, looking at the path that the packet flow is going to take—this is all a very complex situation. For all real-time or near-real time services, the correct amount of bandwidth neces-

FIGURE 3

Internet Access

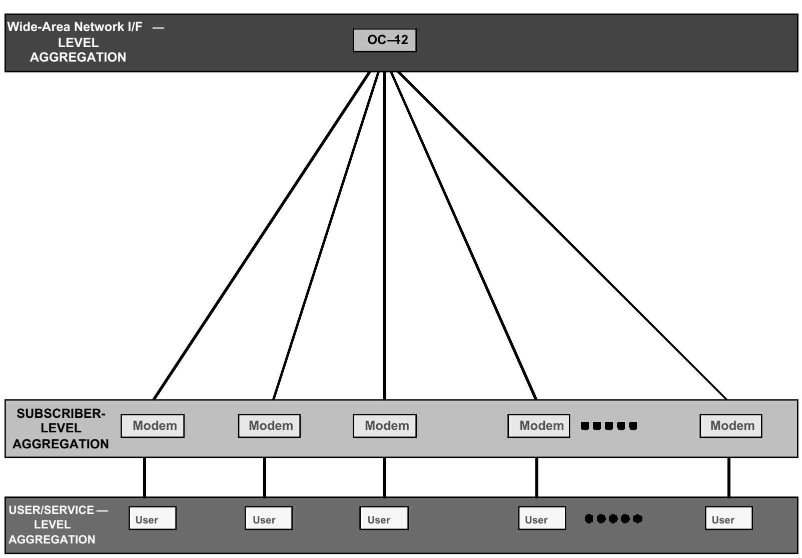


FIGURE 4

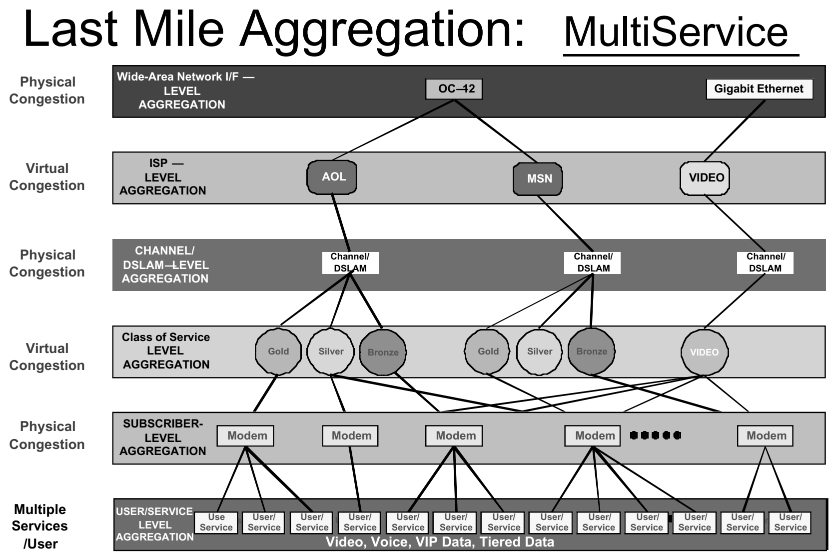
Multiservice



sary to meet each of the services' quality definition must be guaranteed, from the PC through the last-mile infrastructure, through each of the congestion points, virtual or physical. However, this deterministic guarantee needs to be implemented in a way that makes bandwidth available at all times for non-real-time traffic if not used.

Another important concept is fair bandwidth attrition for non-real-time traffic—in other words dealing with what happens to best-effort data while all high-priority traffic is being served. As more services that consume bandwidth are introduced, data services are going to degrade if not enough attention is paid to them. Again, bandwidth in the last mile is not elastic. Access providers should use IP traffic-management technology to make sure that each of the subscribers receives a fair amount of bandwidth.

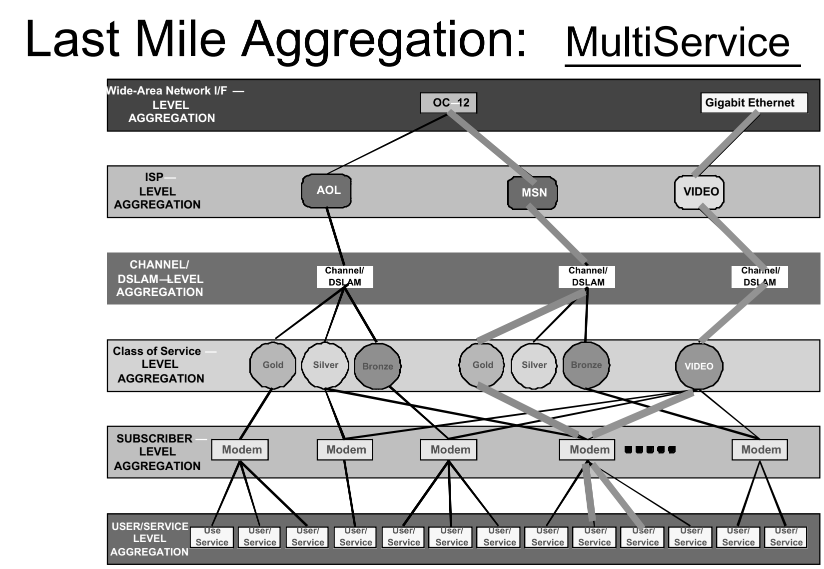
The Multiservice Switch—A Potential Physical Congestion Point



Multivendor OSSs: The Challenge Is Speed

George Cray
Executive Director
Telcordia Technologies

Topics

This paper considers the problem of multivendor operations support systems (OSS) and multivendor networks from the perspectives of a network operator, a network equipment vendor, and an OSS provider. Multivendor networks present real challenges, and foremost among them is to deliver a full solution, especially from a customer's point of view. To examine some of the demands, it is best to consider the different perspectives around multivendor networks.

The paper also examines what is needed to provide OSS and network element (NE) interoperability—in other words, what is needed to make them work together. While many boast of "plug and play," the reality is that plug and play is never truly attained. There are techniques and standards that can shorten the time frame, but the integration effort remains formidable. A real example, one that involves digital subscriber line (DSL) technology, will provide some lessons learned regarding today's environment.

A Network Operator's View

Basically, network operators want everything. They require OSS solutions that support multiple services, voice over DSL (VoDSL) or voice over Internet protocol (VoIP), data, and Internet protocol (IP) virtual private networks (VPN). Ultimately they want to use networks to transport any service they sell, so trying to get to a truly multiple-technology, multiservice network is the goal. Multiple technologies clearly come into play. These include traditional time division multiplex (TDM) technologies, synchronous optical network (SONET)/synchronous digital hierarchy (SDH), optical-based technologies, frame relay (FR), cell relay going across that, IP services, and asynchronous transfer mode (ATM). Operators ultimately are involved with multiple-vendor networks. That could be because they want different options from a purchasing perspective. It could mean that they acquire different operators' networks along the way.

Network operators do not want to be limited. While they go after solutions that handle multiple services, multiple technologies, and multiple vendors, they need to be scalable and to deal with transfer of assets very cleanly. Of course, they want it easy to use, easy to maintain, stable, and affordable. While the targets of ease of use, ease of maintenance, and stability might be attainable, they might make the solution unaffordable. It really is a challenge to try to make these networks operate the way a network operator would like them to.

The Network-Equipment Vendor

Network-equipment vendors want to be first to market with new technology. No one can blame them for trying to roll out new products first. After all, is it better to be first or second in a market? What that means from an integration perspective is that, typically, a lot of these new technologies or even the service offerings are ahead of any standards, and network-equipment vendors are actually hoping to set them. When it comes to new technologies, standards are few and far between.

Equipment vendors also want to differentiate their product from the competition. So, again, even if a set of standards exists, certain companies are trying to push the envelope and create new features and functions that maybe are not addressed in the standards. Maybe vendors address them differently from what is described in the standards. Equipment vendors want to innovate constantly. Thus, even if the standards start falling in line with the products rolling off, situations will invariably arise where someone will come out with that next new capability, and many new releases will follow. From a network-management point of view, element management systems (EMS) are quickly trying to churn out new releases and new interface specifications, not to mention acquisitions of new products.

For example, network-equipment vendors might develop strategies that try to bring innovations all under one EMS, whereas, previously, a number of NEs may have been managed by completely separate EMSs. However, when one company aggressively pursues market-share, that company, out there acquiring other companies, will have different strategies for supporting the elements underneath EMSs. Vendors want to stay in front, and they do not want to wait for OSSs to catch up. They do not want to wait for operators. They are being pushed by operators to give the next greatest capability.

An OSS Provider's Opportunity

For an OSS provider, one of the big challenges is that, initially, many of the network operators may be doing things with hardly any OSSs. They may be trying to put in equipment, maybe in a stand-alone mode segregating their network. They may be in a situation where they are in low growth at a certain point, pre-provisioning or manually activating the network itself. But as they grow they want to become fully automated, dynamically provisioned, and large-scale, with multiple services that will create a high-growth environment. That is why they are going after the OSSs.

The problem that OSS providers need to account for is that operators are already operating. So, OSS providers cannot impact the current ability to provide and maintain service. They must be able to provide automated data conversions to the new OSS. Data may be in another OSS or, more likely, in a spreadsheet system. The trick is figuring out how to get that data into the new OSS. The network operator will not own the entire network. There will be many handoffs with other trading partners, which only complicate trying to provide that end-to-end service.

Hence, vendor selections and service offerings will change, and they typically change on or before initial deployment of OSS, which is yet another challenge. What is stipulated in a contract for delivery versus what is ultimately put into service typically does change, even if it is in a three- or six-month window. That is simply the reality of what it takes to win business today. Everyone has a different perspective, yet the challenge is to make it all work three months from the start of signing a contract or in *x* number of weeks after a decision is made to purchase a piece of equipment.

OSS–NE Interoperability

A number of issues need consideration regarding OSS and NE interoperability. Integrating OSSs with NEs to simplify network operations requires communications protocol standards (for example, X.25, transmission control protocol [TCP]/IP, and open systems interconnection [OSI] Layer 7). Obviously, the idea is to synchronize with what the protocol is going to be. The problem is that picking a standard does not mean that it will work automatically. Unfortunately, these protocol standards allow for implementation variations via parameters and protocol data. Simply selecting OSI Layer 7 or TCP/IP does not mean that all standards are equal.

Similarly, OSS and NE interoperability requires message protocol standards to define the syntax, message structure, and punctuation. Again, vendors usually adhere to message protocol standards, but minor deviations exist. A good example involves common object request broker architecture (CORBA), with such variants as VisiBroker® and Orbix®. Likewise, there are different versions of simple network-management protocol (SNMP). While message protocol standards will help interoperability, they are not a guarantee that systems, whether a network-management system (NMS) or an EMS, will really plug together.

Interoperability also depends on data and information-modeling standards to define how to interpret message contents. But several management information bases (MIB) exist, both with SNMP and common management information service element (CMISE). CORBA has an interface definition language (IDL). Certain types of interfaces can be standardized, but all standards are subject to interpretation, and all allow for extensions. An illustrative example involves ATM where SNMP was being used. The SNMP standard for ATM called for about six traps from a surveillance perspective, and the ATM switch in question had more than 100 traps. A good portion of those the network operator really might want to use, and it does not mean all must be used, but care should go into determining what will really be used and what needs to be standardized for that network operator. Simply having a standard will not allow network operators to deliver all the functionality unless they get beyond that standard and talk about the underlying EMS or NE and determine what is going to be used by the network operator to take advantage of some of the features and capabilities that were in that NE.

Integrating OSS with NEs also entails equipment and network modeling, dealing with physical to logical representation of equipment and networks. Typically, NEs are fundamentally designed and engineered differently. Some things are relatively standard, such as physical layout (bay, shelf, slots, and ports), features (types and quantities of drops), and certain supported architectures (chain, ring, or hybrid), but every vendor chooses to implement things slightly differently. That must all be accounted for from both a physical and a logical perspective to do assignments and deal with alarms.

Interoperability testing (verification according to specifications) is another integration issue concerning OSS and NEs. What stands out foremost is the challenge of speed. Network architects spend much of their time actually defining the requirements and doing the testing. Time is not spent writing the code or putting the interfaces together. Getting through the actual requirements—what the interface will be, what it will be standardized on, and what the extensions are—takes the most time. Once the code is written, testing must follow, and testing really is where the rubber meets the road. That is what determines whether the integration will work. Testing also uncovers numerous other things not obvious from reading the documentation. It is clear that documenting these northbound interfaces is not the first thing on an equipment vendor's list of things to do, and, therefore, trying to keep up with the capabilities in the EMS or the NE becomes a challenge when looking solely at documentation. For interoperability testing, it will be necessary to verify the synchronization of logical representation in support of multiple–OSS flow-through environments.

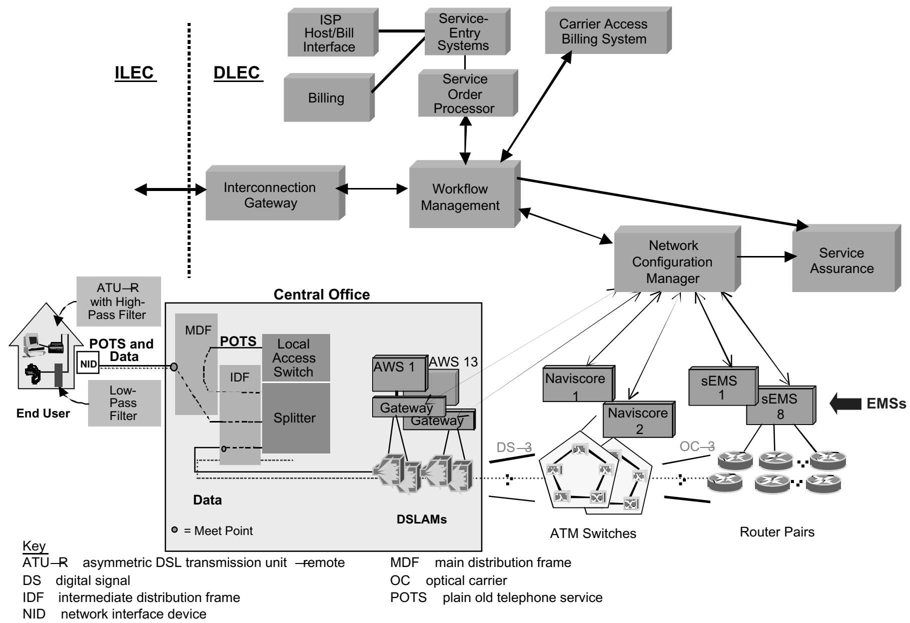
Ultimately, the end-to-end solution will deal with some methods and procedures. It is critical to establish how to handle irreconcilable differences. There will be out-of-sync conditions, and, through order discovery, network operators will find things that are not the way they thought they were. In these different areas, methods and procedures may come into play, and to think differently is foolish.

A Real Example

A real example will provide an overview of a network that was in place when management efforts began (see *Figure 1*).

FIGURE 1

DLEC DSL OSS Solution



In this case, a data local-exchange carrier (DLEC) wanted a DSL OSS solution. The focus in this example will be on the network configuration manager, which is basically an NMS for configuration or provisioning. It talks to a multivendor network and to EMSs, all under the guise of doing DSL provisioning. The DLEC had NEs that were performing the DSL access multiplexer (DSLAM) capability—in this case, an Alcatel 1000 ATM subscriber access multiplexer (ASAM). There were also RedBack routers and a Lucent ATM switch and that were managed through a Nortel EMS.

The network operator was looking to turn up service in a flow-through environment. There is no need to concentrate on the rest of the OSSs involved because the goal here was to activate that network. What must be done to provision in a multivendor environment?

DSL Activation: The "Real" Process

Figure 2 breaks down the configuration process. When actually messaging to the EMSs, the interaction is very different based on whether it is the DSLAM, the ATM switch, or the router.

The first step is a request for network activation. The "–1 Day" refers to a day before the due date, which can be set arbitrarily. In this case the network operator chose to activate a day before the due date, and the orders were sent down to the network configuration manager, which is really only an NMS dealing with the provisioning aspect across a multivendor environment. That network configuration manager can now talk to the various EMSs through a variety of protocols: transaction language 1 (TL1), SNMP, and CORBA. Recall that this is in a supposedly homogeneous network, but that different standards apply.

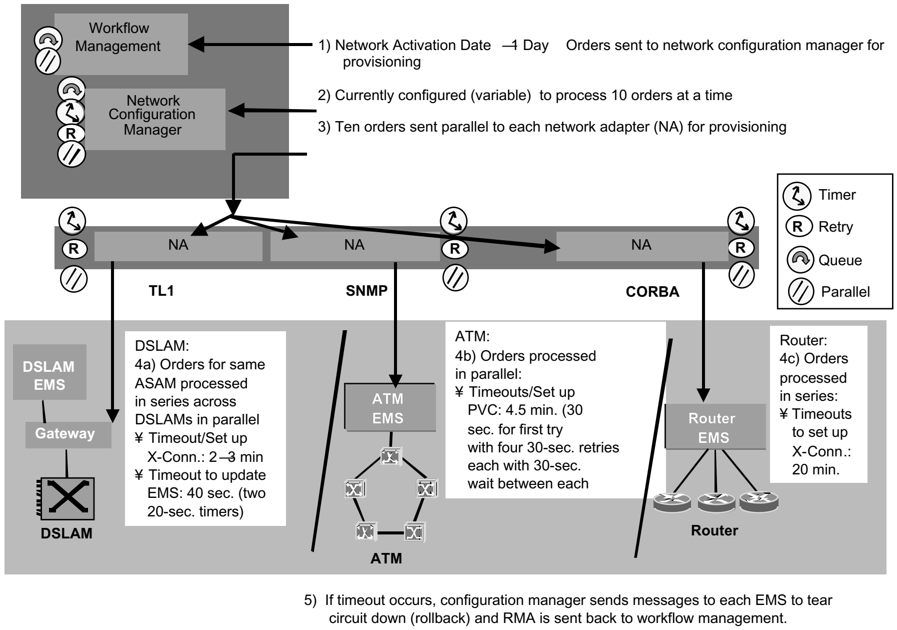
In the case of talking to the DSLAM EMS, times have been greatly improved. The 1000 ASAM could basically handle the orders only in series across DSLAMs in parallel, resulting in long wait times to set up the cross-connect (XC). Then timers were set. If no response was received, another attempt was made. Often this happened several times, averaging a three-minute total lapse time to get, potentially, a successful activation. Now this typically takes less than a minute, and the typical XCs are done in eight to 15 seconds. After an EMS is placed in an automated flow environment, the performance becomes a serious factor, and operators start asking what this does to their overall ability to provision services. Initially, the interface was serial, meaning there were great limitations on the number of orders it could process. Problems with timeouts required looking at that interface. The network operator, the equipment vendor, and the OSS provider worked to reduce that into a much more reasonable time frame.

The ATM switch had a different set of issues. There the northbound interface dealt with parallel processing, meaning many orders could be sent down through the EMS. In that case there were different timeouts, which were set up based on the capability of that EMS to process orders. A request for a permanent virtual circuit (PVC) operated on a 4.5-minute lapse: 30 seconds for the first try, with four 30-second retries each with 30-second waits between them. At the router EMS, orders were processed serially, which was a problem, and the timeouts to set up the XC were set to 20 minutes because the goal was to provision all three of these components successfully.

If that was not done, the network configuration manager sends messages to each EMS to tear down the circuit (rollback) and a request for manual assistance (RMA) is sent

FIGURE 2

DSL Activation: The "Real" Process



back to workflow management. If the DSLAM or some portion of the ATM network was activated, but not all the way through to the router to the Internet service provider (ISP), ultimately all that was provisioned has to be rolled back and manual assistance has to be requested. Network operators want these services to be provisioned end to end and do not want to encounter problems with the router or the DSLAM. Once everything is rolled back, the network operator can choose to have the systems retry or to have a user provision manually.

Lessons Learned

Two of the lessons learned involve network health and the OSS software solution. Network health depends on capacity planning and scalability to ensure that the network and the EMSs were able to provision the expected volume. This lesson is often learned in production and may not be known ahead of time. EMSs tend to be job aids for engineers and technicians, if initially no thought is given to northbound interfaces. In that case, the expectation of that EMS as a job aid versus an integral part of flow-through provisioning is very different. The idea of supporting simultaneous (versus serialized) requests is critical. Scalability depends on the ability of the number of NEs actually supported underneath a given EMS.

Obviously stability and availability are important. Both the NEs and the EMSs must be stable and highly available for provisioning with service assurance actively monitoring the EMSs and NEs. If EMSs go off-line for significant chunks of time and are not able to be queried or given provisioning orders, trying to provision in a flow-through environment will be difficult. That lesson is something probably learned in a lab or through testing rather than through reading any documentation.

The OSS software solution needs solution scalability. Clearly in the real example above, the operator wanted to deal with all order types and all order passes. There were situations with local service requests (LSR) and access service requests (ASR) with multiple providers providing pieces of the network that got in the way of providing an end-to-end service. Solution stability must deal with error conditions, and it must involve a process to handle rollbacks and to keep volumes down. Solution operability must contend with network and EMS unavailability and timeouts, and, hence, solutions should be engineered to limit the amount of error conditions. It must provide an increased view of network data, a single view of an order across the total environment, and message queuing (user interactions versus flow-through). That is why network operators are buying an automated set of systems, so that the network can be provisioned error free. Having the right interface specification is not the whole answer, but improved OSS is tied to how the NEs and EMSs behave. Availability is the heart of the matter.

An OSS Answer for Increased Speed

One of the answers to how OSSs will improve NEs and EMSs is a fully integrated network database. The value is in single data entry and single data retrieval. Obviously, using the network as the database will be helpful, but the trick is in crossing functionality—whether it is provisioning, assurance, or performance—and in not relying on separate databases. The goal is to have a single network touch point for all EMS interactions focusing on available standards. This will simplify network interaction. But if the goal is touching the network once, a common platform is the best path to take. A common platform will have a consistent standard operating environment (SOE), a common graphical user interface (GUI), system interface specification and documentation, integrated capacity planning and performance, and improved integration. Fewer servers will be needed, systems administration will become easier, and user interconnection will be simplified, multifunctional, and ready for system integration. A fully integrated network database, a single network touch point, and a common platform will make implementation more rapid and hopefully will simplify the lives of users and network operators. Replication requires simplification.

Summary

Multivendor networks are a reality, but their management is difficult. There are no quick steps to get around the interoperability testing to understand how EMSs behave. Following the element-management layer (EML) and network-management layer (NML) standards is helpful, but to think that they will solve the problems is naïve. Close relationships are needed between the OSS vendors and the equipment vendors to work on the expectations of what the EMS should or should not be doing. Following standards is not sufficient; the question of interface expectation needs to be addressed. Managing multivendor networks goes far beyond gaining connectivity to multiple vendors' NEs or EMSs.

Billing for Wholesale Services: Just Like Retail, or Is It?

Becky Dancy
Director, Business Development
Abiliti Solutions

Like a stadium used for both baseball and football, a billing and customer-care system used for both wholesale and retail billing can present challenges. While the stadium must change field configuration, sports equipment, and the team players, the software system must support differing business models, business drivers, and network architectures. A billing and customer-care system supporting both types of services must balance differing invoice formats, account structures, customer access, reports, taxation, usage guiding, collections capabilities, rate plans, reconciliation, and so on.

Customer demographics and expectations for wholesale and retail services vary greatly. For example, a wholesaler may have 40 to 50 large customers while a retailer's customer base can number in the hundreds of thousands. And, while the retailer's customers may charge only a hundred or so dollars each month, the wholesaler's customers can have thousands of dollars of monthly billing. The differing service-level expectations and functionality needs for retail and wholesale services make their mark across all components of a billing and customer-care system.

To illustrate, existing retailers entering the wholesale market may assume that they can simply use their traditional retail systems to support their new business. However, this assumption may not be accurate. While traditional retail systems may very well get the wholesale invoices out the door and enable the providers' customer-service representatives (CSRs) to answer simple customer inquiries, they may not efficiently or cost-effectively meet the providers' actual wholesale business objectives.

Product Management

All billing systems must be able to support product creation and maintenance. So, why would a wholesaler need any special functionality in this area? If a billing system can support local, long-distance, or data services in a retail market, it should have no problems supporting wholesale flavors, right?

While this idea might be correct in many situations, wholesale businesses often extend beyond traditional telecommunications services. Services such as 800-number translation or caller-name delivery service are not standard retail telecom products, and a traditional retail system may not be able to define or rate these services. Specifically, most traditional retail billing systems support only two-digit charge amounts, such as $4.95 for caller ID. Database services such as the ones mentioned may require rates up to four or five digits (i.e, $0.00175 per look-p). The wholesaler that maintains a caller-name database and offers that service to other telecom providers must have a billing system that can define and maintain this "unique" service.

Additionally, typical wholesalers use individual case basis (ICB) pricing for a large percentage of their customers. So, a wholesale billing system must be able to efficiently support special pricing for each customer. While a retailer probably places more importance on a system that supports global, mass pricing updates, a wholesaler needs a simple and quick way to make individual customer-rate updates. This is critical in many situations. For example, a wholesaler of international long-distance services with 10 percent of revenue from delivering traffic to Germany discovers that a competitor has introduced a lower rate to Germany. If the billing system is not able to support ICB updates quickly, the wholesaler is likely to lose a large portion of its business.

For a retail provider, the ability to offer the infamous "buy one, get one free" or a "purchase local and long-distance service and get Internet free" promotion is critical. This type of packaging is not really crucial for wholesalers. The ability to provide tiered and stepped volume and contract-based discounts, however, is essential. A wholesaler must be able to discount based on term of contract and committed usage (revenue, minutes of use, packets, etc.), and be able to discount not simply on the current month's activity, but also on the aggregate usage over a period of months or years.

Order Management and Provisioning

Billing and customer-care systems must be able to support order entry for all the services that they plan to offer, both traditional and nontraditional. This includes the ability to capture the data elements for each service type, as well as the ability to manage the ordering and provisioning process.

For instance, in a wholesale environment, where service providers are likely be involved in the final testing of the circuit or service, the billing system's order-management function must allow the capture of the end user's contact information, as well as the wholesaler's customer. It should also allow the addition of new provisioning steps to include end-user testing—without significant programming. Further, a wholesaler needs to be able to notify its customers—either via an application programming interface (API) or a manual process—that their service has been activated and tested, so they may begin billing their end users.

An increasing number of service providers are offering their end users remote access to account information through remote dial-in, direct connect, or the Internet. This allows the customers to query order status and even perform order entry themselves. When taking this route, service providers must ensure that their billing systems allow easy navigation around account data and that they contain adequate security measures to prevent inadvertent access to unauthorized information, or changes that could negatively affect service levels.

Event Processing

Because wholesalers may process 500 million event records or more per month, their system must be able to support greater throughput than the amount traditionally required by retail systems. But, throughput is not the only event processing-related question that must be considered.

Another, perhaps even more important, question is, "Can the system guide and rate the various types of event records that need to be processed each month?" If the system cannot guide the records, it is irrelevant how great the throughput of the system is. To illustrate, consider the situation of the before-named wholesaler that provides a caller-name service. These event records may be guided by point code or a customer ID, rather than "traditional" keys such as automatic number identification (ANI) or an 8xx number. In other words, the wholesaler may need a billing system with a flexible event-processing engine, not one that just has a high throughput capability.

Taxation also plays a major role in terms of event processing because, in most cases, taxes are not applicable in the wholesale arena. Not only does this eliminate the requirement for an event-processing system that can tax efficiently and correctly, it eliminates maintenance of tax tables and the creation of multiple tax log reports.

Customer Care

Wholesalers typically service their customers with dedicated account teams, while retailers usually have centralized customer call centers with hundreds of service representatives. These divergent approaches result in different demands on a customer-care system.

Because retail customer-care centers are often driven to effectively process a high number of calls with minimal call duration, the application must facilitate efficient navigation. This feature is not as critical in a wholesale environment where, generally, the interactions between the service providers and their customers are not necessarily as time sensitive. While it is obviously just as important to have all the necessary customer information available to the representative of a wholesale provider, it is usually acceptable if the navigation to get to that information is not as efficient.

Other issues related to customer care are account structure and scripting. In most cases, wholesale clients require less complex account hierarchies than retail business customers—wholesalers typically do not have to be able to represent their customers in two or three tiers with complex relationships. Likewise, the use of scripting to support customer-care dialogs and additional product sales is a more prominent issue for retail businesses.

The data-entry requirements for wholesale versus retail systems vary as well. In fact, a typical retail system may capture a high amount of extraneous information that is not necessary for a wholesaler's basic customer profile. For instance, a consumer system may have data fields for a driver's license number and a social security number, which are not applicable for a wholesale business. For both wholesale and retail applications, being able to hide or modify customer profile fields so they are more applicable to a service provider's business is a critical capability.

An area that is receiving increasing attention in both the wholesale and retail markets these days is customer self care. Service providers in both segments view the ability to allow customers to access account information and perform basic self-care functions—such as remote, real-time access for order entry and order status; invoice preview and payment; and trouble reporting—as a competitive advantage.

Credit and Accounts Receivable

On the financial side of the business, retail systems typically have more demanding requirements than wholesale systems. Wholesalers usually do not need automated credit checks and credit scoring to support their business, while these features are critical to a retail provider. Additionally, since most wholesalers use account teams to support their customers, they have less of a demand for sophisticated collections modules. However, the wholesaler's system will need to be able to create standard financial, aging, and collection reports.

Similarly, many billing and customer-care systems offer a wide variety of payment options, such as lockbox, Web, credit card, and bank draft. While this range of options is often very attractive for retailers, wholesale providers may not necessarily need such a big range, and they can end up paying for functionality that they do not really require if they aren't careful.

Invoicing and Reports

The invoice is the key mechanism that a service provider has to communicate with its customer base—in some cases it is the only way. For wholesale customers, however, the invoice and its associated reports are vital tools for managing their business. The invoice is their single device for reconciliation and network-cost management. For example, in a wholesale environment, the customer may be reselling services from a single source or from multiple providers. Whatever the case, the client has to manage and reconcile the amounts he is charged with the amounts he is billing to his end customers. The analysis involved in this mission-critical function can be very complex, and an effective wholesale billing system is one that enables the process for the wholesaler's customers.

Therefore, wholesale invoice information must allow the customer to easily and accurately compare invoice information to financial records. In most cases, this will mean providing the information electronically and allowing customers to freely manipulate the data and massage it into layouts that cleanly match their own records or billing-system outputs. For example, the billing system may produce reports (or invoices) that sort all services by product type. While this is certainly an acceptable, logical approach, the customer may record financial or billing information by customer or service ID. To simplify this customer's reconciliation and analysis process, an invoice format that allows the resorting of information by unique requirements is needed.

Another key item in the wholesale reconciliation process is allowing the customer to tie the amount that they are being charged for a given service or product to the amount that they are billing their end users. Or, more basically, enabling them to easily ensure they are actually billing an end user for all of the services and products for which they are being billed. Doing this requires the creation of a common identifier that can quickly and easily tie the services together. In some wholesale cases, this is more complicated than it might first appear. In the long-distance or local environments, for example, where the common identifier in most cases can be the 10-digit ANI, this process is relatively straightforward. However, it can become much more complicated when the identifier needs to relate features or other additional charges to the base service. For instance, wholesalers of local services may sell local features *à la carte,* while the customer retails the same features as part of packages. Reconciling the individual charges on the invoice or report to a package charge in their records may be complicated.

In the data world, where circuits are often combinations of various pieces, the reconciliation process can be very complex. For instance, an asynchronous transfer mode (ATM) circuit may consist of a local-loop circuit and 5 megabits per second (Mbps) user network interface (UNI) port in Denver, a local-loop circuit and 10 Mbps UNI port in Kansas City, and the 5 Mbps permanent virtual circuit (PVC) midlink. Not only may data providers have multiple ways to bill the service—each charge broken out on the invoice, combining charges based on node charges and PVC charges, flat rate versus usage based, etc.—but they may also take different approaches to identifying each piece. Specifically, does the port have a unique ID, or does it carry the same ID as the local loop?

In most cases, the circuit IDs provided to the wholesale customer will not be the circuit IDs that the customer will use to identify the circuit for their customer. They may simply change the lead letters or numbers (for example, ID ABC1234 becomes XYZ1234) or they may implement completely different number schemes (either by choice or required by their operations support system [OSS]). The ability to tie these network elements (NEs) and their charges from the information a wholesaler provides on an invoice or report to their records is critical for reconciliation. A wholesaler must ensure that its billing and customer-care system makes the reconciliation process as simple and streamlined as possible.

Conclusion

In the increasingly competitive telecommunications industry, the features and functionality of a service provider's billing and customer-care system can provide true competitive advantages. When selecting a billing and customer-care system to support your operation, there are many questions that you must ask and considerations to balance—regardless of whether you are a wholesaler, retailer, or both. When evaluating your options, be sure that you weigh the availability of particular system features against how important those capabilities actually are to your business. A single system solution for both wholesale and retail operations may support your business, but you may have to accept some limitations. In other cases, the preferred solution may be to purchase two separate systems to support the complete list of business drivers and objectives. In other words, if you are both a wholesaler and retailer, you will need to strike a balance between the meeting the drivers for each business, the capabilities that a single system can provide, the cost of modifying a single system to support both businesses, and the cost of purchasing and maintaining two systems.

In any situation, be sure you match the system capabilities to your business needs, to ensure that you are spending your money wisely and are investing in those functions that will bring you the best return on that investment. In other words, don't pay for functionality that you don't need and, moreover, you'll pay dearly if you need functionality that you don't have.

QoS Support in the DMA Architecture: Implementation and Performance Analysis

Abstract

We have recently proposed the intra-domain mobility management protocol (IDMP) as a part of the dynamic mobility architecture (DMA), a two-layer hierarchical solution for managing the movement of mobile nodes within a cellular access domain. Like most Internet protocol (IP)–layer mobility management protocols, the basic IDMP specifications aim only to ensure uninterrupted roaming connectivity. This paper describes how the DMA architecture uses enhancements to IDMP to provide quality of service (QoS) guarantees for mobile users within a cellular access domain. DMA's QoS framework uses a modified form of the Differentiated Services (DiffServ) architecture, with a centralized bandwidth broker (BB) performing admission control and resource provisioning for different traffic classes within the access domain. We present the enhancements to the signaling and functional architecture necessary to seamlessly migrate QoS guarantees as a mobile changes its point of attachment. After describing our Linux and FreeBSD-based prototype implementation of this framework, we present performance results obtained on our testbed.

I. Introduction

IP–based mobility management solutions, such as mobile IP [Perkins:01], primarily aim to maintain basic network-layer connectivity to a mobile node (MN) as it changes its point of attachment to the fixed network infrastructure. For future wireless Internet access scenarios, an IP–based mobility management framework must not only provide ubiquitous connectivity, but also satisfy the often-divergent QoS requirements of different application sets. In fact, the ability to provision, ensure, and migrate QoS guarantees as an MN moves is an essential component of true multimedia mobility support.

Two principal models, the DiffServ [Blake:98] framework and the Integrated Services (IntServ, a.k.a. resource reservation protocol [RSVP]) [Braden:94, Braden:97] approach, have been proposed for QoS support in the Internet. Of these two, the DiffServ model is judged to be more scalable, as the IntServ model not only requires each intermediate router to maintain flow-specific state, but also needs additional tunneling mechanisms to work across IntServ-incapable intermediate nodes. Both models were, however, primarily designed for the fixed Internet: In DiffServ, the classification and traffic-conditioning policies at the network edge are typically set up offline, while in IntServ, reservation guarantees established via RSVP apply to a specific path and need to be re-established if one of the communication endpoints move.

Since the connectivity from the cellular domain to the Internet backbone is essentially static, traditional DiffServ mechanisms can be used to guarantee performance bounds up to the ingress, or beyond the egress, point of the cellular domain. To extend the QoS guarantee up to the mobile wireless device, it is also necessary to develop reservation protocols to over the wireless link (the "last hop")—a number of intelligent wireless link layers have thus been proposed to provide QoS guarantees over the error-prone wireless channel.

Our focus is, however, on the cellular access domain, which lies in between the wireless edge and the Internet backbone. As different mobile users, potentially with widely varying QoS requirements, continually change their point of attachment to the cellular domain, the traffic loads and the necessary QoS bounds needed on each intra-domain route can exhibit significant fluctuation. Accordingly, the conventional static QoS provisioning mechanisms are not appropriate for the cellular access domain; we require a QoS framework where QoS bounds can be signaled and network resources provisioned in a fairly dynamic manner. As such, we focus on adding two specific functions to the conventional DiffServ architecture:

1. *Dynamic QoS Signaling:* The QoS requirements of different MNs are communicated to the appropriate network nodes, especially as the MN changes its point of attachment.
2. *Resource Provisioning:* Since node mobility makes the traffic load and associated resource requirements on any path dynamic, the framework must be capable of dynamically altering the network resources (such as bandwidth, buffer sizes, etc.) allocated to different traffic classes or flows.

Since the cellular domain can easily have a few thousand (or tens of thousands) concurrent mobile users, such a QoS–aware framework must not, however, a) impose the maintenance of per-flow state information at all intra-domain nodes or b) require resource re-provisioning at each individual node movement.

In this paper, we present our DiffServ-based hierarchical QoS architecture associated with the IDMP. IDMP has been proposed in [Misra:00A, Das:00] as a two-level hierarchical mobility management protocol that reduces handoff latency and the signaling overhead of frequently roaming hosts by localizing most mobility management signaling within a wireless access domain. In IDMP, a specialized node called the mobility agent (MA) provides a stable gateway to the Internet, while subnet agents (SAs) located at the wireless access edge provide the MN an additional local care-of address (CoA) to handle intra-domain mobility. The QoS solution is part of the DMA, which assumes the existence of multiple MAs in the access domain to provide robustness and uses load-balancing strategies to dynamically distribute the MN population set among different MAs.

The DMA QoS solution is based on the use of a BB [BB], a centralized node that controls all resource allocation and admission control strategies inside the wireless access domain. Prototypes and simulation studies have demonstrated the feasibility of using such a centralized solution for provisioning resources and performing admission control in moderately sized domains. The DMA QoS solution was first introduced in [Misra:00B] and consists of the following additional features:

- Additional *IDMP signaling* between the MN, the MA, and the SAs that allows the MN to communicate its QoS guarantees during its initial entry into the domain, and obtain seamless QoS support without additional re-negotiation on subsequent intra-domain movement.
- Additional *coordination* between the MA, the BB, and a new node called the mobility server (MS), which allows different MNs to be assigned different MAs, based on their individual QoS requirements and the network's current traffic-load patterns.
- Dynamic *provisioning* of resources for an MN. Whenever an MN changes its point of attachment, the corresponding MA determines if additional resources are necessary on the new traffic path and subsequently requests the BB to re-allocate intra-domain resources as necessary.

We first present the functional architecture for DMA–based QoS support, including the signaling flow among the constituent functional nodes and the enhancements needed to the IDMP specifications. We then describe our current implementation of the DMA architecture and the validation of our design on our experimental testbed. Performance results indicate that our IDMP–based QoS mechanism is able to support differential performance guarantees for MNs in a scalable manner. Additionally, the performance results demonstrate the rationale for our preference for certain MA–assignment strategies.

The rest of the paper is organized as follows. In the next section, we present an overview of basic IDMP and DMA functionality, as well as review alternative proposals for QoS support in the wireless access domain. In section III, we present the functional components of the QoS solution using IDMP and define the messaging interaction between the component nodes. In section IV, we detail our implementation of QoS–enabled IDMP and the BB, while, in section V, we discuss the performance results obtained on our testbed. Finally, section VI concludes the paper.

II. Review of IDMP and Alternative Intra-Domain QoS Strategies

In this review section, we present a short summary of IDMP functionality and discuss related work in the area of integrating QoS support with IP–based mobility management solutions. In understanding the functional details, it is helpful to distinguish between IDMP (which is a protocol) and DMA (which is an architecture for scalable, QoS–aware mobility management that uses IDMP).

A. IDMP and the DMA Architecture

IDMP is one of several approaches and protocols proposed for introducing a mobility management hierarchy. IDMP is part of a class of solutions, such as mobile IP regional registration (MIP–RR) [Eva:01] and hierarchical mobile IPv6 (HMIPv6) [Soliman:01], which develop an agent-based hierarchy by associating an MN with multiple CoAs and which do not require modifications to the current routing protocols. In contrast, proposals such as cellular IP [Campbell:00A] and HAWAII [Ramjee:00] use a more decentralized approach for intra-domain mobility management. In this approach, the MN is associated with a single CoA that has no locational significance. Host-specific routing entries are established at all intermediate intra-domain nodes to correctly forward packets addressed to this CoA to the MN's current location.

IDMP was introduced under the name TeleMIP in [Das:00] as a two-level hierarchical mobility management protocol for IP–based cellular networks. The DMA architecture [Misra:00A] uses IDMP for intra-domain mobility management; additionally, the architecture specifies the use of distributed MAs and the interaction with multiple global binding protocols. In this approach, networks are partitioned into mobility domains, each consisting of multiple IP subnets. To route packets to the MN's current location, the MN is associated with CoA. The global care-of address (GCoA) resolves the MN's location only to its current domain and hence remains unchanged as long as the MN moves within the domain. The local care-of address (LCoA) identifies the MN's precise point of attachment within the domain and accordingly changes with every change in subnet. To support this hierarchy, IDMP specifies a new functional entity called mobility agent (MA), which is similar to the foreign agent (FA) in conventional mobile IP but resides at a higher level in the network hierarchy. Global updates (to external servers such as mobile IP's home agent (HA) or to correspondent nodes (CNs) are generated only during *inter-domain* mobility and provide the MN's GcoA. In contrast, the MN informs its MA of its new LCoA via intra-domain binding updates whenever it changes its point of attachment. Packets from external nodes are routed (either directly or via tunneling) to the MN's GCoA. The MA intercepts these packets and then tunnels them to the MN's current LCoA. Besides limiting the scope of most binding updates to the local domain, IDMP also provides configurable support for additional mobility-related features, such as fast handoffs and paging (see [Misra:00C]).

B. Related Work on QoS and Mobility Management

Relatively little work has been performed on investigating alternative approaches for combining QoS guarantees with IP mobility support. The problem of using RSVP for mobile nodes was discussed in [Raj:96], which showed how MIP tunneling prevented RSVP RESV and PATH messages from correctly allocating resources along the path from the HA to the MN. Since all packets were encapsulated and tunneled by the HA to the MN, intermediate nodes did not directly see RSVP messages and could not set up appropriate reservations. Moreover, IP–in–IP encapsulation also obscures the inner header; even if the intermediate routers between the HA and the MN did have reservation states set up, they would be unable to classify packets without looking inside the encapsulated payload. Accordingly, it would be difficult to ensure specific QoS guarantees to *a subset of flows* directed toward a specific MN. To solve this problem, Foo and Chua [Foo:00] proposed a modified version of tunneling support in RSVP. In this approach, RSVP PATH and RESV messages are generated by the tunneling endpoints (such as the HA and the FA) to allow intermediate routers to process such messages. In addition, the proposal defines a user datagram protocol (UDP) encapsulation technique that permits the HA to put additional QoS–specific information in the outer header to enable differential treatment by intermediate routers. However, the absence of a hierarchy in MIP for decomposing the resource reservations leads to problems with this approach. Whenever an MN changes its point of attachment (and hence its CoA), new RSVP messages will need to be exchanged along the entire path from the CN to the MN, even though the change may have been confined to the last hop. MRSVP [Talukdar:00] is another approach toward modifying standard RSVP for mobile hosts. In this approach, the MN is assumed to know the set of potential subnets that it may visit during the lifetime of the session; specialized agents on such subnets set up passive resource reservations in advance to account for possible changes in the MN's point of attachment.

A multiprotocol label switching (MPLS)–based solution for QoS in MIP was presented in [Choi:01]. This approach essentially requires the HA to set up a label-switched path (LSP) for MPLS–based forwarding of packets to the MN. In typical implementations, packets addressed to a registered MN are intercepted by the HA and tunneled to the MN's CoA along the fast path through the use of virtual interfaces. The MPLS–based solution however requires additional per-packet classification and labeling functionality at the HA, thereby disallowing use of the fast path and leading to potential performance concerns.

A DiffServ–based architecture for QoS support in mobility domains has been proposed in [Chen:00]. The architecture uses a centralized QoS global server, or QGS, (functionally equivalent to the BB) to manage resources and perform admission control for all MNs in a domain. The QGS also interacts with the ingress nodes, called QoS local node (QLN) located at the ingress edge of the wireless interface to dynamically set up the conditioning and marking functions for individual MNs. However, unlike IDMP's QoS framework, this approach does not separate intra-domain QoS from inter-domain QoS management. Moreover, the solution potentially requires all ingress routers in the domain to parse the inner header in encapsulated packets.

III. The QoS Architecture in DMA

Under the DMA approach, we split the end-to-end QoS management into two distinct parts. The global QoS framework uses the conventional Diffserv/MPLS framework to manage resources between the MA and the global Internet, while the intra-domain QoS framework localizes the dynamic component of resource provisioning within the domain and provides QoS support between the MN and the MA. The architecture requires all inbound (to the MN) and outbound (from the MN) packets to be routed via the MA. Since the MAs are static nodes and handle traffic for an entire population of MNs, global (inter-domain) QoS provisioning can be handled by static resource provisioning and the specification of conventional service-level agreements (SLAs). Intra-domain resource provisioning, on the other hand, is more dynamic (on account of node mobility) and requires enhancements to the base IDMP specifications. In accordance with the DiffServ architecture, the wireless access domain conditions the traffic for the MN at the following two points:

1. For inbound traffic, the MA shapes/polices traffic (before it is tunneled to the current LCoA) to the specified inbound rate.
2. For outbound traffic, the SA shapes/polices packets (before they are tunneled to the MA) to ensure conformance to the outbound traffic descriptor.

A. Functional Layout of QoS-Related Elements

The functional architecture for QoS support is shown in *Figure 1*. The DMA specification includes two new entities, the mobility server (MS), which implements the load balancing algorithm that dynamically assigns MA(s) to an MN, and the bandwidth broker (BB), which dynamically modifies network resources reserved for different traffic classes at each intermediate domain node. In simple terms, the QoS functionality involves the following fundamental steps:

1. The MN must first specify its QoS requirements during its initial registration with an SA in the domain.
2. These requirements are relayed by the SA to the MS, which uses a load-balancing algorithm and other policies to dynamically assign the MN to a specific MA. When the MN registers with the MA (to obtain a valid GCoA), the MA may subsequently modify the QoS assurances.
3. On every subsequent movement within the domain, the MA is responsible for communicating the MN's outbound traffic descriptor and classification policies to the new SA—this obviates the need for additional QoS signaling from the MN at every move.
4. Since the MN's movement changes the path between the MA and the MN, the current resources allocated for the MN's traffic classes along the new path may not be adequate to satisfy the assured QoS levels. In that case, the MA will request the BB to provision additional resources on this new path.

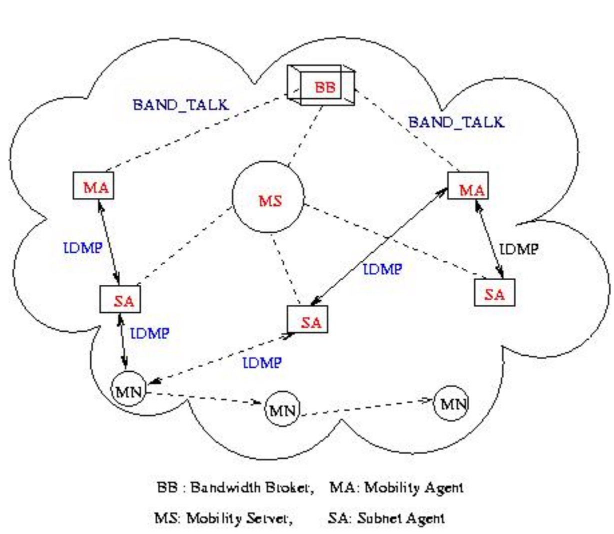
We now provide a brief description of the QoS–related functionality of each of the conventional IDMP elements, as well as the function of the new IDMP elements.

MN: The MN is responsible for indicating its QoS requirements (possibly for different classes) during its initial registration in the domain through extensions specified in the IDMP subnet-specific and intra-domain location update messages.

SA: The SAs essentially behave as edge nodes for the cellular domain. For outbound traffic, the SA classifies packets into different classes (marking) and conditions (policing/shaping) them to ensure conformance to the negotiated traffic descriptor. Since inbound traffic is policed for conformance at the MA, the SA simply forwards such traffic to the MN. The SAs are informed about an MN's traffic profile by the corresponding MA(s) using IDMP control messages. When an MN first moves into a domain, the serving SA also queries the MS to obtain the identity of the appropriate MA(s).

FIGURE 1

QoS–Related Functional Elements of the DMA Architecture



MA: The MA delineates the boundary between the global and intra-domain QoS portions. For outbound traffic, the MA is responsible for conditioning the aggregate traffic to ensure conformance to the global (inter-domain) traffic descriptor. For inbound traffic, the MA must condition packets and mark packets on a per–MN (and per-class) basis to ensure conformance to the specified downstream traffic profile. To perform admission control for a new MN, or to provision additional resources as existing MNs move within the domain, the MA interacts with the BB. *We assume that the MA typically contacts the BB to request bandwidth based on aggregate traffic, rather than issuing reservation requests for individual MNs*. Whenever an MN changes its point of attachment, the MA will need to inform the corresponding SA of the MN's current traffic descriptor and the necessary conditioning actions. In the vast majority of such cases, the MA will not need to interact with the BB, as the aggregate resources will usually prove to be adequate. The MA will interact with the BB only when the current aggregate reservation levels on the new path are not adequate to handle the new traffic load.

BB: The BB is the central entity for admission control and QoS provisioning and maintains information about the resource allocation and consumption at all intra-domain nodes. When the MAs request the BB for additional bandwidth (and other resources) on specific paths to accommodate dynamically varying traffic loads, the BB issues requests to internal domain nodes (including the SAs and the intermediate routers) to dynamically alter the resources allocated to different classes. The BB can also negotiate with BBs in other external domains for provisioning global QoS bounds.

MS: The MS acts as the intelligent control entity that allocates MA(s) to a new MN in the domain. When an MN moves into a domain, the serving SA requests the MS to assign one (or more) MA(s) to the MN. Unlike the BB, the MS is not involved in configuring resources at intermediate nodes but simply in balancing the specified traffic load according to configured policies.

B. Typical Messaging Flow

Figure 2 provides the messaging flow as an MN first enters a new mobility domain in the QoS–aware DMA architecture. The added functionality required the definition of additional IDMP messages and message extensions as follows:

- The *Subnet-RegistrationRequest* message has been extended to include QoS–specific extensions, such as the peak rate and desired packet delay.
- Extensions to the *Intra-domain LocationUpdate* message allow an MN to specify the requested QoS parameters to the candidate MA.
- Extensions to the *Intra-domain LocationReply* message allow an MA to specify the assigned QoS parameters to an MN. This is necessary as the MA may modify the QoS parameters requested by an MN.
- The *UserUpdate* message is sent by the MA, upon an intra-domain movement by the MN, to the new SA to

provide it with the MN's traffic descriptor and conditioning policy.

- A corresponding *UserAcknowledge* message has also been defined for communication from the SA to the MA.

Additional non–IDMP message exchanges are necessary for communication between the IDMP–specific nodes, such as the MA and SA, and the QoS–specific entities, such as the MS and the BB. We shall describe our current implementation of the *MA/SAfl‡BB* communication in section IV.

C. MA Assignment Strategies

As the entity responsible for assigning an MA to an MN registering in the domain, the MS is a key component of the DMA architecture. Different MA assignment algorithms may be appropriate for different QoS differentiation scenarios. In the simplest (and most common) form of QoS support, different users are guaranteed different traffic rates (from a small subset of rate profiles), with uniform treatment for all traffic belonging to a single user. For this model, [Misra:00B] recommends that an MA manage the mobility and QoS requirements of users belonging only to a single traffic class; different sets of MAs are used to handle traffic belonging to different traffic classes. Since an individual MA supports only a single class of traffic, it can apply a uniform header-marking policy for all inbound traffic. Removing the need for differential treatment of different user packets reduces the potential for performance bottlenecks, since experimental evaluation of our implementation (discussed later) shows that QoS–related functionality can significantly add to the packet forwarding latency at the MA. In the more advanced differentiation scenario, different flows belonging to a single user are classified into separate traffic classes; a single user thus subscribes to multiple QoS classes. Even in such a scenario, analysis shows that it may be better for a specific MA to service traffic belonging to only one service class: Not only does this alleviate processing-related concerns, but it also allows an MN to request different mobility support features for different traffic types. Of course, this approach requires enhancements to IDMP, since an MN must now be concurrently associated with multiple MAs (and hence multiple GCoAs). For a detailed discussion of the pros and cons of different MA–assignment strategies and their effect on IDMP messaging flows, the reader is referred to [Misra:00B].

IV. Prototype Implementation

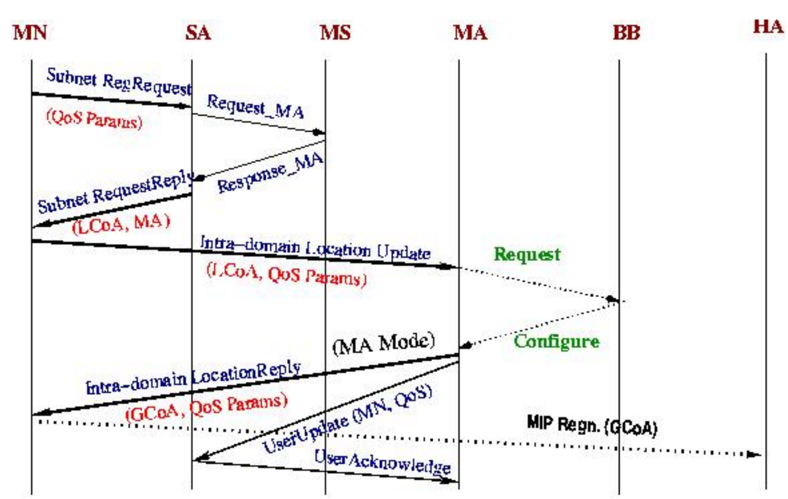
In this section, we describe our prototype implementation of the DMA functional elements. In our current version, we do not have the MS functionality; thus, all requests for traffic belonging to a specific QoS class are routed to a single MA, based on manual configuration of policies at the SA. Our implementation of the MN is obtained by modifying the Linux-based MosquitoNet [MosquitoNet] implementation of MIP; the MA, SA and BB code are based on the FreeBSD platform.

To allow communication between the BB and the MA/SA, we implemented a simple UDP–based BAND_TALK protocol. This is a simple message-exchange protocol where communication takes place through four different message types: request, query, report, and configure. The sequence of messages exchanged by this protocol can be briefly described as follows:

1. When an MA needs to allocate bandwidth on a certain path, it issues an appropriate *request* to the BB.
2. The BB then issues *query* messages to the appropriate intermediate domain routers, asking them for current resource reservation and utilization figures on various links.
3. All the intra-domain nodes then send their status information through appropriate *report* messages.
4. Finally, the BB issues new *configure* messages to the various intermediate routers, as well as to the MA, indicating the successful completion or rejection of a new reservation.

FIGURE 2

Signaling Flow for QoS in the DMA Architecture



In our current implementation, differential treatment for packets belonging to different classes is implemented via the class-based queuing (CBQ) code (CBQ/ALTQ) from [ALTQ], which implements TOS–based classification and priority scheduling of packets. For our prototype implementation, we implemented just two traffic classes: the default best-effort traffic class and the premium gold traffic class. Service for the gold traffic class is specified through a guaranteed service rate; the service essentially mimics the virtual leased-line service that is developed using the expedited forwarding (EF) per-hop behavior (PHB) [Jacobson:99]. Admission control/provisioning for the gold class is performed by checking that the available bandwidth on the traffic path is greater than the requested rate; traffic conditioners (SA/MA) *shape* the traffic to ensure that the profiled peak rate is not exceeded. We now detail the software architecture of the various DMA functional elements.

A. Mobility Agent

Figure 3 shows the distinct components, and their logical connectivity, in our implementation of IDMP's MA. The main components of the software suite are as follows:

- *MA_Server:* This module establishes the communication between the MA and the BB. It uses a well-known UDP port to communicate with the BB, with retransmissions for reliable data transfer. The MA_Server sends request messages to the BB to provision a new MN (or an MN that has changed its point of attachment). In response to the corresponding configure message from the BB, the module interfaces with the ALTQ/CBQ daemon to update the bandwidth reserved for different TOS classes. To allow the BB to obtain resource utilization from the various intermediate routers (including the MA and SA), the MA_Server daemon must also respond to BAND_TALK query messages that are multicast to a domain-scoped multicast address. Accordingly, it includes a Multicast-Server module that manages the multicast socket interface that responds to multicast messages from the BB.
- *BAND_COLL Agent:* This process calculates the current traffic loads associated with each Layer-2 interface and returns the current bandwidth utilization (for each class) to the MA_SERVER process. The monitoring of traffic loads on each interface is achieved through the netstat system call and a Java-based parser to collect statistics by appropriately parsing the netstat generated data.

In addition to the above components, the MA kernel code has also been upgraded to provide traffic-conditioning functionality. The *conditioner* filters/polices/shapes incoming packets on a per-user basis and is embedded into the kernel, with the use of virtual interfaces to redirect packets to the appropriate conditioning code. New iotcl calls are defined to allow the MA_Server to communicate the traffic descriptor for an individual user (IP address) to the conditioner and to allow the MA_Server module to update the CBQ/ALTQ daemon with modifications in the bandwidth reservations.

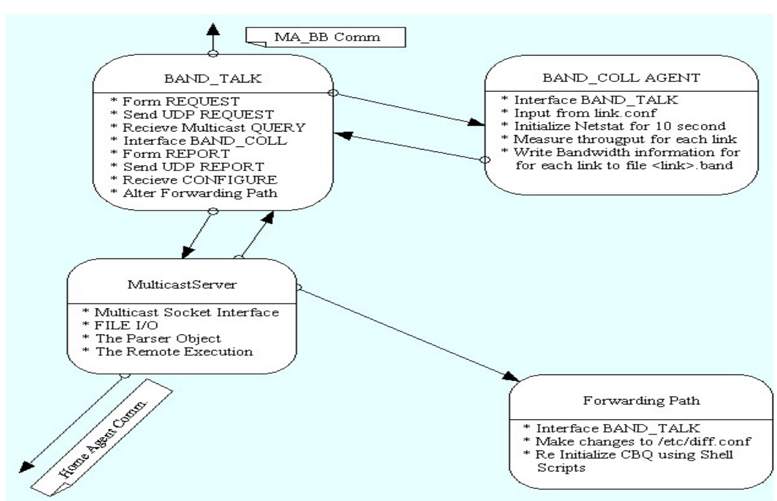
B. Subnet Agent and Intra-Domain Routers

The SA software component is very similar to that of the MA; both the SA and the MA are essentially edge nodes in the DiffServ–enabled cellular access domain and thus perform similar actions such as traffic classification and conditioning. The SA component thus not only contains the ATLQ/CBQ code, but also the functionality of the BAND_COLL agent and the conditioning agent, as well as the kernel-layer conditioner code. Furthermore, as shown in *Figure 2*, the SA and the MA are responsible for exchanging IDMP messages that inform the SA of the traffic descriptor corresponding to a specific MN.

For our prototype implementation, each intermediate router in the cellular domain was configured to run the SA_Server code to allow such nodes to respond to query messages from the BB and also to receive configure messages that

FIGURE 3

Organization of MA's Software Modules



adjust the resources reserved for different service classes.

C. Bandwidth Broker

Fundamentally speaking, the BB has several different functions to fulfill in the QoS assurance process:

- It must receive new configuration requests from the MA(s) and then respond to them.
- The BB must query all intra-domain nodes to determine current resource reservation and traffic utilization levels for different traffic classes.
- Given the set of concurrent resource requests in the domain, the MA must be able to determine the appropriate resource provisioning required at all intra-domain nodes. If adequate resource provisioning is not possible, the BB must reject such reservation requests.
- Finally, the BB must be able to communicate any changes required to the current resource reservations for various traffic classes back to the intermediate routers in the domain.

For portability, the BB functionality was implemented as a Java-based application. The software architecture of the BB consists of the following components:

- The *BAND_TALK* client: This process interacts with the MA to receive and respond to new reservation requests, as well as with the SA and other intermediate routers to obtain utilization information and send configuration requests. As stated earlier, the BB collects usage statistics by sending BAND_TALK query messages to a multicast address and provides new configuration parameters to domain nodes via configure messages. On receiving report messages from various domain nodes, the BB spawns separate threads that store and process the reported link utilization information. To store this information efficiently, the BB uses a synchronized array object that allows consistent access to data across multiple application threads.
- The *BAND_FLOW* process: This process is at the heart of the BB functionality, since it implements the admission control and resource-provisioning algorithm that must be invoked for every new BAND_TALK request from an MA. The admission control for a best-effort user is simple: By definition, best-effort flows are always admitted. To perform admission control for a gold class (priority) user, we have implemented a simple max-flow–based algorithm described next in *Figure 4*. The algorithm assumes that the entire cellular domain is represented as a graph, with vertices corresponding to the intra-domain nodes and edges corresponding to the traffic links between such nodes. Link i is assumed to have a maximum capacity of C_i.

The algorithm is very simple to understand. Whenever a new request arrives at the BB, the BB first obtains the least-loaded path from ingress to egress, i.e., the path that maximizes the residual bandwidth on the bottleneck link. Subsequently, it computes whether the requested resources can be reserved on that particular path. The first path of this determination is straightforward: If the reserved rate for gold class traffic can be increased by the requested rate without violating the capacity constraint, then it is always accepted. As a secondary heuristic to improve network utilization, we also admit the new traffic request if such provisioning would not cause the current utilization levels to exceed the capacity by more than *15 percent*. (This is based on our observation that multimedia traffic often does not utilize the reserved peak rates; hence, some statistical gain is possible.) We do not make any optimality claims about this heuristic mechanism; indeed, our focus here is not on the exact admission control scheme but on the associated signaling architecture. Thus, an operator that wishes to perform worst-case admission control for the gold class would clearly run the Ford-Fulkerson procedure with link weights set to $Resid_i = C_i - Resv_i$ and accept the request only if $Req + Resv_l < C_l$ alone.

V. Experimental Set-Up and Implementation

To study the performance features of our implementation, we set up a testbed as shown in *Figure 5*. Two independent IEEE 802.11-based subnets were defined, and the SAs (not shown in the figure) were co-located with the wireless local-area network (LAN) access points. As the MN moved across

FIGURE 4

Admission Control Algorithm for Gold Class

- ❖ Assume that a new request is made for *Req* capacity from node *A* (ingress) to node *B* (egress).
- ❖ Use the BAND_TALK protocol to obtain the current utilization, $Util_i$, as well as the resource reservation for the gold class, $Resv_i$, for each link i in the domain.
- ❖ Set up a graph ***G*** representing the domain topology with the weight of link i equal to the residual capacity $Resid_i = C_i - Util_i$.
- ❖ Run the Ford-Fulkerson algorithm to determine the max-flow path P in G from A to B.
- ❖ Obtain the bottleneck link $\boldsymbol{l}$ (one with the least residual capacity) in path P using $\boldsymbol{l = \arg\min j: Resid_j ; j\ e\ P}$

If $Req + Resv_l <= C_l$, then accept request;
If $Req + Util l <= 1.15 * C_l$, then accept request;
Else reject request.

- ❖ If request is accepted, then upgrade $Util_i$, $Resv_i$ for all links[1] on path P.

the LANs, it would be assigned a new LCoA, although its MA would not change (thus, the entire network was treated as a single domain). The QoS–related code was implemented on the MAs and the SAs. Depending on the traffic path, an MA might also act as an intermediate router. For the purpose of comparison, we also deployed a publicly available version [CIP:01] of cellular IP on our testbed and performed identical experiments. It should be noted that, in contrast to our IDMP implementation, this implementation of cellular IP lies in the user space. Experiments with various settings of the reserved rate for the gold class, and concurrent gold and best-effort flows, verified that our architecture was able to ensure preferential queuing for premium flows and insulate their performance from the best-effort traffic load.

To further study the effects associated with our QoS implementation, we performed experiments where only a single active traffic flow (UDP or TCP) was present in an otherwise unloaded network. We carried out experiments by first classifying the active flow as gold traffic and enabling the QoS feature of DMA, and subsequently by classifying the active flow as best-effort and disabling DMA's QoS support. In the absence of any cross traffic, the effective throughput and loss characteristics should ideally be independent of whether the flow is classified as gold or best-effort; any differences in performance results can really be attributed to the processing and forwarding overheads associated with our QoS implementation. We now report on experiments that attempt to investigate the following:

1. The impact of QoS processing on the handoff latency in IDMP
2. The effect of the DMA QoS features on the forwarding latency at various intra-domain nodes and consequently the overall throughput for TCP flows.

A. Handoff Latency

To first evaluate the handoff latency under IDMP, we injected a periodic UDP traffic stream from the CN to the MN, varying the intra-packet gap allowed us to adjust the transmission rate. By observing the sequence of packets lost during a manually triggered handoff, it is possible to bound the potential handoff delay. Under the assumption of constant one-way delays, a handoff loss of exactly N packets, each generated at a uniform interval of X ms, corresponds to an upper bound of $(N+1)*X$ ms and a lower bound of $(N-1)*X$ ms on the handoff delay. *Figure 6* plots the number of packets lost during handoff against the inter-packet gap, with both DiffServ–enabled (gold class) and DiffServ–disabled (best-effort class). For comparison purposes, we include the corresponding results observed on our testbed with the publicly available implementation of cellular IP hard handoff [Campbell:00B,CIP:01].

In our topology, we can see that the IDMP handoff is bounded by ~150 ms; additional IDMP fast handoff mechanisms proposed in [Misra:00c] should reduce this transient loss and handoff delay significantly. More importantly, note that the introduction of QoS mechanisms actually decreases the handoff loss somewhat; the processing and forwarding delay of QoS–related processing can actually lower the number of packets incorrectly forwarded to the old point of attachment. The graph also indicates that the *QoS–related signaling in IDMP does not significantly increase the handoff latency.*

We can also see that, even after incurring the overheads associated with QoS–related processing, the IDMP handoff delay is lower than that obtained with cellular IP. While we suspect that this is largely due to the user-space implementation of cellular IP, our results indicate that IDMP performance is, if nothing else, at least as *competitive* as alternative intra-domain mobility management solutions.

B. QoS–Related Processing Overhead

To quantify the forwarding overheads incurred due to the QoS–related processing in DMA, we subsequently observed the throughput of a single TCP flow as a function of the MSS

FIGURE 5

Topological Layout of Testbed

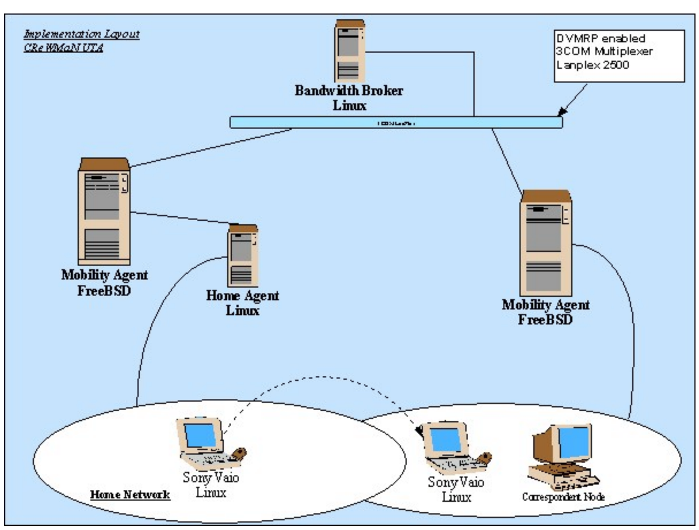


FIGURE 6

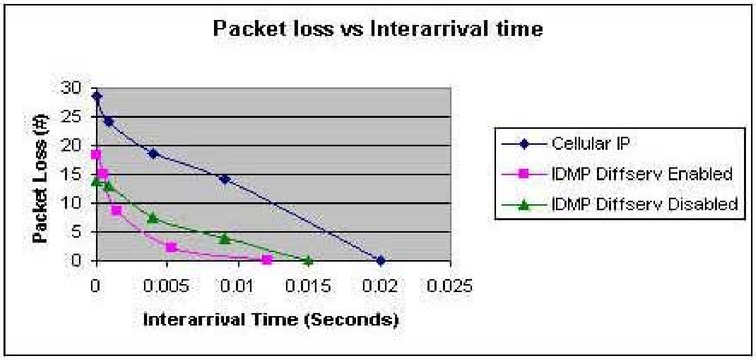
Packet Loss during Handoff Transient



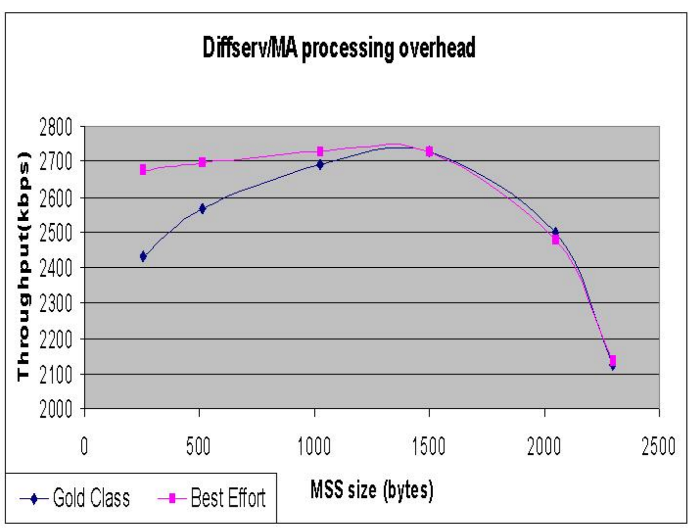
of the TCP connection, first with DiffServ enabled and TCP classified as gold traffic, and then with DiffServ disabled and TCP classified as best-effort traffic. This set of experiments involved no handoffs, as the MN was kept stationary. Clearly, functions such as classification and conditioning (on a per-user basis) at the MA and policing/shaping (on a per-class basis) at all intermediate nodes, including the MA and the SA, contribute to forwarding overhead. Since the overheads typically occur for every individual packet, the difference between the DiffServ–enabled and DiffServ–disabled cases is accentuated if the number of transmitted packets is larger. Accordingly, we would expect throughput differences to be larger for smaller MSSs, since a larger MSS implies that data is transferred in larger chunks (and consequently a lesser number of individual packets). This behavior can indeed be observed in *Figure 7*, which shows the variation in throughput as the MSS is varied between 256 and 2,400 bytes. The figure shows that the Diffserv–processing overhead can indeed be significant, since the throughput drops from ~2.7 Mbps to ~2.4 Mbps when the QoS–related processing is activated. However, this difference diminished as the MSS values correspond to larger (and more realistic) values. The sharp drop in the throughput beyond an MSS of 1,500 bytes occurs because the MSS exceeds the Ethernet link maximum transmission unit (MTU). The behavior is then dominated by the effects of packet fragmentation, which increases the layering overhead and degrades the effective throughput. The graph in *Figure 7* illustrates the potential for bottlenecks at the MA and supports our suggestion for MA–allocation architectures (as described in section III-C) that minimize the classification and marking functionality necessary at the MAs.

C. Handoff and Processing Overhead Trade-Offs

To further investigate the trade-offs between the processing overheads associated with traffic conditioning/policing and the mobility-related signaling in IDMP, we studied the throughput of a TCP connection as a function of the handoff

FIGURE 7

Impact of IDMP's QoS Processing on TCP Throughput



rate. *Figure 8* shows the plots for IDMP and cellular IP as the number of handoffs per minute is varied from *0* to *10*. For IDMP, we experimented with both DiffServ–enabled (gold-class traffic) and DiffServ–disabled (best-effort traffic) scenarios. The plot shows that for small handoff rates, the DiffServ–disabled TCP flow obtains a higher throughput than an equivalent DiffServ–enabled TCP flow. However, as the handoff rate increases beyond six handoffs per minute, the DiffServ–enabled TCP flow obtains a higher throughput. In fact, the performance of DiffServ–enabled TCP is relatively independent of the handoff rate. This can be explained by realizing that, at higher mobility rates, the throughput is affected more by interruptions due to handoff latencies than due to per-packet processing overheads. In fact, the processing delays caused by CBQ and classification functions at the MA serve to reduce the number of misdirected and lost packets during the handoff transient, thereby averting a significant reduction in the TCP throughput. The plot also shows that, even with the forwarded overheads associated with QoS processing, our DiffServ–enabled IDMP implementation is able to achieve better throughput than the cellular IP implementation (which does not suffer from any QoS–related overheads).

VI. Conclusion

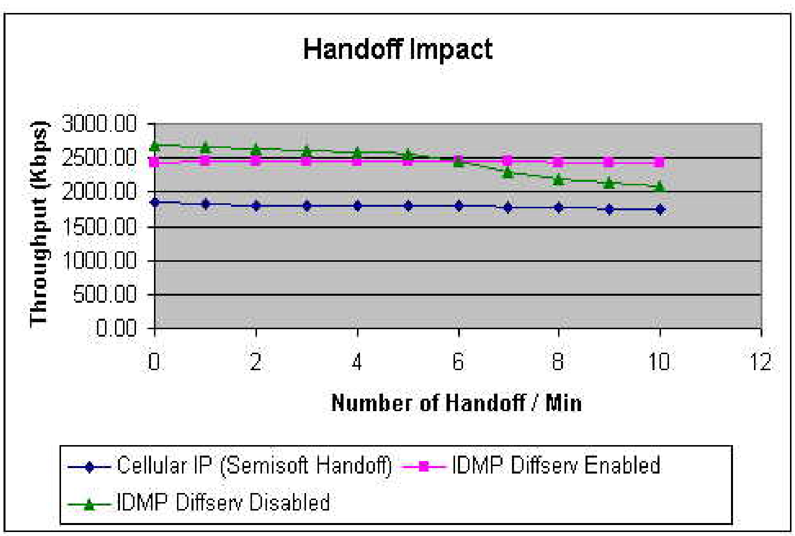
In this paper, we presented architecture for supporting QoS guarantees to mobile nodes under the DMA framework. Our proposed solution tackles the signaling and dynamic provisioning challenges in the cellular access domain that result from the potential mobility of hosts *within* the domain. We have shown how the IDMP two-layer intra-domain mobility hierarchy can be augmented to allow the MN to signal its QoS requirements during the initial registration in the domain. The architecture proposes a load-balancing strategy, where each such MN is dynamically assigned to potentially different MAs through an MA–assignment algorithm executed by a centralized MS. We avoid the need for subsequent QoS–related signaling during intra-domain movement by having the MA dispatch the MN's traffic and QoS profiles to the new point of attachment (SA), which can then condition outbound traffic appropriately. To provision resources between the MA and the MN's current point of attachment, we have used the centralized DiffServ–based BB architecture, which is responsible for signaling all intra-domain nodes with the appropriate reservation levels for different traffic classes. We have presented a simple, yet effective, admission control policy for a basic differentiation scenario involving two classes of service—one peak-rate controlled premium and the other best effort.

By experimenting with our prototype implementation on our testbed, we have developed an understanding of the performance and implementation issues. Our experiments show that the handoff latency does not differ appreciably in the presence or absence of QoS control in IDMP, indicating that our signaling framework does not incur significant latency. However, throughput studies show that activating the QoS–specific functions do result in somewhat lower than optimal throughput due to the forwarding latencies associated with QoS processing at the MA. Accordingly, we recommend architectures where the classification and marking functions at the MA are kept to a minimum, thereby alleviating a potential forwarding bottleneck.

Several pieces of our architecture need further development and investigation. For example, the MS still needs to be implemented, especially with suitable algorithms for load balancing across candidate MAs. Moreover, our architecture currently requires *both inbound and outbound traffic* to be relayed via the corresponding MA. In a more optimized framework, outbound traffic need not be relayed through the MA but can be directly routed to the domain egress routers. We need to develop protocols that allow such asymmetric packet forwarding. Security and authentication, especially in the context of QoS support, is another important area. For example, we need to investigate techniques

FIGURE 8

Impact of Handoffs and QoS on TCP Throughput



for the secure transmission of UDP–based BAND_TALK messages and their impact on the signaling overhead. Finally, we are also working on evaluating the relative performance of our architecture against implementations of other mobility management solutions, such as NUS mobile IP with RSVP tunneling and HAWAII, on our testbed.

Acknowledgements

The authors would like to thank Muni Bajpai and Wei Wu of the University of Texas at Arlington for their help in setting up the testbed and running the experiments. The work of Sajal Das was supported by an NSF grant, numbered EIA-0115885.

Notes

1. In addition to implementing such an algorithm, the network must also have the technological capability to ensure that packets from A to B actually follow the designated path P. This can indeed be achieved by technologies such as MPLS, where explicit paths can be set up, and is orthogonal to our QoS discussion.

Streamlining Operations for Service Providers in the Next-Generation Network Infrastructure

Olivier Daures
Product Manager
Compaq Computer Corporation

Introduction

This paper addresses operations from the point of view of a service provider rather than a vendor, concentrating on the new trends in next-generation networks, in particular wireless mobility and the growing role of IP networks, which bring new challenges to the service providers in terms of operations support systems (OSS).

There are three sections to this paper. The first section discusses services; the second, challenges for service providers in the years to come; the third, OSS requirements.

Services in the Coming Years

Real convergence over Internet protocol (IP) is extending IP everywhere, and everything nowadays tends to support IP. It is predicted that within the next few years, even the radio part of Universal Mobile Telephone System (UMTS), a wireless mobile standard, will be supported by IP. This is not the case now, as the radio part is supported by asynchronous transfer mode (ATM). Another example is low-level optical layers, which tend to support core router connectivity directly. This move forward will continue.

There are clearly two kinds of services worth distinguishing: Internet access (and everything around that) and virtual private networks (VPN) (a service that will increase dramatically in the years to come). It is very important for today's OSSs to be able to support both public and private services. The Internet itself is a large public network, but private IP–based networks, such as those that are made for third-generation (3G) networks and for voice over IP (VoIP), promise to grow. Convergence will affect services because the same services will be provided through a mesh of various access, network, and content providers. Mobility over 3G networks means wireless operators will both compete and cooperate with Internet service providers (ISPs) and network service providers (NSPs). The telecommunications industry is using mostly fixed lines at this point. But in the years to come, a new generation of devices and protocols will bring about value-added wireless mobile services, which will be made available through tiny hypertext markup language (HTML) or new versions of the wireless application protocol (WAP).

VPN Services

VPN services will be based mostly on differentiated services (DiffServ) and multiprotocol label switching (MPLS), providing new features such as closed user group (CUG) and class of service (CoS). IP VPNs are taking over from overlay VPNs, where point-to-point connections, such as frame-relay ATM, support intranets and extranets for business-to-business (B2B) support. Other services on top of VPN include VoIP and IP security (IPSec).

Also, with VPN, products, such as bandwidth on demand (based on resource reservation protocol [RSVP]), will allow for video streams and multicast broadcasting. This, in turn, means things like medical images can be shared in real-time between hospitals. VPNs will enable various value-added services (VAS), such as storage-area networks (SAN) and remote content servers for Web hosting, as well. Furthermore, wireless access will be an important feature in general packet radio service (GPRS) and 3G networks. No longer will laptop users have to make an extra connection. When business users have the opportunity for wireless mobile access, they will buy it; and what is interesting is that they will buy it from wireless operators, not from the current NSPs or ISPs. That may change, however. The ISPs will have to provide that access, so they will have to deal with the wireless operations to find agreements to provide such access.

3G Services

Third-generation services include high-speed data mobile access services in which the 3G network is used purely as access—it can be an access in itself to the Internet, for example. But 3G networks will bring specific services, such as electronic payment (e-payment) and location services, as well. Those application services will mostly be enabled by IP. Other 3G services will rely on voice and value-added voice services.

Architecture for 2.5/3G Services

The classical architecture for the 2.5G services is shown in *Figure 1*. Such 2.5G services include GPRS and UMTS, connecting mobile terminals to the radio network and onto the core backbone, where IP transfers the traffic to the services network. From there, users can be connected to networks of other service providers.

Examples of Mobility

Examples of mobility and its unique offerings abound. *Figure 2* shows how users, with certain handsets, can drag and drop for WAP, accessing HTML to create a page on their telephone set. This capability should prove to be of great interest to most consumers owing a WAP–enabled mobile phone. Another example of specialized mobile applications, as illustrated in *Figure 3*, is downloads with personal digital assistants (PDA). For instance, if an end user is walking down the street and passes a movie theater, that person might want to get some information about one of the movies playing. With a PDA and appropriate mobile access, the user will be able to effectively gather this kind of information. Indeed, it becomes staggering to think about all the potential services that can be and are being made available to consumers today.

Managing More Complexity

Given the shifting landscape in the telecommunications industry, service providers today must be able to manage change and increased complexity effectively (see *Figure 4*). As evidenced by the break-up of AT&T, companies can and must be split up in order to successfully specialize certain domain content providers. Access network operators and core transport network operators today have created a very complex scheme that is a challenge to business support systems (BSS) and OSSs.

Challenges for Service Providers

Service Assurance

Service providers must, first and foremost, reduce the cost of managing their network. They must increase service value by facilitating service level agreements (SLA) or service objectives (SO) for specific services and customers, especially for VPNs. Once SLAs are in place, providers have to define the parameters of their service guarantees and monitor the level of service being offered; ideally, these providers might even be able to exceed customer expectations by proactively resolving problems. Service providers must optimize the use and repair of the network for most revenue-generation services to strengthen service assurance capacity.

Service Delivery

Equally important as establishing this service assurance, service providers must also concentrate on reducing the lead-time to connect. That is, they must shorten the time necessary to deliver service to a customer. Automated service activation is crucial for this.

Time to Market

In addition, a service provider must work to reduce time to market so that it can be among the first to deliver a given new service. Doing this, however, can place an enormous amount of strain on the BSS–OSS chain. For example, a provider might have to put VoIP service on VPNs in five months' time. But that provider must realize the tremendous, if slow and progressive, pressure and strain that such an endeavor will be causing the BSS–OSS chain.

OSS Solution Requirements

OSS solution requirements include service assurance and service fulfillment. Service assurance includes such features

FIGURE 1

2.5G/3G Services

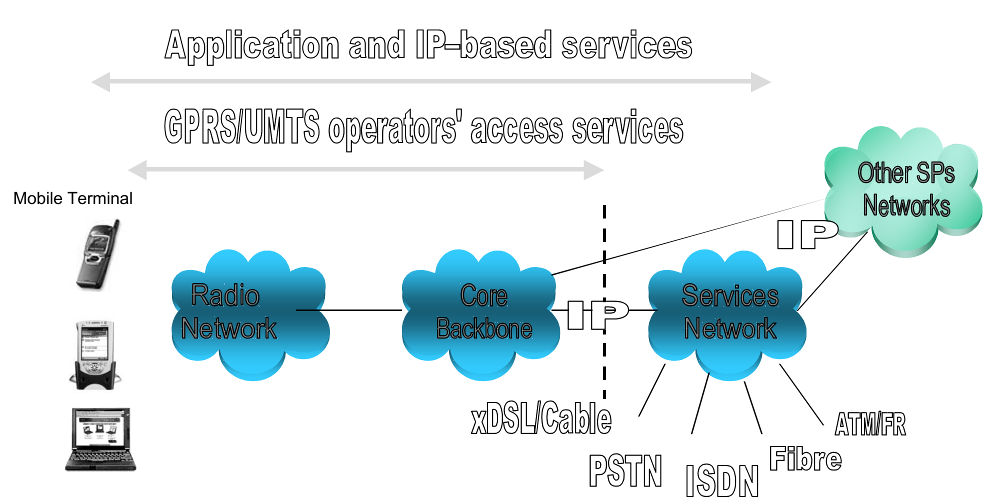

FIGURE 2

Drag and Drop for WAP

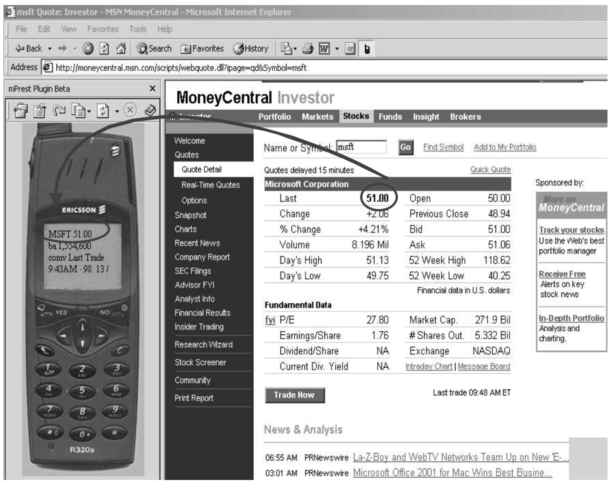

FIGURE 3

Downloads

fault and trouble detection, performance guarantees, service impact analysis, service-level monitoring, and SO monitoring. Taken together, such features might be considered a commodity. However, this is not the case right now because convergence has constraints to consider. In terms of service fulfillment, which entails more than mere service activation, service providers must deal with many challenges, such as the whole provisioning process and workforce management. Other service-fulfillment issues include configuration and inventory management and subscriber and end-user management (something that is forgotten from time to time). New on the horizon is mobile-device management with wireless services.

In terms of architecture, OSS solution requirements must account for cross-domains, such as IP, radio, and other access networks. OSS solutions must accommodate multiple vendors because nowadays it is unlikely that service providers will take everything from one vendor. A multivendor environment means having to manage disparate elementsæa requirement that also means any solution must be scalable. If not, it will be obsolete in a few years. In the IP world, many solutions came from the enterprise market. It is clear that availability and scalability of the system is key for many service providers; and it is very challenging for some OSS vendors to adapt to this kind of environment. It is very important, in fact, for service providers to take into account from the very beginning a solution that is cross-domain, multivendor, scalable, and highly available.

Key Service-Assurance OSS Requirements

In terms of key service-assurance OSS requirements, it is important for service providers to be proactive rather than reactive. To do this, they must monitor services, SOs, and SLAs before a problem occurs. Service providers need a complete end-to-end view, from the end user to the applications. For example, for UMTS, service providers must monitor the radio access part (air interface), the switched network, the core backbone, and the services network(s) of the applications. When a problem arises, service providers must be able to know where the source of the problem is, and they must be able to understand what they have to do to fix it. Service is not just an application on a server somewhere. It goes through the network, or several networks; and when a problem occurs at the end user side, it is very important to know exactly where it is.

OSS service assurance has to be customer oriented. Service providers need to have information in their OSS not only about their services but also about their customers. Service assurance, now more than ever, also needs to support the diverse business relationships that exist in the world today.

Key Service-Fulfillment OSS Requirements

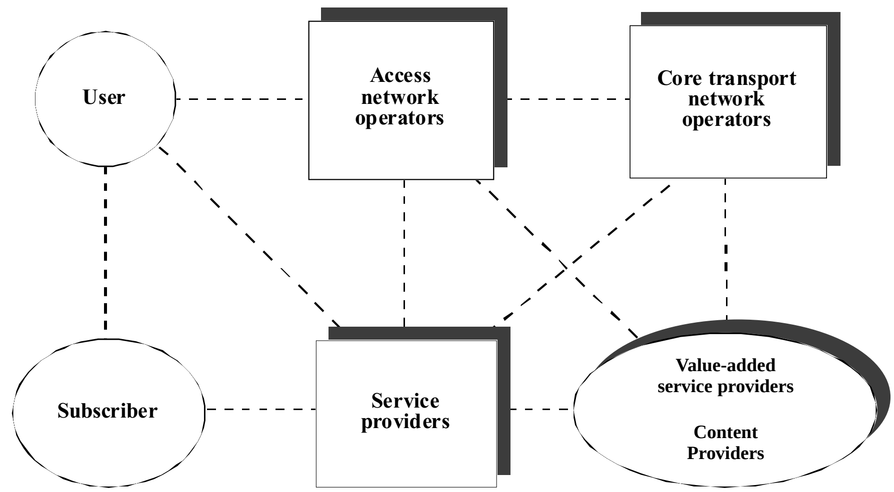
In terms of service-fulfillment requirements, OSS needs to handle convergence for services and technologies. A good example is GPRS, which is perhaps more widely known in Europe than in the United States. Basically, GPRS provides radio access to deliver IP connectivity over the Global System for Mobile Communications (GSM). In GSM, users are managed in a home location register (HLR), which is a completely separate system from the IP subscriber-management system. Does the user have to be managed via the GSM or the IP solution? In dealing with this convergence, issues such as this one are indicative of the types of questions that providers will have to deal with on a daily basis.

Another aspect of service fulfillment is hierarchical support of services and components. Whatever service providers release in their service, they never know if the service will or will not be used as the basis for another service. When service providers delivered frame relay access a decade ago, they did not imagine how that could be used for the IP networks. So OSS requirements demand flexibility to build things on top of the others.

Auto-provisioning is also a key area, one that comes mainly from the wireless world. It is very important for users to be

FIGURE 4

Managing Complexity



*Source: UMTS Forum

able to change services themselves, if possible with their handsets in hand. Users will eventually demand such a service, and service providers will have to comply with SLA and quality of service (QoS) support.

OSS service fulfillment must be workflow driven and take into account service provisioning of the various service elements and workforce management. For example, in VPN service fulfillment, key actions are delivered by human beings, not by systems. Service providers must follow the whole process.

The architecture should be repository based, mainly because there are too many components to deal with using any other approach. Enterprise application integration (EAI) and flexible formats, such as extensible markup language (XML), are important as well. And it is usually a good idea to have a steady plug-in capacity for applications. What is often challenging is trying to implement a "Big Bang" approach: the Big Bang approach generally does not work because the legacy environment is too complex for a large service provider; plug-in capacity allows for a steady way of dealing with this, though. Finally, Web access is another (perhaps obvious) requirement as well.

When Power Management Becomes a Power Struggle

Dennis DelCampo
Vice President, Customer Fulfillment, North America
Marconi Communications

Power Is the Starting (and Stopping) Point

Dependable power is the starting point for every network system and device, and continuous connectivity is vital to the profitability of any network—be it voice, video or data, copper, fiber, or wireless. Research studies[1] indicate that more than 45 percent of accidental data losses are attributable to power anomalies. Other studies[2] disclose that 50 percent of organizations account for downtime losses from power outage at $1,000 per hour, while 9 percent put their loss costs at $50,000 per hour or more. That is why many Internet-based companies, financial institutions, and other service providers are demanding higher-power system reliability, as high as 99.9999 percent ("six nines").

Growing and Changing Business

At the same time that network operators are striving for greater reliability, the rapid growth and restructuring of the telecom industry has placed additional demands on the distribution of hard-to-acquire capital and the utilization of technical personnel.

This has led to a major philosophical shift—from ownership and maintenance of networks by carriers and service providers to renting from network operators. This new direction is allowing the carriers and service providers to focus their resources and attention on providing an ever-expanding menu of customer services.

Paralleling this shift is a loss of network maintenance expertise through retirement and the discontinuation of the extensive training programs that Western Electric and the Bell companies once conducted—while large amounts of legacy equipment are still functioning in central offices (COs) and other installations that may have been in place for 50 or more years.

The Solution

Obviously, the network won't go away; indeed, it will continue to grow. And new, smarter ways are evolving to maintain it. The transition from reactive maintenance to preventive maintenance to predictive maintenance is a clear indication that this change is under way. Today, telecom industry leaders no longer look upon predictive maintenance as an expense; it is considered a *strategic investment in availability assurance*.

At the forefront in satisfying the demand for increased network dependability are dedicated network service companies with the skills, technology, and global presence to monitor, maintain, and manage telecom power from network operation centers (NOCs) and tech service installations strategically located around the world.

When the network owner cannot or does not choose to handle all or some part of the network-management tasks in-house, the owner can outsource specific tasks or the total network power management activity to a network service company.

Technology in Place

To monitor power systems at thousands of manned and unmanned sites without actually being there, network service companies rely on computerized data-collection equipment and telecommunication links to their NOCs. This data-collection equipment can gather data (including proprietary legacy communications) from a virtually unlimited number of shunts, probes, and sensors installed at the site to monitor equipment performance and site environment conditions. Basically, any condition that can be transformed into a voltage or current can be monitored.

Connectivity to the NOC can range from dial-up modems to switch provisioning to the Internet in order to carry data to a different area and transmit it to the NOC. The reams of data generated and transmitted to the NOC are handled with a variety of software, including event managers, element managers, performance-management packages, tracking packages, and database engines; and the data are transmitted using simple network management protocol (SNMP), a protocol that provides the framework for managing power devices.

How Service Company NOCs Work

The service company's NOCs (see *Figure 1*) are normally staffed by analysts who are very skilled, highly trained individuals that are able to operate in a multivendor environment (can deal with all brands and kinds of power equipment and ancillary equipment as well). The service company itself will normally have a historical understanding of power-equipment performance. Often, the service company may be affiliated with a manufacturer of power equipment.

Through the use of its remote network-management platform, the NOC's element-manager software talks to all attached devices, "polling" the data-gathering equipment installed at the remote site with a regular frequency determined by the network owner. The network owner also works with the service company to establish specific readings or equipment status levels as alarm thresholds.

Major, Minor, and Predictive Alarms

Alarms may be designated as major alarms requiring emergency attention (immediate dispatch of service personnel to the site) or minor alarms that may be deferred for resolution until the next business day. The network owner may also choose to establish "predictive" alarms for further evaluation. Predictive alarms indicate that the likelihood of equipment failure is imminent and that rebuild or replacement should be considered before service interruptions occur. Monitoring and tracking changes in battery string voltage, float current, and conductance, for instance, will enable end-of-life predictions to be made.

When a fault condition is detected, a NOC analyst will diagnose the situation and isolate the trouble source according to a "rules-based" workflow process. The analyst may also confer with technical experts on the system or equipment involved. When the fault is isolated, the NOC analyst will notify the network owner's designated contact if the service company is only responsible for fault *detection*.

If the service arrangement includes fault *reaction* as well, the NOC analyst will attempt to clear the fault remotely if possible. If the condition requires on-site repair and restoration, the analyst will notify the network owner's designated repair contacts within a predetermined time frame. Or, if the service company is also responsible for on-site repairs, the NOC analyst will dispatch the appropriate service personnel from the nearest service center or contact a third-party service provider if special expertise is required.

In addition to power system fault detection and reaction, the NOC, if desired, will monitor any other designated devices at the site, including gen sets, A/C, batteries, room alarms, and other ancillary equipment. Events and data logged by the NOC can then be used for performance reporting and network-planning activities, including energy procurement, power-system coordination, power-capacity planning, network-reliability improvement, and other critical network-management functions.

The Choice Is Yours

Whether you choose to outsource your complete network service needs on a round-the-clock basis, outsource specific tasks, or rely on the service provider for after-hours and weekend support, the use of a network service provider (NSP) will augment your in-house service capabilities or replace lost expertise.

In any case, it will help you to dedicate your personnel and efforts to the core business of providing revenue-producing services and managing your customers, instead of managing your network.

The Business Challenge

The challenge of securing networks is rapidly gaining momentum with the increase in e-commerce. Companies are quickly realizing that to stay both competitive and successful, e-business *has become* their business and that the resources to enable their business, namely the computers and the networks, are information assets. GartnerGroup says that business-to-business (B2B) e-commerce transactions will generate $7.3 trillion in 2004. To build successful e-business strategies, organizations will need to rapidly respond with secure electronic transactions over networks. Regardless of the access technology implemented for e-transactions, the networks will require to be secure.

Broadband networks based on digital subscriber line (xDSL), cable-modem, fixed wireless, and Ethernet-based metropolitan-area networks (MANs) refer to communication lines or services that operate at T1 rates (1.544 megabits per second [Mbps] and faster). xDSL, with two million consumers and one million business subscribers is projected to cover 70% of homes in the United States by 2002, while offering very low data and network security levels. Cable modems provide high-speed Internet data access to 30% businesses and an estimated 5.1 million consumers in the United States, while offering very low data and security levels. Fixed wireless is a developing market in 60 major metro cities, offering very low data and security levels. Ethernet-based metro networks are a developing market, providing services in 20 major metro cities and offering medium levels of data and network security.

Broadband networks share a common network cloud. The network cloud gets defined as each subscriber, business, or residence is added to the same segment and is managed by a common Internet service provider (ISP). These networks share a common network segment and are prone to threats related to sniffing of administrative passwords, data scanning, and transaction monitoring.

Today's threats are by-and-large the same as before, except that e-business has made it relatively easier to access the data and thus lowered the access threshold.

A recent computer crime and security survey of 538 security administrators from various computer industry, government, and academic organizations shows that the high price of computer crime and security breaches is on the rise. In 2000, the price of computer crime was estimated at $67 million, and in 2001 the price will top an estimated $151 million.

The Anatomy of a Network Exploit

A typical attack starts with establishing the footprint as the first step. As shown in *Figure 1*, this step is used to set up the scope of the attack through an analysis of publicly available information. The next step in performing a scan is to identify the vulnerability associated with each target of the attack resource. The step to follow is to exploit the target using a library of tools and techniques. This includes buffer-overflow exploits, address spoofs, and password and denial of service (DOS) attacks. The final step is to own the target causing damage, including blackmail, graffiti, information espionage, and destruction.

Computer threats and attacks can be broadly classified into two categories:

1. Random attacks
2. Targeted attacks

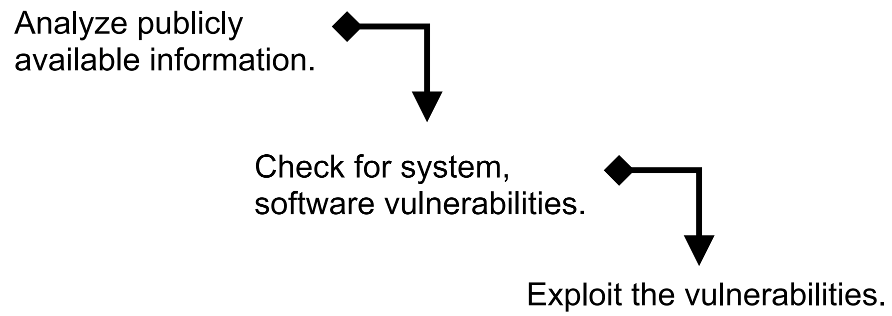
Random attacks include pervasive virus attacks, low-technology reconnaissance, port-scan attacks that exploit vulnerabilities inherent in the operating systems' software application configuration. In addition, the random hacks have been developed to exploit one or more vulnerabilities associated, for example, with integration of common gateway interface (CGI) scripts, hypertext transfer protocol (HTTP), or Java code. These attacks are more commonly orchestrated by the inexperienced script kiddie. In this case, the attacks are indiscriminate trolls on the Internet with little or no regard to who may own the networks.

Targeted attacks are performed by more experienced attackers who take time identifying the targets and conducting detailed reconnaissance before launching an attack. The attacks include DOS of prominent services, extraction and theft of vital information, or social engineering, physical break-ins, dumpster diving, war driving, and war dialing to locate modems.

DOS attacks allow the hacker to gain access to several computers connected to the Internet to execute a malicious code. The computer systems, at the hacker's signal, start sending data to the targeted Web sites.

FIGURE 1

The Anatomy of a Network Exploit



Social-engineering attacks are performed by an unknown person who calls on the telephone pretending to be another employee looking to verify sensitive information (including how to perform a particular task on a computer configuration) or inquiring about the company's stock performance, or pretending to be a system administrator calling an employee to fix his or her account on the system (which requires using his or her password). A successful means used by attackers to establish credibility in some organizations is providing a phone number that is on the organization's own phone system.

Attacks using dumpster-diving techniques are more effectively used for computer espionage amongst each other. Dumpster diving is a form of physical break-in. In this case, it involves rifling through an organization's garbage in an attempt to find sensitive information. As part of the search, the attacker may find a complete diagram of the network configuration or a carelessly tossed post-it note with an employee's log-in name and password.

War dialing searches for modem in a telephone private branch exchange (PBX) to obtaion access to a computer on the network. The war-dialing tool dials large pools of phone numbers to find unprotected network modems. As a variation, the demon-dialing tool searches for a password to gain network access to a known single telephone number.

Security of DSL and Cable Modems or Lack of…

DSL is an always-on technology providing a risky open door to the Internet. Attackers frequently scan the ISP address spaces that offer DSL services to exploit the computers of telecommuters and home-office workers. Although data may be shared by the same organization, with regional offices in different geographical locations, DSL provides network stovepipe connectivity and lacks a means to bind DSL sites securely, as shown in *Figure 2*. This exposes each Internet DSL connection, as any data traffic between sites is in the clear across the Internet. This risk is augmented by the fact that there are very few direct solutions serviced by several regional access providers that tie DSL back into the intranet.

In the recent distributed DOS (DDOS) attacks, zombies (or component codes) of the DOS attacks are being installed on vulnerable servers at universities or home-user systems connected to the always-on DSL. The attacker establishes groups of zombie-installed machines. These machines are in turn controlled by special control tools installed on additional exploited machines. The control tools instruct the zombies to conduct a DOS attack.

While secure tunnel-based authentication, session-based deployments are being used for xDSL–based systems, common point-to-point (PTP) clear text log-in and password data exchanges are more common. Owing to this shortcoming, many enterprise data information technology (IT) managers prefer to stick with the simpler-to-deploy dial-up solution.

Cable modem is a shared media network with an always-on connection analogous to the network segment of an Ethernet network. The shared media network is a combination of cable network subscribers for home cable entertainment, telecommuters with high-speed Internet connections, and small office/home office (SOHO) businesses.

A curious neighbor or malicious attacker, with sufficient knowledge of data-packet analyzers can access the data being exchanged by all subscribers of the network segment (see *Figure 3*). The network bandwidth offered by cable-modem networks is also temporary, and data access speed diminishes as the number of subscribers on the data segment increases. All cable subscribers share the same data pipe.

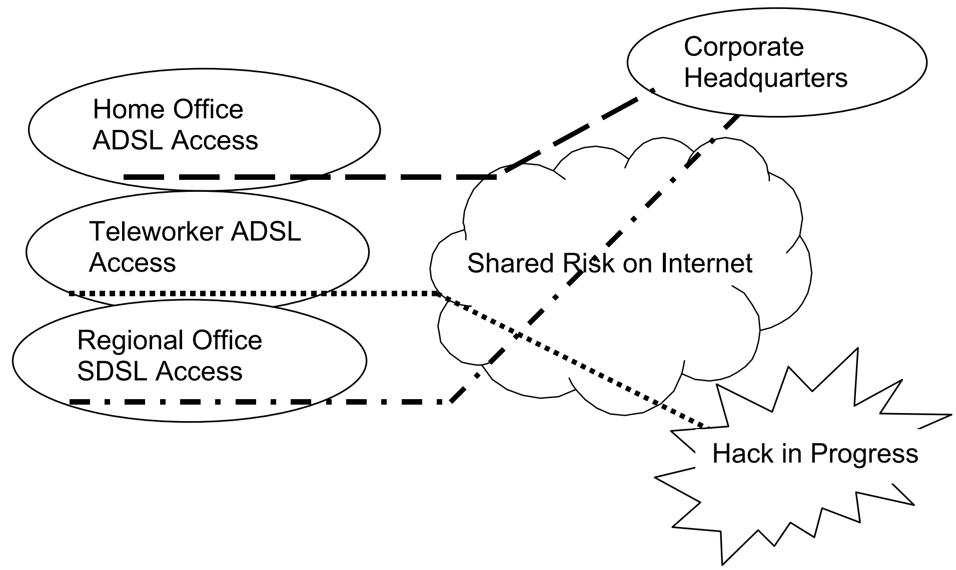
Security of Wireless Networks and Metro Networks or Lack of…

802.11b–based networks have rapidly gained popularity with the recent development of interoperability standards. The Wireless Ethernet Compatibility Alliance (WECA) can be accredited for the popularity of the 802.11b standards for interoperability, namely the wireless fidelity (WiFi) standard. Most vendors provide interoperability to the WiFi standard for data access points and network interface cards (NICs).

Fixed wireless networks use a local multipoint distribution system (LMDS) that decreases the deployment time of local access business circuits in the MAN. While the multichannel multipoint distribution dervice (MMDS) expands broad-

FIGURE 2

xDSL—Secure for Enterprise Network Access?



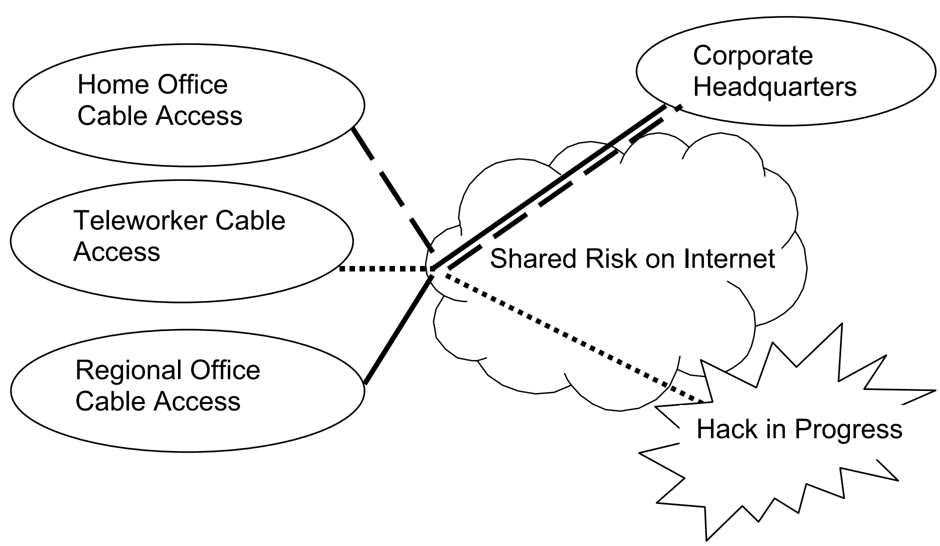
band access to consumers needing high-speed data access, the data is passed in the clear over the open airways.

The 802.11b standard includes Wireless Equivalent Privacy (WEP) provision for encryption. The WEP, depending on the vendor, offers two data-protection levels. One level is the virtually insecure combination of the 40-bit encryption key and 24-bit initialization vector (also called the 64-bit WEP encryption). The other level is the 104-bit key and 24-bit initialization vector (also called the 128-bit WEP encryption). Recent advances in the decryption of the RC-4 algorithm, owing to the key weakness, have been published and outline a method for extracting the master WEP key that will allow a potential attacker to pose as a legitimate user of an enterprise network.

Although the 802.11b standard employs weak static keys as part of the data encryption, there are an alarming number of access points to these wireless networks that are being deployed without WEP being activated. Furthermore, many wireless routers that provide data access have their default passwords. This data is captured by free data-analysis tools

FIGURE 3

Shared Medium Results in Shared Security Risk



that are able to log vital system parameters, including the media access control (MAC) address of the access point, the name of the network, session ID (SSID), vendor name, data channel, WEP enable status, etc. Furthermore, a global positioning system (GPS) used in conjunction with the analyzer tool provides latitude and longitude for the data access point. Armed with the analysis, network information, and default passwords, malicious attackers can not only surf the Internet using the organization's network, but also change the router configuration and modify the Internet protocol (IP) addresses within the intranet.

Wireless network security is analogous to physical security. A malicious attacker given sufficient time, interest, and resources can gain access to the network. As shown in *Figure 4*, the malicious attacker with access to a wireless protocol analyzer, a Linux system with a 802.11b NIC, can listen to wireless data traffic communications between the basic local/remote service sets, which ase bridges between the wired Ethernet local-area networks (LANs) and the Internet.

The Ethernet MAN) offer a high-speed local wide-area network (WAN) connection. Limited by connection distance, MANs can extend from 70 km to 150 km. The virtual LANs provide secure high-speed links in the metro ring similar to the frame-relay permanent virtual circuits (PVCs). However, the long-haul connectivity back to the main office is over an insecure connection.

Security Alternatives

Broadband network-based data access using the PTP tunneling protocol (PPTP) connectivity provides a medium level of data security. This is because of rather weak encryption offered by the challenge-handshake authentication protocol (CHAP) and the remote authentication dial-in user service (RADIUS) embedded in Windows 95, 98, and 2000 operating systems. Data access using the Layer-2 tunneling protocol (L2TP) connectivity provides low-level data security using data encapsulation embedded in Windows 2000. Data access using the IPSec, site-to-site virtual private network (VPN) connectivity provides high-level data security. This provides data security using strong encryption (3DES), data authentication (HMAC and SHA-1), and user authentication (RADIUS and PKI) embedded in Windows 2000.

Routed private networks consolidate broadband pipes into a unified intranet (see *Figure 5*). A virtual private managed service network allows a subscriber to gain access to data through set of partitioned virtual routers (VRs). Each VR is the equivalent of an independent hardware router and is a gateway to the Internet. The virtual router is the backbone of the WAN with the firewall layered into the network. The layered approach allows secured sharing of networked resources for VRs to connect frame-relay and IP networks.

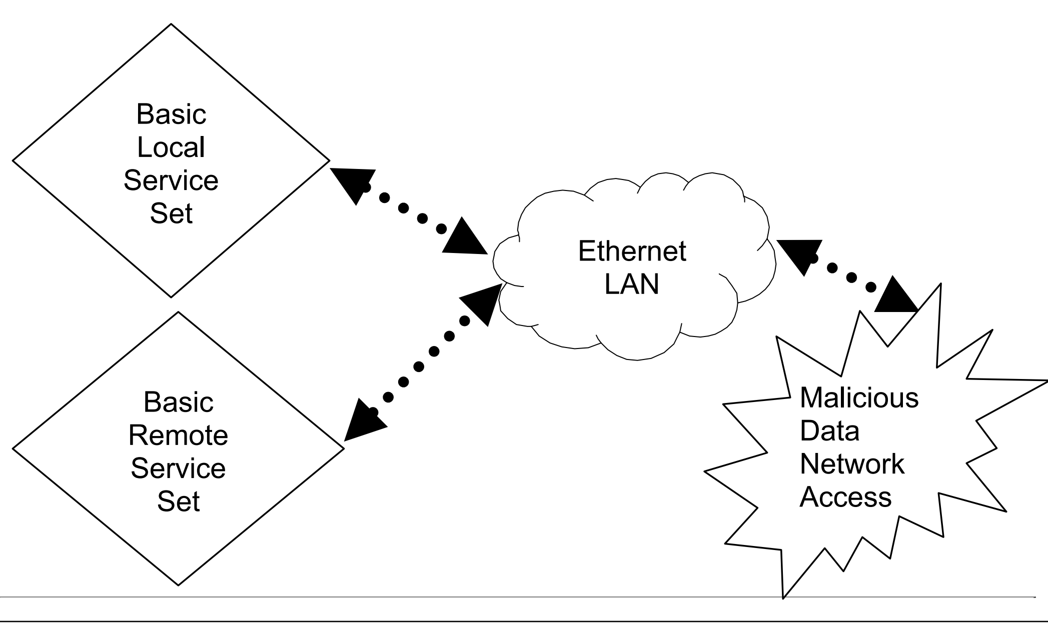
The VR enables customized services per subscriber, and data traffic is completely partitioned over the shared infrastructure. The subscriber data intermingles at the ISP VR just as it would in the ISPs' edge router.

Virtual firewalls or distributed firewalls provide a network-wide security with global policies distribution. This allows administrators to establish separate intranet and extranet policies per data site.

The trend in the industry is to deploy firewalls on individual laptop and desktop computers that access the Internet using

FIGURE 4

802.11b Network Exploit



always-on DSL or cable-modem technology. These personal firewalls are deployed along with the corporate firewalls to providing additional data security. Malicious attackers scanning users with DSL and cable-modem services are easily blocked using personal firewalls. Working in the same way as the network firewall, the personal firewall is focused on monitoring network traffic coming into and leaving the computer. When the personal firewall detects malicious data traffic, it logs the traffic and blocks it prior to its causing potential damage. However, these firewalls are limited to monitoring the data traffic to and from the computer and do not analyze the installed programs or the operating system on the computer.

Traditional packet filters focus on monitoring individual data-packet header information and the data-packet direction. The data packets are monitored by defining a series of packet-filtering rules, also referred to as access control lists (ACLs), when they are defined on routers. Stateful packet filters extend the traditional packet-filter capability by remembering the data packets that have traversed the network. The defined rules control the decisions to either allow or reject data packets.

Wireless networks can be secured by ensuring that WEP is enabled. Next, it is recommended that the default SSID be changed, as the default ID is set using the manufacturer's default ID and password. Furthermore, the SSID should not be broadcast and should not point to the company address, as this will provide a relatively easy scan location. It is always recommended to change the default passwords for the access point or wireless router. Most network-analysis programs identify the manufacturer based on the MAC address.

More Secure than Passwords

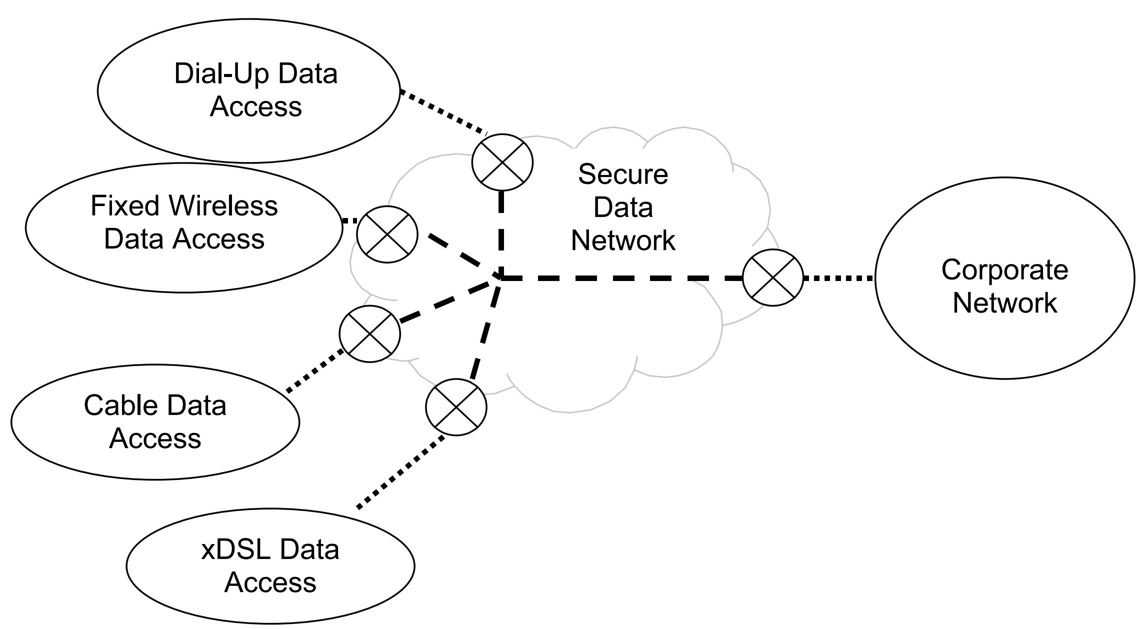
Most users in an enterprise log into more than one system today to access e-mails and databases. Most of these systems require secure access with more than one user name and password. Each system has an individual account requiring its own user name and password combination. Users of these systems are faced with the daily challenge of dealing with several user name and password combinations, which in turn results in the exposing of vulnerabilities, such as when users write their names and passwords on Post-It notes sitting next to their desktop computers or monitors. Furthermore, some users have to share their access passwords with other individuals via an e-mail for system-maintenance purposes.

While single–sign-on systems can alleviate password-related security risks, enterprise-wide implementation of the single–sign-on is both expensive and complicated to deploy. Password-based access systems pose potential security risks to the enterprise owing to passwords compromises that may be accomplished using keystroke-logging, shoulder-surfing, and social-engineering techniques. In the event of a malicious activity using a password, the authorized user of a password does not know if his or her password has been compromised until the act is completed, because nothing physical has been taken. These risks can be minimized using the two-factor authentication hardware or memory tokens.

The intelligent hardware (disk-on-key) or memory-based tokens function as two-factor authentication devices and provide twice the assurance of a commonly used single

FIGURE 5

Secure Network-Based VPN Data Access



password scheme. While desktop or laptop password-based access is both easy to steal or compromise, the easy-to-use memory-based token or disk-on-key protects the shared secret, encrypted password, or the public/private key pairs by denying access to the laptop or desktop once it is removed from the universal serial bus (USB) or serial/parallel port. The secured public/private key pairs allow the authorized user to perform cryptographic functions, key generation, key negotiation, and user authentication. Only an authorized user, with physical access to the disk-on-key or memory-based token and the password can unlock the token.

Four Ways to Tell If Your Outsourcing Provider Is a True Business Partner or Just Another Vendor

Michael Filak

Senior Vice President, Outsourcing and Business Engineering

CGI

OK, you've done it. You've studied the global market and witnessed the shrinking windows of opportunity. You've identified three discontinuities: digitization, globalization, and deregulation. You realize how they are affecting your value chain and your supply chain. You've grasped how rapid technological change is making local companies global, disrupting value chains, and creating new competitors, many with fewer fixed assets and lower-cost structures than yours. You've also internalized a fundamental principle of life in e-Space: Information technology (IT) solutions must do more than simply create positive impact within your walls. They must also provide value throughout the extended enterprise—to your customers' customers and to your suppliers' suppliers.

Now you are ready to translate your worldview into action. In your search for the optimum IT solution, you have taken to heart objective voices of the academic community that say, "If an organization is not "best in world" at a critical activity, the organization is sacrificing competitive advantage by performing that activity internally or with its existing processes."[1]

You have studied industry analysts, such as G2R who say that "those companies who are best equipped for success in today's global information economy are not necessarily those with the largest volume of resources under ownership and management. Rather it is often their *access* to those assets, combined with traits such as speed of execution, intellectual capital and knowledge base, and business expertise—i.e., *specialization*—that result in work class performance. Such performance is achieved through innovative alliances with external providers."[2]

Yes, you've done it; you have made the strategic decision to outsource your IT. Further, you have identified qualified outsourcing vendors. All have favorable credentials in terms of financial strength and backlog. All will be around for some period of time. All can provide you the services that you need today, and all have the potential to provide you services in the future. Each of them promises to save you money on your IT. And while that is important, you also know that saving 10 percent to 20 percent on 3 percent to 5 percent of your operating budget is not the major driver for you to outsource.

Your primary outsourcing objective is this: You want to capture the opportunity side of IT—and that requires a true IT partner. The decisions you make now will affect the future of your organization. You are not ready to entrust that future to a "vendor." You want a partner who cares if you're successful—one dedicated to your success. You want a partner who sees outsourcing relationships as long-term commitments that must be win/win to survive. You want a partner who views quality IT services as the prerequisite to growing revenue, expanding profits, increasing speed-to-market, reducing competitive threats, and generating shareholder wealth. In fact, you know that financial strength, operating capabilities, and lower costs are merely table stakes for you to even consider a particular outsourcing provider as your strategic IT partner.

Test the Providers: Partner or Vendor?

The American Heritage Dictionary defines a partner as the following:

"One associated with another in an activity or a sphere of *common interest*."

The key point here is "common interest." Common interest means that you and your outsourcing provider are working together toward the same goals and objectives. Ideally, you also have a shared vision and a mutual passion for achieving the same positive outcomes for your business.

But how do you know that an outsourcing provider views *you* as a partner and not simply a cash cow? How can you be sure that you've entered into a relationship where through commitment, sharing of information, and intellectual capital a win/win partnership is established in which everyone moves toward the same goals?

To find out whether outsourcing providers view themselves as your true partners, try this simple test. Discuss the following concepts with each contender and see how they respond. Providers that embrace the following partnership models will aspire to a relationship deeper than a typical vendor/customer relationship. Those who don't, won't—and can be crossed off your list of partner candidates.

Flexible Business Model

First examine the provider's proposed business model. The model should make it clear that the provider is the delivery arm, and it must be flexible and adaptive to your needs, your industry, and your competitive marketplace. No "one size fits all" mentality here! For that reason, it is important that overall technology decisions and directions remain with you. Leverage the provider and the intellectual capital that is available. Seek out advice and recommendations. Even if you want the outsourcer to make all the decisions, understand that you ultimately determine whether or not you are successful and that it is your decision regarding how responsibilities should be divided. The chart in *Figure 1* demonstrates how responsibility is shared in a true partnership relationship.

As shown, you maintain what I like to call the "thin CIO" organization with ongoing responsibility for definition, authorization, supervision, and control. And, as it should be, the outsourcer appropriately becomes the delivery vehicle for you.

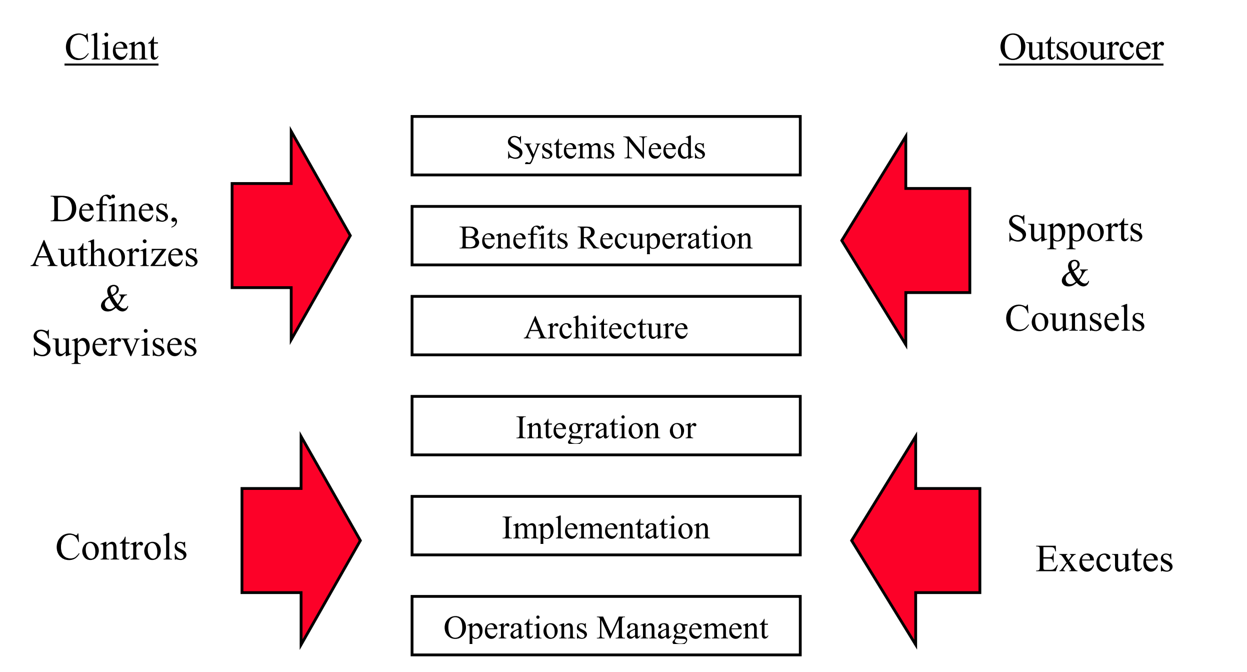
What's the flip side of this? Many outsourcers take the following approach: "Let us worry about technology; all you should really care about is the service." Outsourcers with this model are basically telling you that you need to adapt to the their business and technology model. The problem is that this model is created to achieve the greatest leverage for the provider. Leverage that must be gained and shared across many different industries and customers whose overall requirements are not the same as yours. Tread carefully with providers that approach you with this "least common denominator (LCD)" mentality. The technologies and models that best serve your needs may not fall within this LCD scenario. Additionally, should you ever decide to bring your IT processing back in-house; you are stuck with your provider's environment. This is even further exasperated when you choose an outsourcing vendor that is aligned with its own hardware or software. Technology decisions are made based on the vendor's product lines—not your needs. Letting your outsourcing provider make technology decisions may earn you an extra 3 percent to 5 percent savings off your operating budget. Yet squeezing out every last penny of savings is not the main driver of outsourcing in the first place. For this, you may be sacrificing true technological and competitive advantage.

No, a true partner puts your needs first. Setting technology direction is a collaborative process between you and your partner. However, the final decision is yours. You must feel confident that the technological solutions that you deploy are the technological solutions that drive success in your business.

Flexible Contracts

Outsourcing contracts are, by nature, longer term—typically seven to 10 years, although 15 years is no longer uncommon. There are very good reasons for this. Unlike typical

FIGURE 1



vendor relationships, outsourcing relationships closely resemble merger and acquisitions (M&A) in that assets and people are transferred into the provider's organization. Additionally, the provider commits to increased performance at a lower overall cost. The outsourcer's necessity to recoup the financial investment required to purchase assets, transfer people, and implement tools, methodologies, and processes to reduce costs typically takes several years.

However, as time passes, your business changes. Your company changes. Your competitors change. Your marketplace changes. Your strategy changes. Yes, the world goes on while your outsourcer tries to recoup its investment. This is when you may recall the warnings you have read about locked-in outsourcing contracts—a situation where your contract is ruling your business decisions. This is unacceptable and not reflective of a partner relationship.

A true partner with your best interests in mind will recognize that the contract must be a living, breathing, and changing document that captures the spirit of the relationship rather than the absolutes. Without you even needing to ask, a good partner will recommend a process or methodology for amending the contract to accommodate your changing business. After all, a partner knows that successful relationships must be win/win. And you recognize that a successful relationship must be win/win.

Your current contractual arrangement must flexibly respond to business changes—even if the result is lower revenue to the outsourcing provider. For example, say your company is going through a period of "refocusing," and you need to sell off non-core portions of your business. Yet your outsourcing contract ties you into certain services and a minimum-billing figure. Obviously, that contract no longer meets your needs. Together, satisfactory arrangements can be made if everyone is working toward a win/win relationship.

Learn up front how potential providers view contract changes. In fact, watch carefully how they negotiate the contract. Do they spend much time and energy protecting themselves from any adverse event no matter how minimal the chances that it may occur? Study any provider's track record. Do their words during negotiation carry over into future issues? It goes without saying that any provider that is the least bit rigid on mechanisms to change the contract cannot be considered your partner.

Open-Book Financial Model

Are prospective outsourcing providers open to sharing financial information directly related to your contract? Sharing of information, especially financial, is a true test of a partner. Providers that cannot take an open-book approach with you are not true partners. Now a typical response may revolve around the issue of benchmarking. Some providers may offer a benchmarking provision to lend an illusion of frank and open-business practices. The provider may say, "I won't share my financial information with you, but I will (reluctantly) let you utilize a third party to benchmark my pricing to you to ensure that I am charging you competitive rates." However, there is usually a caveat—"competitive for deals with similar size and scope." The major problem here is that typically there is no exact match on similar size, service, and scope. So the benchmarking provision may provide no value at all. Similarly, there are times where the rates may be market rates, but the provider is realizing enormous margins and not sharing the windfall with you.

No, a true partner has nothing to hide and should be more than willing to share the financials regarding services to you. This openness works to your benefit in two ways. First, by accessing the financials, you can be assured that you are paying a fair price for your services. After all, the provider's internal cost structure must be competitive to guarantee success in the marketplace. Second, you will be able to see your partner's margins. Nothing is more destructive to your outsourcing relationship than a growing feeling that your outsourcing partner is taking advantage of you. The sharing of financial data alleviates this issue. This openness fosters trust between the two parties. Should technological breakthroughs occur that have a significant positive impact to the outsourcer's cost structure, you will be able to see it. A true partner will be flexible toward changing the overall pricing structure to share these savings with you. The flexibility of your contract should ensure that you are not locked into a financial structure where you become a cash cow to the outsourcing provider.

Now, what is the best way to accomplish this open-book approach? I recommend that a third-party auditor be retained to review the books of the outsourcer. Ahead of time, both parties meet with the auditor and define the goals and objectives of the audit.

Another financial issue to look at closely is the manner in which the outsourcer leverages its technology alliances for you. These technology alliances should be built for the sole purpose of providing better and more cost-effective services to you. For instance, how does an IT outsourcer leverage its buying power on your behalf? If the outsourcer can purchase a particular piece of hardware for 25 percent less than you can, how is that passed on to you? A true partner passes on the total savings, less a small management fee, to its clients. Another method, though not quite as partnership-oriented, is to split the savings equally. However, the most common method amongst non-partner–oriented outsourcers is to plug the entire amount plus overhead plus profit margin into the price. In this case, the outsourcer functions as a reseller. Besides the financial implications, this method also removes objectivity from the outsourcer, which will look to increase their profit by recommending technology (hardware and software) where the outsourcer can realize the largest profit.

Transition/Migration Continuity

During the sales process, competing outsourcing vendors may parade before you a cadre of experts to impress you with their technological and business prowess. You need to ask each vendor, "How many of these experts will stay around and be directly involved after the contract is signed during the transition/migration process?" During the sales process and subsequent contract negotiations, an abundance of intellectual capital is generated as to how this contract will operate. It is extremely important that the contract gets off the ground running as per negotiations. The learning curve must be minimized. It is imperative that key personnel remain committed and involved throughout the transition/migration process. If the outsourcer's sales/pursuit team merely cedes the operations to another team, you can be assured that they are off and running, looking for their next cash cow. Once again, a true partner is just as interested (if not more interested) in making sure that your contract works to your satisfaction and benefit as they are in finding new contracts.

Careful Evaluation Now Yields Positive Results Later

Before you enter into a long-term agreement with any outsourcing provider, carefully investigate the four partnership concepts presented here: flexible business model, flexible contracts, open-book financial model, and transition/migration continuity. Do your prospective IT outsourcing partners readily accept these concepts? Do they have to be pulled "kicking and screaming" to your position, or, worse yet, do they flatly refuse? Remember that outsourcing agreements are more than just bottom-line revenue support of lower IT costs and better service. The best agreements focus on top-line revenue—generation of increased competitiveness, enhanced services, speed-to-market, expanding markets, and an overall internal focus on your core competencies. These vital goals can only be attained with a true partnership relationship with your IT outsourcing provider.

Architecting Software Systems for Network Availability

Chris Ford

Senior Product Manager

Équipe Communications Corporation

Introduction

In the last few years, equipment vendors have been focused on developing products for carrier networks that meet the skyrocketing demand of data communications. Carrier networks are built and continuously expanded to satisfy the relentless expectation of a paper-free, instant-information society. Our dependence on networks continues to increase exponentially, placing further pressure on equipment vendors and carriers to build networks that are resilient to change, growth, and intermittent failures.

During the past few years, we have seen numerous catastrophic data-networking failures that have halted productivity for many sectors, including financial, education, and retail, at a cost of hundreds of millions of dollars. Several outages within Internet service provider (ISP) networks and at network access points (NAPs) have resulted in widespread network unavailability. Major frame-relay (FR) interexchange carrier (IXC) networks crashed and remained down for as long as 11 days, leaving thousands of high-paying corporate customers without service.

A recent study conducted by Sterling Research, Inc. estimates that an hour of downtime for a retail stock broker in New York City costs as much as $6.5 million and that a "down" automated teller machine costs about $15,000 per hour. However, it's not only the end customer who suffers from the network outages: Rick Malone, a principal at Vertical Systems Group, indicates that recent domestic IXC outages have cost those carriers more than $200 million. The service market for data communication is *billions* of dollars, which means that a single drop in market-share caused by network outage translates into tens of millions of dollars in lost revenue.

Perhaps more disturbing than the frequency of recent data-network failures is the anticipation of what the future holds. New technologies such as multiprotocol label switching (MPLS) and generalized MPLS (GMPLS) are emerging to allow carriers the freedom to converge voice, video, and data traffic—all across a common backbone with a single control plane. Service-level agreements (SLAs), virtual private networks (VPNs), customer network management (CNM), and other value-added services are also adding tremendous complexity to the relatively simple networks of today. As carriers migrate toward single, collapsed data networks and advanced data services, the stability of the public network will be increasingly challenged. Thus, solving the network reliability problem is an imperative. Given the inevitable increase in size and network complexity (see *Figure 1*) and the fact that networks are still running on software architectures designed in the 1980s, the problem is poised to get worse, not better.

The underlying cause of a vast majority of network failures has been *software*. Management synchronization issues, runaway software faults, memory leaks, data corruption, inadequate upgrade procedures, and routing storms that flood networks with control traffic are all examples of how software can impact network availability. Unfortunately, software reliability has been neglected in favor of meeting demands for new features and for speed to market in delivering them. As a result, vendors in the data communications field have failed to introduce new, more reliable software architectures.

This paper will identify the following:

1. Software architectures that exist today and why they continue to make networks vulnerable to outage
2. A strategy for designing software architectures that will provide true carrier-class reliability for next-generation networks

Limitations of Today's Legacy Software Systems

This overview provides the opportunity to shed light on some legacy networking platforms, underscoring the need not only for a new class of networking equipment, but also for a new class of networking software.

Let's start out by analyzing the anatomy of a typical switch/router within the network. The trend in hardware design is toward modularity, flexibility, and scalable, nonintrusive growth. These very principles can and should be applied to system software. For example:

Carrier-Class Hardware: Today's switch/router is rack-mountable with many slots in which a variety of hardware modules may be inserted, hot swapped, and upgraded. Modular hardware enables carriers to do the following:

- Scale as required (pay as you grow)
- Hot swap modules without bringing down the switch/router
- Purchase media-specific modules

Today's modular hardware provides flexible "speeds and feeds" and reasonable reliability required for network growth. This design approach has become more common within the industry.

Legacy Software: Today's switch/router software (see *Figure 2*) is still based on a single, monolithic image that is typically bound to the hardware. This can make the software:

- Vulnerable to a single fault (A rogue pointer or memory corruption can bring the switch/router to its knees, forcing a restart.)
- Fragile under network load (An excessive load can force a system panic and automatic reboot.)
- Difficult on which to perform problem isolation and pinpoint the root cause of software problems
- Difficult to upgrade, since extensive testing cycles are required to validate each release
- Unwieldy and difficult to manage as it grows with every release

In fact, a monolithic code base can drastically increase the amount of time it takes to isolate and control faults, pinpoint the root cause of the problem, and deploy a fix. Not only does this reduce the overall availability of a service-provider network, but it also impedes the deployment of new features and services. This is evident in the life cycle of system software, depicted in *Figure 2*.

Today's monolithic software does not meet the scalability or reliability requirements of highly available networks. Monolithic images are becoming increasingly problematic and unable to meet the needs of tomorrow's networks.

The solution is to leverage the principles of hardware modularity and advances in software technology to achieve a software solution that scales linearly to meet tomorrow's growth and reliability needs. Next-generation hardware requires platform software that stays synchronized with the element manager even during failure. It also requires that faults be contained according to predefined policies, without system reboots. Lastly, platform software must allow for upgrades that are non-disruptive to customers and result in predictable outcomes. Scalability, reliability, and availability: the cornerstones of the carrier-class platform software architecture.

Leveraging Distributed Architecture

Within networks today, distributed architecture is widely used to provide performance, scalability, and overall network availability. The Internet itself can be viewed as a distributed system comprised of thousands of loosely coupled elements that work together to provide the end user a single, richly connected network.

A well-constructed software design can be viewed as a network of loosely distributed processes that work together,

FIGURE 1

Network Complexity and Size over Time

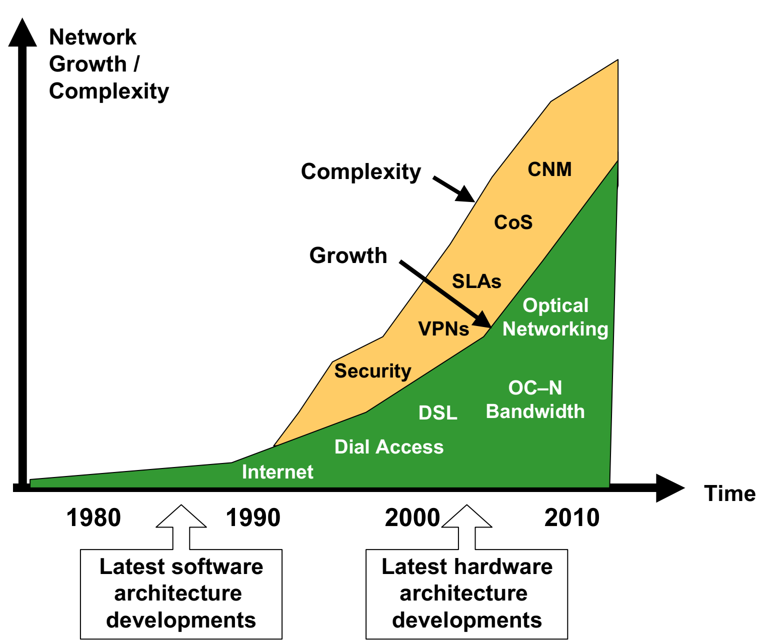

FIGURE 2

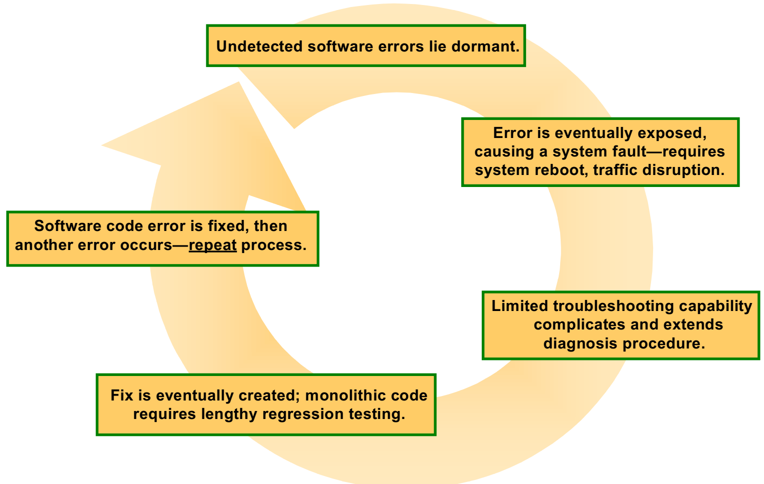
The Life Cycle of Legacy System Software



not unlike the processes that comprise the Internet. Like the Internet, it leverages a distributed architecture to achieve the performance gains of parallel processing to provide system scalability and to deliver better overall availability of network service.

Distributed Control Architecture

Many legacy switch/routers have built on the aforementioned theory, adopting distributed architectures within the data plane to achieve the aggregate bandwidth required for today's networks. By running many "fast forwarding engines" in parallel, data can be switched or routed at higher rates of speed, increasing the overall forwarding performance and subsequently enabling networks to scale.

While distributed processing techniques are currently used within data planes, the control plane has remained largely centralized. Until now, this architecture has performed reasonably well and was simple to program. However, many of the same forces that shaped the evolution of the data plane are now exerting similar pressures on the control plane. The next generation of switch/routers will run resource-intensive control protocols that will be difficult to scale in a centralized architecture. Some of the features to be supported include the following:

- Signaling protocols
- Connection path routing
- Differentiated services
- Software interface scaling

Because these control services are hungry for central processing unit (CPU) cycles and system memory, a *distributed control architecture* is required to scale next-generation platforms and provide the desired level of network availability (see *Figure 3*). Fortunately, these services are relatively straightforward to distribute: They are localized to individual interfaces and require little, if any, shared global state. When these applications are deployed in a distributed fashion, their performance and scalability will increase linearly as processing modules are added to the platform—far exceeding the performance and scalability that can be achieved in any centralized control architecture. Distributed control architectures are a prerequisite to achieve the scalability required in carrier networks.

Location Transparency Provides Significant Flexibility

To offer the flexibility needed for today's networks, application software must be constructed without concern for the location of other services on which it depends. In other words, software components must have *location transparency*. With location transparency, software designers can focus on clean design partitioning, independent of the hardware architecture. This approach insulates the software system from changes in hardware as the product evolves.

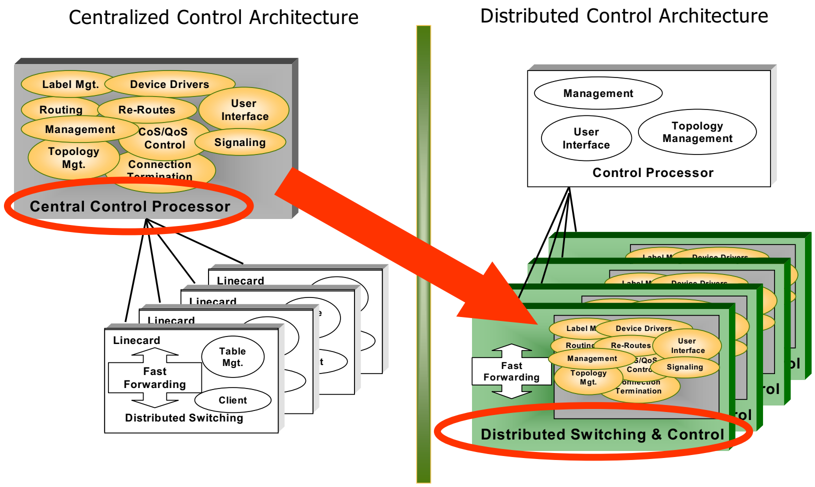
In addition, a flexible distribution scheme enables software components to be relocated, tailored, and optimized without redesigning the core system. This flexibility is especially important, since the design team often learns more about the processing, communication, and resource-consumption characteristics of a product as it is tested and used in production networks. The result is a scalable, flexible software architecture that can easily be adapted to support emerging product requirements, new product families, and even new hardware platforms.

Improved Availability

Perhaps the most significant benefit of adopting a distributed control model is the impact on availability. When a component fails in a centralized architecture, it has an adverse effect on the entire system. A significant loss of data, control, and management services usually occurs. In contrast, failures in a distributed architecture are localized to the affected component. Only a small fraction of the system's services is affected. The outage is significantly shorter because there is much less work required to recover. A good distributed control software must mitigate the effect of single component failure by isolating the failure to the offending component. Service disruption is contained to services

FIGURE 3

Distributed Control Architecture



that utilize the offending component rather than all services provided by the entire system.

Automated Fault Detection and Recovery

Even the best, most reliable software system will contain defects that generate system faults. The key then is to properly manage these faults so that system disruption is minimized. Thus, fault isolation and containment are fundamental to any next-generation software architecture. Several developments in operating system (OS) technology enable next-generation platform software to reduce the likelihood of software faults and several mitigate and contain the effect of software errors.

Use of Protected Memory

Most contemporary switch/routers are built using a real-time, monolithic software architecture. These architectures achieve efficiency by running all programs in unprotected kernel mode. If a failure occurs in any piece of software (e.g., a corrupted pointer), the entire system will crash or become unstable. Instability is often worse than a hard failure because system operation can degrade severely without any indication of the cause. The only way to recover from a failure in these systems is to reboot. Unprotected, kernel-mode architectures make it extremely difficult to achieve high-availability goals.

A higher level of reliability may be realized by using hardware and OS features to implement a *protected memory* model. In this model, each application runs in its own protected memory space, ensuring that the failure of one application will not adversely affect the operation of others. In the earlier example, an application with a corrupted pointer will terminate before it can do damage to any other part of the system. Employing a protected memory scheme eliminates much of the instability and indeterminism seen in monolithic architectures. As a side benefit, protecting applications also facilitates the development of clean, well-defined application programming interfaces (APIs), a prerequisite to the software modularity discussed earlier in this document.

The Importance of a Microkernel

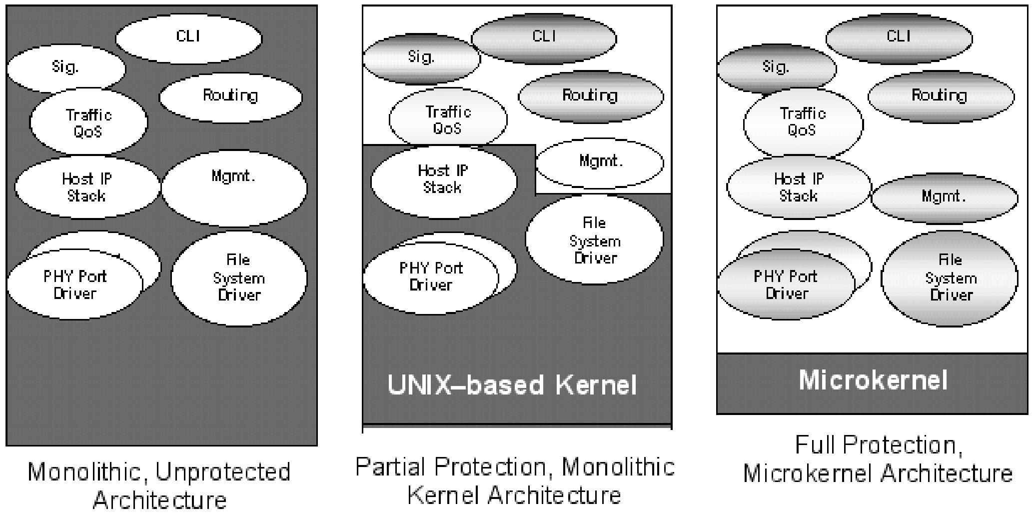
A few newer switch/routing platforms have made the shift to a programming model that uses protected memory. However, many of these are built on top of large, UNIX–derivative kernels that still compromise the reliability and modularity of the system. In these systems, there is a significant number of OS components and system device drivers that run unprotected in kernel mode. A failure in one of these unprotected components will cause a reboot of the system. In addition, time-critical control tasks are often written to run in kernel mode (as shown in gray in *Figure 4*) to avoid the performance penalties of a large OS. As the amount of code running in the kernel increases, the likelihood of a kernel fault rises dramatically. A microkernel architecture greatly improves system availability. Only the most basic system services (e.g., interprocess communication and scheduling) should run in kernel mode. All applications, device drivers, and higher-order system services run as user processes. This approach greatly reduces the amount of code running in kernel mode. The following characteristics are important qualities of any microkernel architecture:

- *Reduced Size:* An efficient microkernel, an order of magnitude smaller than a traditional kernel, greatly reduces the possibility of a service affecting failure.
- *Granular Process Control:* Processes can be started and stopped independently. The microkernel tracks all process resources so they can be recovered in the event of a failure.
- *Superior Performance and Scaling:* High-performance and scalable applications can be developed without moving the applications into kernel mode.

Traditionally, fault detection and monitoring do not receive a great deal of attention from network equipment designers.

FIGURE 4

Full-Protection, Microkernel Architecture



To reach high availability goals, however, systems must adopt a proactive approach to fault monitoring. To provide comprehensive fault detection, switch/router-resident management software must intelligently monitor components and determine when action needs to be taken. It must do the following:

- Unobtrusively inject heartbeats throughout the system
- Query active components for status in real time
- Monitor the resource (CPU, memory, etc.) consumption of each software module
- Actively monitor redundant hardware and software components to ensure that they can take over successfully in the event of a failure

This strategy provides coverage for a wide array of failure conditions and automates the detection and notification processes. The result is an intelligent, cohesive, automated fault-monitoring service.

Adaptive Fault Handling

Part of effective fault handling is customization and intelligent processing of faults. To be adaptive at handling faults, system software must do the following:

- Use an intelligent, policy-based recovery scheme (e.g., recovery policy may dictate process restart, process re-initialization, module switch over, process termination, or another corrective action)
- Maintain a complete history of system faults
- Leverage heuristics to determine whether a failure is indicative of a more severe problem and automatically escalate the recovery action

Rapid Fault Recovery

Speed of recovery is one of the primary considerations for picking an appropriate fault-recovery action. Restarting a single software process running on a software module is much faster than switching an entire slot to a redundant component. Clearly, when a single process is restarted, only a fraction of a module's services is affected.

Two measures may be employed to ensure rapid recovery from hardware and software failures. First, the protocol stacks may be multithreaded, so the failure of a software process affects only a fraction of the module's capabilities. For example, an eight-port module might have eight separate instances of the protocol stack. If one process fails, only one port's service is affected. Second, all software entities are designed to recover from failures of an adjacent or peer entity by performing dynamic state *checkpointing*.

Checkpointing

For a backup component to take over from a failed or removed component without operational downtime, the backup needs to receive and maintain current state information from the active component. This transfer of dynamic state is called checkpointing. With checkpointing, the following are done:

- The backup process state is maintained by sending information from the active to backup components at regular intervals.
- Dynamic state can be used to recreate a module's processes on the designated redundant module in the event of a failure.
- Recovery from a software failure is normally complete in milliseconds, resulting in no discernible service disruption. With an entire hardware module failure, it may take only a few seconds to restore service—a great improvement over existing solutions.

More important, the affected interfaces never "go down" from an operational perspective, so the routing topology and forwarding tables remain intact. There is no need for the other modules in the system (and other network elements in the network) to reroute around the temporary failure.

Unprecedented Availability

Performance under stress, day-to-day management, and smooth periodic upgrades are important aspects of the network life cycle. Network integrity must not be compromised with normal or abnormal traffic spikes or unplanned network events. In addition, software modularity, innovative management techniques, and upgrade tools are an important part of providing unprecedented software availability.

Stability under Network Load

One common and disastrous problem seen in data networks today is that of instability under severe network loads. Often, this network load is created by control traffic. It is for this reason that a discrete separation must exist between the control and data planes. Using a dedicated control plane enables the distribution of high-performance software applications without affecting the data plane of the platform. Priority queuing on the control plane ensures that critical control traffic (e.g., routing protocol updates and "keepalives") receives priority service during times of heavy network congestion. This will ensure that excessive control traffic does not interfere with user data and that dropped control traffic does not further exacerbate the amount of congestion.

Software Modularity

Since modularity is a fundamental technique for controlling complexity, its application to a fault-tolerant, distributed system brings significant rewards. Software modularity is the practice of functionally dividing a software system into individual modules, which can then be designed and implemented independently and later integrated into a cohesive solution. All interactions between modules are made through well-defined APIs, ensuring that modules can continue to be developed independently.

Modularity is a powerful tool for the following:

- Controlling and simplifying the design, construction, testing, and maintenance of complex software systems
- Encouraging the reuse of functionality, which in turn improves efficiency and minimizes bugs
- Facilitating customization and extensibility of products
- Enabling less intrusive, more contained software upgrades

Discipline and enforcement are the keys to delivering true modularity. Core system services can encourage disciplined treatment of APIs by providing one (and only one) way of communicating between programs. This forces developers to communicate through the main API because it's the only way to exchange information between two applications. The creation of back-door mechanisms, which compromise software integrity, becomes impossible.

Because of this strict enforcement of APIs in software modularity, the use of shared memory between processes is forbidden; *message passing* is the single interprocess communication method. Protected memory helps to enforce this physical separation of software modules. Every logical component is compiled and linked as a separate program, and each program runs in its own protected memory space. There is no way to share memory between two separate programs, so the programs are forced to communicate via message passing. Thus, the software system's modularity also helps to minimize the disruption associated with deploying a new software release. As will be seen subsequently, individual software modules (fixes or features) may be upgraded without impact to the rest of the system.

Release Management

Suppliers of monolithic software are forced to adopt a very conservative release strategy because of the logistical problems associated with testing and deploying large, single-image software. Typically, major feature releases can be delivered just once or twice a year, and "patch" releases must target a large collection of customer concerns. This conservative strategy limits the vendor's ability to react to evolving customer needs. Given the rate of change in the networking industry, this approach can severely hamper a provider's ability to upgrade the network or offer new services.

Modular software design allows a platform vendor to adopt a progressive release management strategy with several benefits:

- New software modules and device drivers can be released to the field as soon as they are available.
- Fixes and features can be safely applied to a subset of elements within a network, significantly reducing the number of wholesale network upgrades.
- Individual components of a modular system can be tested in isolation with confidence, facilitating higher-quality, timelier releases.

Upgrade/Downgrade Agent Features

In terms of system availability, operator errors during software upgrades can be a significant contributor to system downtime. To minimize these errors, upgrades to software must be automated. An intelligent "upgrade agent" would be charged with determining the scope of the upgrade and applying the necessary changes to the affected modules.

Manageability

No comprehensive system design would be complete without careful attention to manageability. The platform must leverage a configuration repository that provides a centralized, standardized, and flexible way to access management data. The repository must provide a set of APIs to enable applications or other parts of the management framework to read, write, and search for data. Rather than using simple network management protocol (SNMP) for this information repository, vendors should consider a transaction-oriented approach, which makes use of relational database technology embedded in platform software. Database transactions can ensure configuration integrity, eliminating partial, incomplete (and thus invalid) configurations. Other important features include recoverability and replication of configuration data. Relational database technology provides a rich suite of features that go far beyond traditional SNMP–based solutions.

To eliminate synchronization issues with an element-management system (EMS), the relational database in system software pushes configuration change to the administrative system, eliminating the need for excessive polls out to the device.

Summary

For networks to achieve the scale, reliability, and availability demands placed on them, a new software architecture must accompany next-generation network hardware. It must be distributed, modular, and include integrated proactive fault detection, isolation, and correction. This revolutionary approach must be built from the ground up—adding scalability and fault tolerance to a legacy software architecture is all but impossible.

Network Optimization Challenges

Daniel Gatti
Consultant
Mayan Networks

This paper focuses on network optimization challenges and their many contributing factors.

Network optimization is big business. Within the past two years, more than 100 vendors developing new solutions and products all geared at optimizing parts of the network have been funded. Within the past six months, a number of companies have been acquired and a few have gone public.

A Question of Fiber

Obviously the network means different things to vendors and service providers. There are 39 million miles of fiber in the United States today, representing tremendous capacity in the long-haul network. In the last two years, the metro core has also been built out with a significant amount of fiber. At the edge of the network, fiber is scarce, and the prevailing physical medium continues to be copper.

There are approximately 770,000 class-A commercial buildings in the United States today. Only seven percent of those building have fiber connectivity. When evaluating network optimization strategies, one of the key issues that remain to be solved is how to get fiber to those major customers at a reasonable cost. Several new carriers are bringing fiber directly to these customers but are hampered by prohibitively high costs associated with carrier hotels and digging up streets.

Optimizing the network to take advantage of the existing infrastructure is a huge challenge. In the United States today, there are 150,000 synchronous optical network (SONET) rings in place. The rest of the world has another 150,000 synchronous digital hierarchy (SDH) rings. The challenge is to take advantage of this capability, try to use it, and maximize the fiber capacity.

Metro Optical Market

Traditional SONET equipment, including basic add/drop multiplexers, accounts for a constant $4 billion-per-year market. However, according to Pioneer Consulting, the metro optical market will grow from less than $5 billion in 2000 to $14.3 billion by 2004. The fastest growth in the metro optical area is in multiservice SONET, or multiservice provisioning platforms. Pioneer expects multiservice SONET to grow from less than $500 million to $6.3 billion by 2004. Multiservice SONET combines traditional time division multiplexing (TDM) functionality with asynchronous transfer mode (ATM), frame relay, Ethernet, or Internet protocol (IP). Optical IP is the fastest-growing service, increasing from relatively nothing to $2.5 billion by 2004. Therefore, a considerable amount of optical capability is coming into the metro.

Higher-layer protocols and services continue to grow. Current thinking has it that packets will dominate traffic volume by 2003, but that multiservice traffic will also grow. Frame relay and ATM growth in the last quarter of 2000 was surprisingly high, and even though the move is toward IP and higher-speed Ethernet, traditional ATM and frame relay revenues continue to grow for carriers.

The Problem of Multiple Protocols

Companies can optimize their networks if they attack the issues at the edge. First of all, multiple protocols make provisioning of services very difficult. A combination of services exists today—ATM, frame relay, voice, TDM, and obviously IP are coming in—but the challenge is how to provision those services to the end-use customer.

Some buildings contract with several different service providers because bundled service is not available from any single one of them. One provider may supply T1, while voice comes from another, digital subscriber lines (DSL) from another, and Internet access from yet another. However, customers do not want to contract with multiple providers, preferring bundled services at an attractive price.

The Problem of Multiple Devices

With each additional protocol that a service provider deploys comes a separate piece of equipment that requires installation, configuration, and maintenance. Whether frame relay devices, ATM devices, or integrated access devices, all require some physical change of equipment and a truck roll—an extremely labor-intensive process. Today's SONET/SDH-based infrastructure was never built to handle data traffic, and a 20 percent utilization of existing SONET rings is the best companies can expect when deploying data services. The inefficiencies of data transport over SONET, configuration and maintenance complexities, and the cost of a truck roll are the key challenges in network optimization.

Dealing with the Network Edge

All of the major carriers have built a huge amount of capacity in the core of the network. Raw fiber capacity in the core creates a real bottleneck at the network edge. The challenges are to bring that core capacity out to the edge, to aggregate traffic and services efficiently, and to transport them back into the core. These disparate issues make edge optimization very difficult.

The complexity at the network edge comes largely from the variety of interfaces and protocols that must be supported. One building may have private branch exchanges (PBX), DSL, and customer-premises equipment (CPE). That equipment includes routers, Ethernet switches, and all kinds of integrated devices handling not only voice, but virtual private networks, storage-area networks, and web hosting. Multiple physical interfaces—including Ethernet, T1, T3, digital subscriber line (DSL), optical carrier (OC)-3, OC-12, and OC-48—are coming in with different protocols, whether TDM, ATM, frame relay, or IP. In addition, new protocols and approaches are constantly being developed. Provisioning this diverse mix of interfaces and protocols is extremely labor intensive and expensive.

The Metro Edge Is Key

The challenge of optimization revolves around service delivery at the metro edge. Service providers must deploy both processes and equipment that reduce the cost and complexity of turning up new customers, bring core bandwidth to the network edge, and increase revenues through reduced operations costs. Those carriers able to achieve this level of network optimization will enjoy great success in the years to come.

A Step in the Right Direction toward Accurate, Consistent, and Reliable Information

Tom Glover
Customer Unit Leader, Communications Industry Sector
Unitech Systems, Inc.

Mary Breier
Marketing Communications Specialist
Unitech Systems, Inc.

In general, we have become complacent with accepting errors as a daily occurrence and a cost of doing business. It is accepted that mistakes happen, data errors occur, and systems and processes are not perfect. Accurate, consistent, and reliable information—also known as information integrity—seems to be a luxury that few companies find time to achieve within and around their business.

In the communications industry, the cost of revenue leakage caused by the lack of accurate, consistent, and reliable information is significant enough to impact bottom-line profitability by as much as 15 percent[1]. Network capacity provisioning and activation lack controls; billing systems are unaware of services being used; accumulated call detail record (CDR) errors are increasing; rating tables are applied incorrectly—and this is merely touching the surface of the problem.

This paper explores the concept of information integrity within the context of revenue assurance. It outlines how to approach the problem in a strategic manner. In addition, it describes how it is possible to provide an autonomous, independent, fully auditable, end-to-end control architecture that gives an organization the capability to detect and pinpoint errors at their origin—when they happen, not after the event. How this is accomplished—through an "early warning system" that alerts the business at the first sign of trouble—is also presented.

If you've never had to complain at a supermarket that the price charged was different than the price on the label, if you've never had a transaction appear on your bank statement that wasn't yours, if you've never had a wrong charge show up on your telephone bill, or if you simply trust information to be 100 percent accurate all of the time, then you should stop reading now. Also, if you are one of those rare people who have never received a bill for a service that you've been provided, then keep quiet!

The Current Communications Industry Situation

During the past five years, most communication company strategies have either actively and aggressively captured customers to maximize market penetration and share or, if you were an incumbent provider, protected and minimized customer churn.

New products are launched almost daily on the unsuspecting public, and customers are enticed from one service provider to the next by the promise of better deals. This constantly changing and complex environment sacrifices quality for quantity.

In an attempt to reduce costs, the communications industry has been downsizing. The *Financial Times* estimates that more than 485,000[2] people have been affected by downsizing efforts in the communications industry between April 2001 and January 2002. Communications companies' share prices have plummeted. Outsourcing is the current trend and a way to "pass off" underlying problems. The number of call centers is increasing to handle the barrage of customer complaints. If you believe the estimated 5 percent to 15 percent revenue-leakage figures, then the top communications companies in the United States alone are hemorrhaging from $15 to $47 billion in revenue per year[3]. The morale within the industry is at an all-time low.

During the next five years, the capital, technological, and intellectual investment required within the wireless industry to develop third-generation (3G) networks and products is massive. Only a few organizations will have the power and stamina to survive and create the communications industry of tomorrow. Those few must have strong supportive cultures, solid leadership, effective operational processes, innovative products that penetrate new markets and address their customers needs (quality being one of them).

Revenue Assurance

Revenue assurance should be seen by top executives as a way to provide a competitive advantage for their organization. If approached correctly, revenue assurance becomes a discipline that provides a long-term, repeatable mechanism for capturing revenue that would have been lost otherwise and not realized in the general ledger. Furthermore, revenue assurance can improve customer satisfaction, reduce operational overheads and reduce the risk of damaging the company's brand through bad publicity.

Revenue-Assurance Responsibility

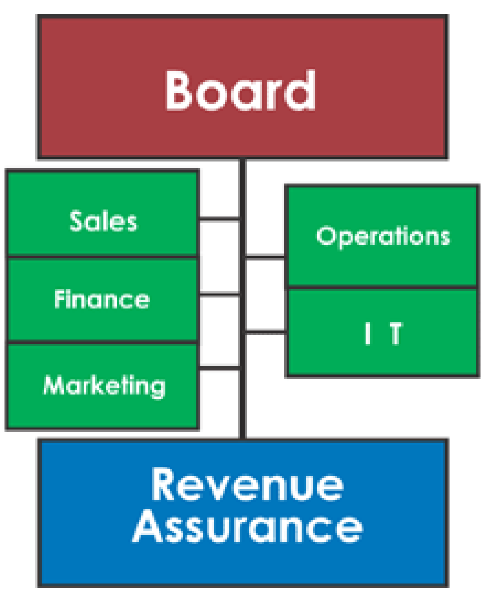
Everyone in an organization should be responsible for revenue assurance. However, from experience, most organizations have many "Revenue Assurance" managers located in several areas—within the network department, others in the information technology (IT) organization, some working specifically in applications such as billing, others in audit, and, in some instances, within finance. Very few organizations have an overall "Head of Revenue Assurance" or a dedicated department that report's directly to the chief executive officer or president of the company.

A department that handles revenue assurance has the potential to increase revenues by 15 percent, making it a critical business function that needs authority and empowerment to instigate changes enterprise-wide. The only way it will succeed is through ownership of the entire organization's revenue-assurance program (see *Figure 1*).

In larger organizations that have a truly global presence, this role often exists both at the group level overseeing the subsidiary parts of the organization and within the subsidiaries.

FIGURE 1

Organization Position for Revenue Assurance



Revenue-Assurance Scope

The scope and impact of revenue assurance can vary depending on business need, but the primary focus to minimize revenue losses and charge inaccuracies and system failures remains consistent.

Revenue assurance goes well beyond simply checking the bills issued and seeing that they are paid. It covers the beginning-to-end process of monitoring every contributing event. We all know the phrase, "garbage in, garbage out." There is no point to having a great billing system if you fail to capture all of the services and products that you want to bill.

Accurate information from the switch to the bill; consistency between applications such as provisioning, billing, and general ledger; and reliable information that can be monitored from the start to the end of the entire process are all within the remit of "revenue assurance."

The End-to-End Operational Process

Within a network, a host of technologies are employed: multiple switches often produced by different manufacturers, network cards that split voice from data to optimize routing, dual-service backbones, and digital subscriber line (DSL)–enabling equipment are but a few. In the near future, these technologies will be expected to provide and manage not only usage data, but also content.

Before a person or company can access a network, he or she goes through a sales process that cumulates in the provisioning and activation of the products and services required from the service provider (see *Figure 2*).

The data generated within the network is the main source of revenue for a communications provider—from the activation and provisioning of new circuits to the generation of CDRs.

CDRs come in a variety of shapes and sizes but generally contain the same information:

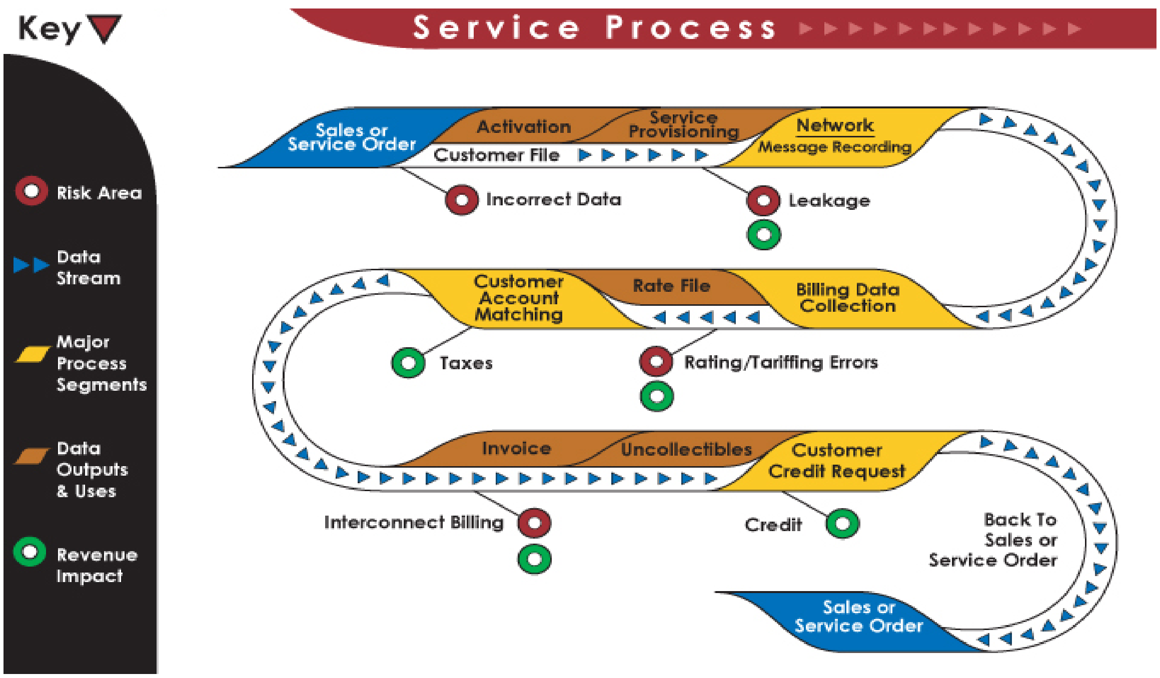
- Date and time
- Qualifier
- Calling number
- Called number
- PRI ID number
- B-channel number
- Time of call to disconnect
- Text

A CDR is generated for every call made, even those that don't connect. The lifecycle of an individual CDR is varied and often ends soon after it begins.

In instances where two or more CDRs are generated for one call, suspense processing occurs—with CDRs waiting for the terminating CDR to be matched to the call-starting CDR and any in between. Once the CDRs are created, they need to be put into a standard format. Mediation devices collect the CDRs and reformat them into a standard layout. Some CDRs are assumed to be non-billable, or never billable, and are discarded. Others may be held for processing later, and

FIGURE 2

A Simplified, End-to-End Process Flow



the remaining CDRs are forwarded for rating. Sometimes rating takes place within billing, and, at other times, it is handled as a separate process.

The rating of CDRs is dependent on many factors, such as the time of a call and a customer's call plan. Multiple rating tables exist, often with contradictory or incomplete information. Many service providers allow customers to view rating tables on-line.

To carry out billing, calls are matched to customers, and the information is pulled together into a billing format suitable for delivery as either a printed hard copy or in electronic form to the customer. Therefore, bill verification is critical, since it is the last point at which the service provider can prevent sending an inaccurate bill to the customer.

As soon as the financial information is available from billing, it is forwarded to Finance in the Accounts Receivable revenue stream. Given the complexities, interdependencies, and size of the systems involved, it is not surprising that a change in one area could have an unforeseen damaging impact elsewhere within the process.

Among the areas where revenue can be lost are the following:

- Switch/mediation/billing
- Activation and provisioning
- Rating tables
- Bill invoicing
- Interconnect billing
- Feeds into general ledger

Here are some examples of the types of information errors that have caused lost revenue throughout these areas:

Missing Switch Sequence Numbers: A service provider that was carrying out maintenance on one of its many switches accidentally turned off the sequence capture number. The mediation process was designed to discard CDRs that did not have a sequence number into an error file. This discrepancy wasn't identified until independent, autonomous controls were implemented from the switch on the mediation input file.

Activated Circuits Not in Use: Records that had not been updated resulted in circuits being logged as "in use" when they were actually discontinued and available for reprovisioning and activation. By introducing controls around these processes, the service provider was able to regain capacity it believed was in use. This provided the company with a potential savings of more than $100 million.

Billing Invoices Not Adding Up: A service provider implemented controls to validate whether a bill's contents tallied correctly around their end bill. Previously, customers complained that bill totals were not adding up to the items shown on their bills.

Zero-Rating Applied to CDRs: Toll-free, or free phone, numbers have a zero-rating applied to their numbers. Rating tables were found to have a zero-rating applied to billable numbers.

Incorrectly Formatted CDRs: CDRs generated by a new switch were in a format not recognized by the receiving mediation device and went unrecognized for several months.

New Products Not Recognized: A wireless service provider launched a new call plan only to recall it immediately after its launch due to the inability to identify the product with its supporting applications Without the supporting applications, the new call plan's customers would not be able to use their mobile phones.

Duplicate Records Processed: A new billing system pulled formatted CDR files from the mediation device while the mediation device continued to push formatted files to the billing system. This caused duplicate files that were in turn processed onto the customer's bill. This error didn't go undetected for long!

General Ledger Accounts Receivable Feeds Lost: After billing for revenues, it's important to ensure that journal entries are transferred and processed correctly in the general ledger. For one service provider, these feeds were lost. The ability to accurately report on cash flow is essential for any service provider's operation.

Interconnect Billing Disagreements: A regulator was asked to look into a disagreement between two service providers. The claim was made that 20 million minutes of billable revenue had not been paid by one of them. The regulator sided with the service provider who had the best controlled interconnect process.

These are just a few examples of many situations that could have been avoided with enterprise-wide planning and end-to-end controls.

Strategic Intent

It is possible to achieve an enterprise-wide set of controls and measurements. The approach does not suggest trying to "boil the ocean." Instead, it is advised that a phased approach will help to ensure enterprise-wide, accurate, consistent, and reliable information, which in turn will help to maximize the organization's revenue assurance.

To deliver an effective revenue-assurance strategy, it is necessary to implement a highly visible control and reporting framework supported by a mechanism that is as automated, flexible, and scalable as possible.

This need is driven by the dynamic nature of the communications business, which forces frequent changes to prices and tariff offerings and often results in new or enhanced technical functionality.

The resource constraints and physical restriction of systems often mean that revenue-assurance controls and reporting requirements are scoped into later phases of projects or lost altogether. This results in gaps in end-to-end control and visibility. Revenue can then "leak" from the systems without detection.

In addition, the current fragmented approach of developing individual systems to include control, reporting, and regulatory requirements results in high-cost, multiple developments. This is neither cost- nor resource-efficient.

Revenue-assurance compliance ensures that operational areas apply and maintain appropriate levels of control and produce metrics to set standards. The strategic intent is to automate the end-to-end tracking and reporting mechanism and to reduce system developments across individual components in the end-to-end process (see *Figure 3*).

Performance measurements should be analyzed for trends and key metrics, and then produced for the board to review. A fully automated system would provide results via a Web-based browser.

Where possible, revenue-assurance control should be maintained through non-intrusive automated monitoring across all components of the end-to-end core business process.

By implementing an automated autonomous approach, end-to-end monitoring and measurement can take place in an independent "live" environment, where it is possible to delivers robust control and reporting capabilities to the desktop. This eradicates the bottleneck for development on each of the end-to-end systems and facilitates accurate, consistent, and reliable management reporting.

Reaping the Benefits

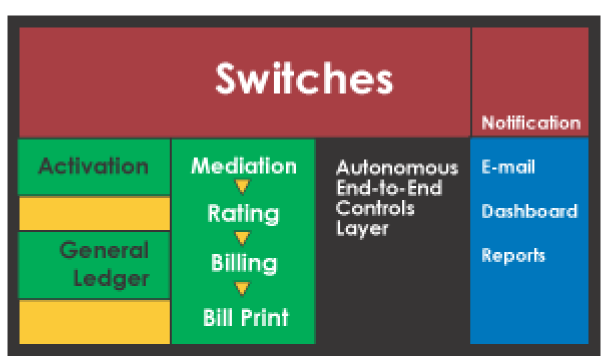
This approach delivers real benefits to the service provider, including the following:

- Vastly improved control and visibility, and early warnings of error, loss, and leakage for all systems
- The ability to action and recover rejected or suspended call data in a timelier manner and, therefore, stem losses and unnecessary write-offs
- The ability to identify potential losses that are not currently visible at all
- Maintenance of revenue-assurance developments that is performed independently of existing systems
- No bottlenecks or priority conflicts on existing systems
- Less people required for extracting data, performing analysis, and producing reports
- "Live" reports that are available to authorized users at any time via a Web site that gives instant visibility to end-to-end core business performance
- A scalable approach that can be flexibly "plugged" into other systems

Although it is not essential, to reap maximum benefits from this approach, the "Revenue Assurance" function should have enterprise-wide responsibility for monitoring and measuring. In addition, it should be recognized at the highest levels within the organization. This would be the optimal situation.

FIGURE 3

Autonomous End-to-End Controls



Everyone recognizes the importance and relative costs of a lack of information integrity, but we seem to be too paralyzed by the potential magnitude and scale of the issue to do anything enterprise-wide.

Phase One: Assessment

In assessing risks to information integrity, the objective is to identify and prioritize the information-error exposures in the business process. To do this, the assessor needs to do the following:

- Develop a process flow diagram
- List all potential sources of information errors and prioritize the list based on risk to the business
- Provide suggestions for next steps, including a recommended approach

The methodology for an integrity risk assessment consists of five phases, which are outlined in *Figure 4.* After the integrity risk assessment is performed, a document is delivered that captures the knowledge of employees and details the processes and procedures between various systems and applications (in this instance, it would be focused on the issue of revenue assurance). The knowledge would be documented to provide one complete end-to-end view of the system.

Furthermore, the assessment needs to assess the effectiveness of these procedures by component and where data leakage could be, or is, occurring. These areas of leakage indicate exposures to information errors and risks to information integrity.

An assessment that looks at the end-to-end revenue-assurance system documents and builds an understanding of the full "CDR life cycle" from point of generation on the switch to production of the billing file to another service provider or end customer, and ultimately into the general ledger.

Finally, where possible, the assessment identifies what happens if there is a failure.

Phase Two: Detection

After identifying the potential information error exposures in the business system and process, the next step is to put a series of sensors in place that will detect errors as they occur.

Because there are many different types of information errors in a process, there are a variety of information-error detection sensors that can be designed around the characteristics of each type of error. A combination of each of these sensors is usually required to identify all of the information errors in a given business process.

These error types are grouped into four categories:

- Data Validation
- Transaction Tracking
- Balancing and Reconciliation
- File Validation

Building an autonomous, automated sensor array around the company's processes creates an "early warning system" matrix of controls to detect information errors before senior executives, business partners, and customers see them—and before the errors become front-page news.

Table 1 provides a detailed breakdown of information error types that could affect a business.

Phase 3: Resolution

Sensors that non-invasively monitor the end-to-end process create the controls architecture layer that provides service providers with confidence that their core business processes are operating effectively and efficiently, because any issues are identified at the source, when they occur.

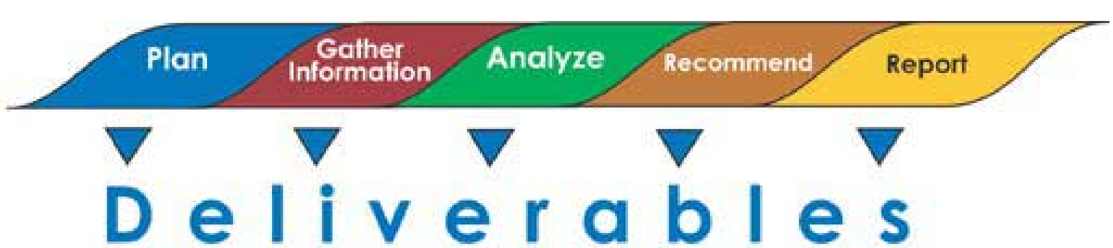
TABLE 1

Error Group Sensor Types

Data Validation	Transaction Tracking	Balancing & Reconciliation	File Validation
Format Content Context Error Rate Profile	Value Time Path	Run-to-Run Point-to-Point Over Time Across Platforms	Usage Sequence Specs

FIGURE 4

Assessment Methodology



Beyond the detection phase, an integrated set of resolution tools is often desired to round out the functionality of the "early warning system."

Firstly, a dashboard view provides the ability to view errors flagged by the sensors and the current revenue flow status of the entire enterprise-wide environment via a normal Web browser. With the dashboard, service providers are able to drill down into "problem areas" and, with complementary communication applications, automatically e-mail or page the appropriate people about the problem, enabling quick resolution.

Secondly, the resolution phase should allow for the automated correction of errors and the ability to provide a workflow and correction environment for any detected information errors. In essence, the resolution piece of an "early warning system" should provide the opportunity to fix the error, thereby assuring the accuracy, consistency, and reliability of the information.

Phase 4: Prevention

After completing the initial deployment of the detection and resolution phases, focus shifts to ongoing deployment to maximize the value received from the "early warning system." This is the prevention phase.

To determine what additional deployment will provide the greatest return, the prevention phase emphasizes measurement of current value to determine next steps.

The optimization of value from the "early warning system" approach relies on two elements:

1. The measurement of value received from the current deployment
2. A prediction of future value from either enhancing the implementation of tools already in place or through implementing new tools in an upstream or downstream process

Using a series of best-practice valuation and analysis methods, the recommended course of continuous improvement can be determined.

Strategic Initiative Advantages

By effectively introducing an "early warning system" strategic initiative that looks at revenue assurance end to end, a number of comparative advantages are realized. These advantages include the following intangible and conditional benefits:

- Improved decision making by providing timely, comprehensive, and accurate information. For example, bad debts that perhaps "disappeared" from a system are identified, allowing for the recovery of the monies owed.
- Replacement of low-value staff activities with high-value work. For example, a lawyer could end up spending less time building, checking, and presenting price lists/rating tables and more time dealing with "legal" issues.
- Established and centralized responsibility for revenue assurance, which reduces the need for every system to track its own part of this responsibility, improving efficiency and reducing costs.
- Protection of the brand from bad publicity, regulators, and customer complaints. Not only will customer retention increase, but new customer sign-ups may increase also.
- Standardized approach to revenue assurance that can reduce costs.
- Proactive approach toward the identification of errors versus a nonexistent approach.
- Assurance that systems have the ability to grow with the company as it grows.
- Utilized information as an asset. For example, marketing could potentially examine and analyze call usage related to new products and identify trends in calls that suggest new products.
- Assurance that *all* revenues earned are being received—an approach that would be well received by shareholders and, ultimately, the stock market.
- True end-to-end audit ability versus application and system disparate auditing.
- Competitive advantage within a highly competitive environment.

In addition to this tangle of intangible and conditional types of benefits, there are a number of "tangible" benefits that have been generated within communications companies[4], including the following:

- A 7 percent increase in billable transactions
- A 95 percent reduction in double-posting errors
- A 53 percent reduction in error-related costs
- A reduction from two weeks to only one day to perform a monthly financial close
- An increase in available network capacity

Once again, effectively addressing critical issues such as revenue assurance requires a strategic approach, good planning, and decision-making authority.

The Information Integrity Coalition

The information age to date has been about the technology that handles the data. The communications industry has played a key role in its ascent. The Information Integrity Coalition, formed in 2001, is looking into ways to address those areas beyond the technology.

According to Madhavan K. Nayar, one of the founders of the Information Integrity Coalition, the time has come to make the information age about information[5]. In outlining the economic impact of information errors, Mr. Nayar acknowledges, "We are aware errors occur; we are resigned to them as a cost of doing business; and we are skeptical that we can do anything about them." However, using current revenue-leakage indicators, he underscores that resignation is not the answer.

The Information Integrity Coalition takes a holistic approach to a solution, seeking nothing less than the formation standards and a new industry. That new industry will be one that Mr. Nayar says will address information integrity as more than a simply technical issue—as something multidimensional. He outlines several inquiry possibilities: data (numbers, graphics), assurance methods (security, audit, controls), assurance activities (prevention, detection, monitoring, correction), system life phases (design, develop, implement), system types (manual, online, interactive), industry-specific (banking, health, education, insurance, communications), business (cost, risk, opportunity), and disciplines (statistics, economics, psychology, ethics).

There are companies out there right now that address some of these information-integrity dimensions, such as security, error detection, information monitoring, industry-specific solutions, and data companies.

Their efforts, however, are fragmented. The Information Integrity Coalition seeks to reconfigure them through the creation of an information-integrity discipline that is complete with standards.

Summary

Communications service providers are seeking ways to become more competitive, efficient, and effective in their daily operations. Revenue assurance is needed within the communications industry, because the cost of revenue leakage caused by the lack of accurate, consistent, and reliable information is significant. Through a holistic, strategic, and phased approach, service providers can introduce a standard way to monitor, measure, and control their core business processes related to revenue assurance. Improved integrity of information is only one result of implementing this approach.

Through this consultative, strategic approach, partly consisting of four phases—assessment, detection, resolution, and prevention—service providers can implement an "early warning system" for information errors so that they can be corrected before they affect customers, the business, or become headline news. This approach helps to create information integrity in the enterprise and helps in the effort to assure that all revenue is recognized.

Few organizations have a true enterprise-wide view of revenue leakage. This is not good business, and, while the task ahead is far from easy, you must (to quote Churchill) "never, never, never, never, never, never, never, never, never…give up!" A company's information is its biggest undervalued and unrealized asset. A board-level–endorsed revenue-assurance strategy is the first step in the right direction.

Backhaul from International Cable Systems: A New Carrier Market Opportunity

John Gudgel
Senior Marketing Manager, Global Carriers
Lightscape Networks

I. Introduction

An optical tidal wave is hitting the shores of the United States. By the end of 2002, at least 24 synchronous digital hierarchy (SDH) international cable systems will have landed in the United States and become operational (see *Figure 1*). The total capacity of these systems is more than 20 terabits per second (Tbps)—a bandwidth sufficient, in theory, to allow every man, woman, and child in the United States to simultaneously make an overseas phone call.

In the trans-Atlantic corridor alone, capacity in the next year will increase by more than 500 percent. This growth is spurred by the demands of hundreds of new global carriers and Internet service providers (ISPs) hungry for international bandwidth to satisfy their Internet backbone demands.

However, international bandwidth is only useful if it can be delivered to the end user. Once an international cable is landed at a cable station, it still has to be extended from the station to a carrier's international point-of-presence (POP) and, from there, via domestic networks, to the end user. This cable system backhaul can be the Achilles heel of international capacity delivery, significantly increasing both the cost and provisioning time to implement service. Yet for those carriers that understand the technical and economic challenges associated with backhaul and that proactively implement backhaul solutions, there is a potentially large market opportunity.

This paper describes the current international cable environment, identifies the technical and economic issues associated with cable-system backhaul in the United States, provides some possible backhaul solutions, and analyzes the potential market opportunity associated with the lease or sale of backhaul facilities.

II. Submarine Cable Systems—A Brief Tutorial

The first international submarine cable system connecting England and France was laid in 1850. Used for telegraphy, it consisted of a single insulated copper wire that could transmit only one message at a time. Unfortunately, the cable was cut by a fisherman less than two days after going operational.

Undersea cables have come a long way since 1850. Most of the undersea cables being installed today are fiber-optic ring-protected systems capable of handling hundreds of thousands or even millions of simultaneous voice calls. The technology that makes this possible is dense wavelength division multiplexing (DWDM) (see *Figure 2*). This technology allows multiple high-speed channels (currently 2.5 of 10 gigabits per second [Gbps]) using different wavelengths (currently as many as 40 colors) of light to be transmitted over a single fiber. Most international submarine cables being installed today consist of two, four, or eight fiber strands, typically configured in a ring configuration. The formula to calculate the carrying capacity of a cable system is as follows:

- # strands of fiber x # channels of DWDM x size of the DWDM channel x the type
- of configuration (one for point-to-point, two for a ring configuration)

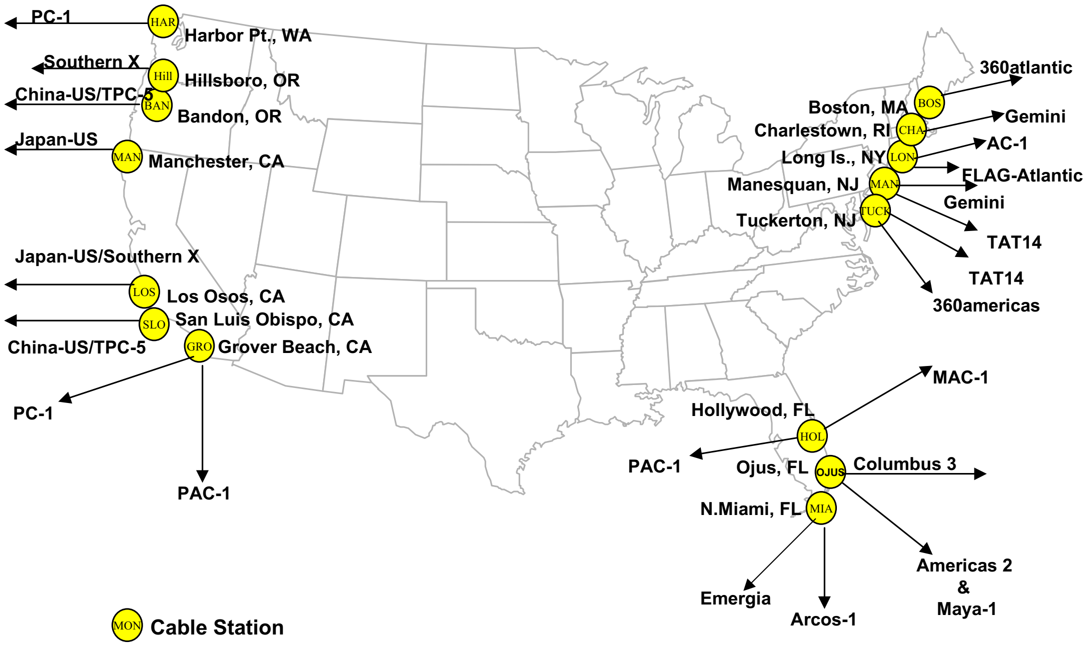
Thus the carrying capacity of TAT-14 is as follows:

- 8 strands of fiber x 32 channels per fiber x 2.5 Gbps per channel x 2 (ring) = 1,280 Gbps
- or 640 Gbps (fully protected)

All international cables are currently being implemented using International Telecommunication Union (ITU) standards that define optical transmission using the SDH. This

FIGURE 1

International Submarine Cables Landing in the United States



optic transmission standard is different from the synchronous optical network (SONET) standard, which is used by domestic carriers in the United States. This difference is an important technical consideration when implementing international circuits, because oftentimes this capacity must be converted from SDH to SONET to be transmitted over networks in the United States.

The basic unit of SDH capacity typically utilized in international cables systems is the synchronous transfer mode (STM)–1, which is a 155 megabits per second (Mbps) circuit. Its SONET equivalent is an optical carrier (OC)–3. Oftentimes, cable systems are sized based upon their number of STM–1 equivalents. Thus TAT-14, which has a carrying capacity of 1,280 Gbps (640 Gbps ring protected), can support as many as 8,192 unprotected or 4,096 protected STM–1s.

Until a few years ago, virtually all international cables were built by consortiums consisting of a large number of global carriers that agreed to share the high cost of building the system. The carriers sign a construction and maintenance agreement (CMA), which defines the amount of capacity that each carrier owns in the system and the terms and conditions for participating in the cable construction and ongoing operation. Cable system capacity is purchased as an indefeasible right of usage (IRU). An IRU is like owning a condominium in a building. The owner pays an upfront capital price for the right to use a specific amount of capacity (e.g., an STM–1) for the lifetime of the cable (typically 15 or 20 years) and ongoing annual maintenance fees (typically 5% to 7% of the initial cost). Under the traditional consortium construction model, the IRU is only for the submarine portion of the capacity (cable station–to–cable station). The terrestrial portion, or backhaul, which connects the capacity from the cable landing station back into the owner's domestic network, is not part of the IRU. This backhaul must be leased or purchased separately at considerable effort and expense.

Recently, a number of new cable systems have been financed and built by ***joint ventures*** (e.g., Gemini, which is a joint venture of WorldCom and Cable & Wireless) or by ***private cable companies,*** such as Global Crossing. These new construction entities are changing the rules by which capacity is purchased. Among the most important changes is that IRUs are now being sold ***city-to-city,*** with a large portion of the backhaul at both ends being included in the IRU. However, for the time being, a large number of cable systems continue to be built by consortiums, cable station–to–cable station, and still require that the capacity owner make their own arrangements for backhaul.

III. Cable System Overview

Table 1 is a list of the U.S.–terminating SDH cable systems currently in operation or under construction. By the end of 2001, these new SDH cable systems will increase the total capacity of bandwidth coming into the United States by more than 5,000 times versus pre-1995 levels. Subsequently, the price of IRU capacity has plummeted from more than $20 million per cable station–to–cable station trans-Atlantic STM–1 in 1995 to, in some cases, less than $500,000 for a similar city-to-city STM–1 in 2001.

Trans-Atlantic Cable Systems

At the end of 2000, there were five SDH cable systems operational between the United States and Europe. They are TAT-12/13 (which went operational in 1995), Gemini and AC-1 (which came into service in 1998), and Columbus 3 and AC-2 (which came into service in late-2000). TAT-12/13 is a ring system that connects the United States with France

FIGURE 2

DWDM allows one to split and combine different wavelengths in a single fiber.

and the United Kingdom. It recently underwent an in-system upgrade that increased its ring-protected capacity from 5 to 10 Gbps. Gemini and AC-1 are larger ringed systems that broke the virtual monopoly that TAT-12/13 had on trans-Atlantic capacity from 1995 to 1997. Gemini and AC-1 have been competing with each other since 1998. In the process, they drove the price down for a trans-Atlantic STM–1 to less than $4 million per IRU. In late-2000, two new systems—AC-2 and Columbus 3—were completed, further intensifying trans-Atlantic bandwidth competition. However, all of these systems will be facing much stiffer competition when several new terabit-capacity trans-Atlantic cables are completed in mid-2001 and 2002.

The new trans-Atlantic systems include TAT-14, FLAG Atlantic, 360americas (formerly Atlantica), 360atlantic (formerly Hibernia), and Apollo. When all completed, the amount of trans-Atlantic ring-protected capacity will have increased by more than 50,000 STM–1s. This may produce a glut of capacity and a buyers market as cable-system owners scramble to sell IRUs before the price drops out of the market. Already, prices have fallen to unprecedented lows. However, many companies are gambling that the demand fueled by the Internet will quickly consume the excess supply. As a result, existing cable system owners are contemplating in system upgrades, and even larger multi-terabit systems are being discussed.

Trans-Pacific Cable Systems

For the past several years, the capacity situation has been very bleak. Between 1995 and 1999, the only SDH cable system with any IRU capacity was TPC-5, and that bandwidth, when you could find it, was very expensive. An in-system upgrade of TPC-5 from 5 to 10 Gbps (ring protected) in 1999 only relieved the trans-Pacific capacity famine slightly. The situation improved dramatically in early 2000, when two systems China-US and Pacific Crossing 1 (PC-1) went into operation. In addition to the cables that have been described, several other SDH cables are schedule to go into full operation in 2001. These systems include Southern Cross, which will connect the United States with Australia and New Zealand, and Japan-US. In 2002, two new terabit systems, 360pacific and FLAG-Pacific are also scheduled to go into service. Further information on all of the trans-Pacific cable systems in given in Table 1.

Cable Systems Connecting the United States to South and Central America

There are a surprising number of new cable systems being implemented that connect the United States to Central and South America and to the islands in the Caribbean. These systems include Americas 2, Maya-1, Arcos, Emergia, and South American Crossing 1 (SAC-1). All of these systems land in the United States in Southern Florida. In the case of SAC-1, this landing is actually via another Global Crossing system: Mid-Atlantic Crossing (MAC), which is a feeder cable that runs from Florida to Bermuda (the actual SAC-1 landing site) and then to the AC-1 landing site on Long Island, New York. Another Global Crossing cable system, Pan-America Crossing -1 (PAC), will eventually connect from the Florida landing site for MAC-1 to the California cable station for PC-1. At that point, Global Crossing will be able to provide transit service between all of its U.S.–terminating cables: AC-1, MAC-1, SAC-1, PAC-1, and PC-1.

IV. Backhaul Issues and Alternatives

When an international submarine cable is landed in the United States, it is natural to assume that it is a fairly easy matter to extend that capacity on-shore from the cable station into a carrier's domestic network and, from there, to the end users' location. After all, fiber-optic transmission is in wide use in the United States, the circuits run over dry land versus under the sea, and one would think that any carrier with fiber capacity and a little bit of ingenuity could easily handle the task. In fact, cable-system backhaul implementation can, at times, be far from easy. There are several technical and economic issues that can make backhaul difficult and expensive to implement.

To begin with, all international cables currently are being implemented using SDH technology. This means that capacity on these systems is being transmitted as SDH, lower-rate circuits must be mapped onto higher-rate SDH circuits, and the hand-off of the circuits at the U.S. cable station is also SDH. Because the standard for fiber-optic transmission in the United States is SONET, delivering this capacity to the end user can be a challenge. More and more, end-user equipment, such as routers and asynchronous transfer mode (ATM) switches, are being designed to support both SONET and SDH interfaces. The problem is getting the SDH circuit from the cable station to the equipment. One obvious solution is to convert the SDH capacity to SONET using some type of gateway protocol converter, multiplexer, or digital access cross-connect system (DACS). These gateway boxes can perform the SDH to SONET conversion (e.g., STM–1 to OC–3) and, in some cases, can also map U.S. standard plesiochronous digital hierarchy (PDH) capacity (T1, digital signal [DS]–3, etc.) onto international SDH circuits.

Another problem with backhauling international circuits is economic. Up until a few years ago, nearly all international submarine cables landing in the United States were terminated at stations belonging to AT&T. AT&T controlled access to these stations and, as a result, had a virtual monopoly on the international cable backhaul business in the United States. Carriers owning capacity on U.S.–terminating cables had to deal with AT&T, which set the rules and costs for activating backhaul capacity. The rules, which were bureaucratically adhered to, could cause lengthy provisioning delays oftentimes resulting in backhaul intervals of six months or more. Furthermore, AT&T charged considerably more for SDH backhaul capacity versus comparable domestic SONET circuits.

Recently, the AT&T backhaul monopoly has been broken. Systems such as Gemini and AC-1, which came into service in 1998, sell city-to-city service. City-to-city service includes the backhaul from cable stations to select major metropolitan area "city sites," which are usually major carrier hotels such as 60 Hudson and 111 8^{th} Avenue in New York City. Examples of other city-to-city systems being implemented include FLAG-Atlantic, MAC-1, PAC-1, PC-1, and 360atlantic. The problem with city-to-city service is that it is only available to certain buildings in specific cities. If users need to extend capacity to a building or city that is not covered, they may still have a problem. They still need to extend an SDH circuit from the city site to their location. In some instances, certain competitive access providers (CAPs) and interexchange carriers (IXCs) are offering SDH service to select locations. Thus, for example, some carriers may be offering leased STM–1s from a city site to a major Internet network access point (NAP), such as MAE East. Or, the operator of the city site may offer SDH–to–SONET conversion that will allow, for instance, the delivery of an STM–1 as an OC–3. It is also possible that a city-site operator will allow customers to co-locate a gateway box so they can do the SDH–to–SONET conversion themselves.

Many international cables continue to be implemented cable station–to–cable station, without any in-system provisions for backhaul. However, most cables now being built allow owners the right to co-locate at the cable station and to provide their own backhaul via dark fiber. For example, several carriers, including Sprint and Williams Communications, have co-located at the Bandon, Oregon cable station for China-US. They have implemented backhaul for their own needs and, also, are competing with AT&T by leasing backhaul facilities to other carriers. This limited competition has driven the monthly recurring cost for a Bandon-to-San Francisco eased backhaul STM–1 from more than $100,000 per month to less than $40,000 per month. Other cable station–to–cable station cables allowing co-location include TAT-14, Japan-US, Southern Cross, Americas 2, and Maya-1.

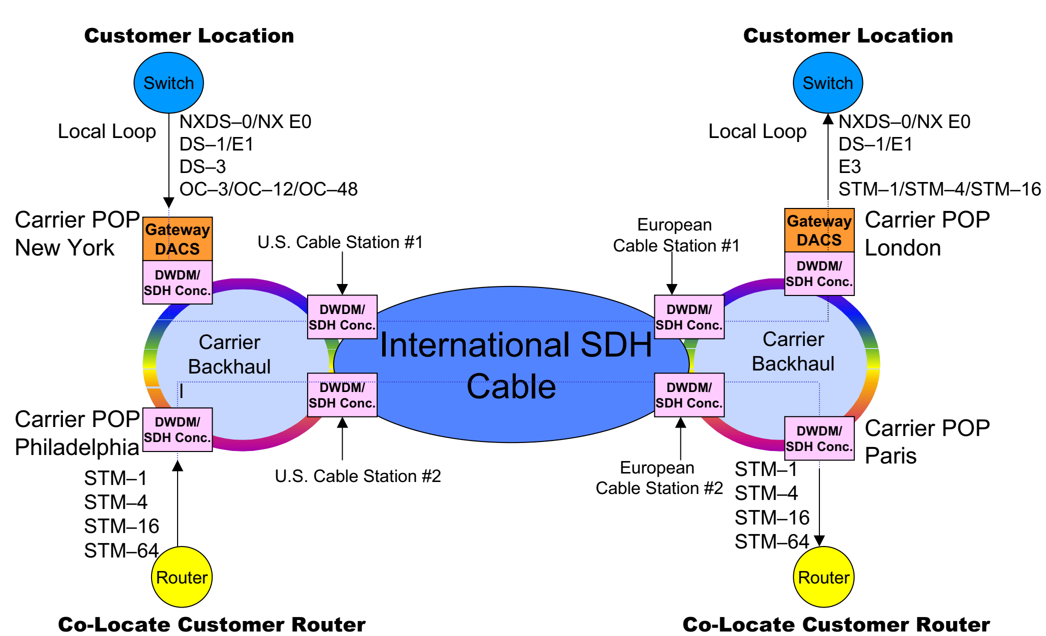
Many carriers, especially those owning large amounts of capacity on these cables, are actively arranging cable-station co-location and the implementation of their own dark fiber backhaul. They are implementing this service not only to save money by not having to pay another carrier for leased backhaul, but also to speed provisioning time and generate additional revenue by being able to sell backhaul themselves. To implement this service, they are installing SDH concentration and DWDM transmission equipment at the cable station and connecting it via dark fiber to similar equipment located in one or more international access POPs. At the access POP, they may have a gateway box to do SDH–to–SONET conversion so that capacity can be delivered to customers. They may also have international voice or ATM switches, routers for Internet access, or co-location space for customers wanting direct access to international facilities. Such a configuration is shown in *Figure 3*.

Thus, carriers that plan to purchase international capacity have a number of alternatives to consider regarding how to backhaul that capacity in the United States. They can purchase a city-to-city IRU and then only have to worry about the last mile between the city site and their POP. They can buy traditional cable station–to–cable station capacity and then either lease backhaul capacity from another carrier or build their own dark fiber backhaul facilities. In any case, they may still need to convert that capacity from SDH to SONET or break the SDH capacity down into DS–3s or T1s so it can be delivered to an end user. They can do this by either purchasing a gateway box to do the SDH/SONET conversion and mux/demuxing or pay another carrier for these services.

V. "Backhaul" Market Opportunities

With the tidal wave of new cables landing ashore in the United States, the proliferation of fiber-optic cable around the country, the willingness of cable-station operators to allow co-location, and the economics of DWDM, a number of opportunities have arisen for carriers to sell backhaul-related products.

FIGURE 3



The first obvious product is the lease or sale of backhaul facilities. Carriers that build their own backhaul networks can lease STM–1s, STM–4s, STM–16s, or whole wavelengths to other carriers. They can also sell these same facilities to carriers as backhaul IRUs at a fixed capital price plus annual recurring maintenance.

Another potential product is transit between two cable systems. This product includes the lease or sale of backhaul from two cable systems (e.g., TAT-14 and Japan-US), as well as a long-haul circuit connecting the two backhaul segments. Once again, these facilities could be leased to a carrier on a month-to-month or term basis, or sold to the carrier as a transit IRU.

Carriers that own backhaul networks to multiple cable systems can also provide restoration services to carriers or to cable-system operators. Under this scenario, backhaul network operators would reserve capacity for customers to be used in the event that a cable system suffers a catastrophic failure that disrupts service. The reserve backhaul capacity would be used to switch a customer's capacity from one cable serving a region (e.g., a Gemini STM–1 in the Atlantic) to another cable serving the same region (e.g., AC-1). In today's age of self-healing SDH cables, many carriers may see this service as unnecessary. However, several cables currently are being deployed initially as collapsed rings or point-to-point systems without restoration, and failures have occurred on supposedly "fully protected" submarine cables. Restoration services can be sold either in advance as a kind of insurance policy against possible failure or "by the drink" during an emergency situation.

Finally, carriers can sell backhaul bundled with other products and services. For example, a carrier that owns facilities at both ends of a cable can offer one-stop-shop, city-to-city leased international private lines or IRUs that can be quickly provisioned for customer use. Delivery of these circuits might include optional bundled SDH/SONET conversion, mux/demux of capacity into lower-rate domestic circuits, or a high-speed Internet port. Thus, backhaul can be used to enhance a carrier's entire portfolio of global products.

VI. Conclusions

The coming year will offer global carriers unprecedented access to trans-oceanic cable capacity. However, those carriers will need to plan ahead to ensure that they have a backhaul solution in place so they can access their international capacity when it becomes available.

These carriers need to ask themselves what they plan to use the capacity for and where it will need to be delivered. Once these questions are answered, only then can a carrier adequately determine the best way in which to backhaul this capacity. Their backhaul solution could be a lit solution that is leased or purchased from another carrier, or one that involves cable-station co-location and dark fiber. They may also need to determine whether or not they require SDH–to–SONET conversion or the breakdown of their capacity into smaller increments. If they do, they need to install a gateway DACS or some other gateway solution.

Lastly, once a carrier has a backhaul solution in place, they can then pursue a number of potential business opportunities that can not only produce direct revenue, but also enhance their entire global product portfolio.

Simulation of the Harmful Consequences of Self-Similar Network Traffic: A Model for Network Engineers

Tibor Gyires
Professor, Applied Computer Science
Illinois State University

Abstract

For a long time, the area of network traffic research has lacked adequate traffic measurements. During the past years, a large amount of network traffic measurements have become available, collected in the Web and high-speed networks. Measurements of real traffic indicate that burstiness is present on a wide range of time scales and show evidence of self-similarity and long-range dependency. Many traditional models originating in conventional voice networks either assumed that the underlying time series are short-range dependent or do not focus on the various, interrelated network components affected by bursty traffic. To provide explanations for empirically observed phenomena, such as burstiness in terms of physical network parameters, we need to develop models that can allow for the details of the complex architecture of today's networks and can analyze the interrelated network parameters that ultimately determine the performance and operation of a network. In the paper, we investigate the harmful consequences of burstiness on various network components using a model implemented by a discrete event simulation methodology. The methodology based on a modified version of the M/Pareto model can measure network performance parameters, such as the momentarily utilization of links, response time, and the queuing performance of interconnected switches and routers along the traffic paths. Our paper intends to narrow the gap between existing, well-known theoretical results and their applicability in everyday, practical network analysis and modeling. Our methodology can help network designers and engineers, the ultimate users of traffic modeling, to understand the dynamic nature of network traffic and assist them to design, monitor, and control complex, high-speed networks in everyday practice.

1. Introduction

Recent measurements of local-area network (LAN) traffic [1] and wide-area network (WAN) traffic [2] have proved that the widely used Markovian process models cannot be applied for today's network traffic. If the traffic were Markovian process, the traffic's burst length would be smoothed by averaging over a long time scale contradicting with the observations of today's traffic characteristics. Measurements of real traffic also prove [3] that traffic burstiness is present on a wide range of time scales. Traffic that is bursty on many or all time scales can be characterized statistically using the concept of self-similarity. Self-similarity is often associated with objects in fractal geometry, objects that appear to look alike regardless of the scale at which they are viewed. In case of stochastic processes such as time series, the term self-similarity refers to the process' distribution-when viewed at varying time scales, the process' distribution remains the same. Self-similar time series has noticeable bursts, long periods with extremely high values on all time scales. Characteristics of network traffic, such as packets per second, bytes per second, or length of frames can be considered as stochastic time series. Therefore, measuring traffic burstiness is the same as characterizing the self-similarity of the corresponding time series.

The self-similarity of network traffic has also been observed in studies in numerous papers, such as [4], [5], and [6]. These and other papers show that packet loss, buffer utilization, and response time are totally different when simulations use either real traffic data or synthetic data that include self-similarity.

1.1. Background

For more details of self-similarity in time series and the associated statistical tests, see [3], [7], and [8]. Our paper follows the definitions of these papers.

Let $X = (X_t: t = 0, 1, 2, ...)$ be a covariance stationary stochastic process. Such a process has a constant mean $\mu = E[X_t]$, finite variance $\sigma^2 = E[(X_t - \mu)^2]$, and an autocorrelation function $r(k) = E[(X_t - \mu)(X_{t+k} - \mu)]/E[(X_t - \mu)^2]$ $(k = 0, 1, 2, ...)$ that depends only on k. It is assumed that X has an autocorrelation function of the form:

$$(1) \quad r(k) \sim \alpha k^{-\beta}, \qquad k \to \infty$$

where $0 < \beta < 1$ and α is a positive constant. Let $X^{(m)} = (X^{(m)}_{(k)} : k = 1, 2, 3, ..., m = 1,2,3,...)$ represent a new time series obtained by averaging the original series X over non-overlapping blocks of size m. For each m = 1, 2, 3,…, $X^{(m)}$ is specified by $X^{(m)}_k = 1/m(X_{km-m+1} + \ldots + X_{km}), (k \geq 1)$. Let $r^{(m)}$ denote the autocorrelation function of the aggregated time series $X^{(m)}$.

1.1.1. Definition of Self-Similarity

The process X is called exactly self-similar with self-similarity parameter $H = 1 - \beta/2$ if the corresponding aggregated processes $X^{(m)}$ have the same correlation structure as X, i.e., $r^{(m)}(k) = r(k)$, for all m = l, 2,... (k = l, 2, 3,...).

A covariance stationary process X is called asymptotically self-similar with self-similarity parameter

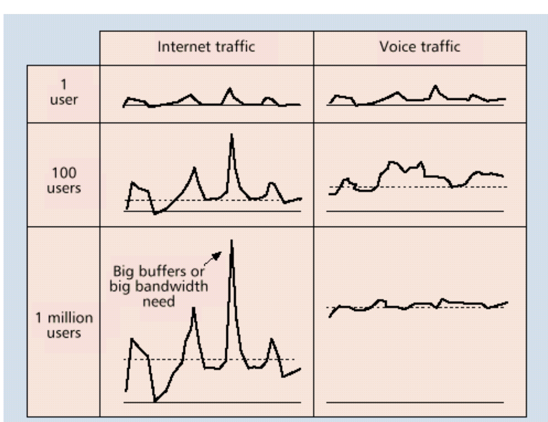
$H = 1 - \beta/2$ if for all k large enough $r^{(m)}(k) \to r(k)$ as $m \to \infty$, $0.5 \leq H \leq 1$.

1.1.2. Definition of Long-Range Dependency

A stationary process is called long-range dependent if the sum of the autocorrelation values approaches infinity: $\Sigma_k\, r(k) \to \infty$. Otherwise, it is called short-range dependent.

FIGURE 1

The Self-Similar Nature of Internet Network Traffic



(Source: M. Listanti and V. Eramo, "Architectural and Technological Issues for Future Optical Internet Networks," IEEE Communications (September 2000), 82-92.)

It can be derived from the definitions that while short-range dependent processes have exponentially decaying autocorrelations, the autocorrelations of long-range dependent processes decay hyperbolically; i.e., the related distribution is heavy-tailed. In practical terms, a random variable with heavy-tail distribution generates extremely large values with high probability [10, 11].

The degree of self-similarity is expressed by the parameter H or Hurst parameter. The parameter represents the speed of decay of a process' autocorrelation function. As $H \to 1$, the extent of both self-similarity and long-range dependence increases. It can also be shown that for self-similar processes with long-range dependency, $H > 0.5$ [12].

1.2. Traffic Models

Traffic modeling originates in traditional voice networks. Most of the models have relied on the assumption that the underlying processes are Markovian [13] (or more general, short-range dependent). However, today's high-speed digital packet networks are more complex and bursty than traditional voice traffic due to the diversity of network services and technologies.

Several sophisticated stochastic models have been developed as a reaction to new developments, such as Markov-modulated Poisson processes [14], fluid flow models [15], Markovian arrival processes [16, 17], batched Markovian arrival process models [19], packet train models [19, 20, 21], and Transform-Expand-Sample models [22]. These models mainly focus on the related queuing problem analytically. They are usually not compared to real traffic patterns and not proved that they match the statistical property of actual traffic data [23, 24, 25, 26].

Another category of models attempts to characterize the statistical properties of actual traffic data. For a long time, the area of networking research has lacked adequate traffic measurements [27]. However, during the past years, large quantities of network traffic measurements have become available and have been collected on the Web and in high-speed networks. Some of these data sets consist of high-resolution traffic measurements over hours, days, or weeks, (e.g., [11, 28, 29, 30, 31, 32, 33, 34, 36]. Other data sets provide information over time periods ranging from weeks to months and years. See, for instance, in [37, 38], signaling system 7 (SS7) data sets in [39, 40] and WAN measurements [11, 28, 40, 41, 42, 43]. Statistical analyses of these high time-resolution traffic measurements have proved that actual traffic data from packet networks reveal self-similarity. These results point out the difference between traditional models and measured traffic data. While the assumed processes in traditional packet traffic models are short-range dependent, measured packet traffic data show evidence of long-range dependency. *Figure 1* illustrates the difference between Internet traffic and voice traffic for different numbers of aggregated users [44]. As the number of voice flows increases, the traffic becomes more and more smoothed contrary to the Internet traffic.

Quite the opposite to the well-developed field of short-range dependent queuing models, there are fewer theoretical results exist for queueing systems with long-range dependence. For some of the results, see [45, 46, 47].

In terms of modeling, the two major groups of self-similar models are fractional Gaussian noises and fractional ARIMA processes. The Gaussian models accurately represent aggregation of many traffic streams as it has been proved in [48] and illustrated by simulation in [49]. The results in [4] demonstrated the effect of long-range dependency on queue length statistics of a single queue system through a controlled fractionally differenced ARIMA (1, d, 0) input process. Another well-known model, the M/Pareto model, has been used in modeling network traffic that is not sufficiently aggregated for the Gaussian model to apply, for example [49, 50].

1.2.1. Black Box versus Structural Models

We share the authors' opinion in [51, 53] calling the approach of traditional time series analysis as black box modeling as opposite to the structural modeling that focus on the environment in which the models' data was collected, i.e., the complex hierarchies of network components that make up today's communications systems. While the authors admit that black box models can be and are useful in other contexts, they argue that black box models are of no use for understanding the dynamic and complex nature of the traffic in modern packet networks. Black box models have not much use in designing, managing and controlling today's networks either. To provide physical explanations for empirically observed phenomena such as long-range dependency, we need to replace black box models with structural models. The attractive feature of structural traffic models is that they take into account the details of the layered architecture of today's networks and can analyze the interrelated network parameters that ultimately determine the performance and operation of a network. Time series models usually handle these details as black boxes [51]. Because actual networks are complex systems, in many cases, black box models assume numerous parameters to represent a real system accurately. For network designers, who are important users of traffic modeling, black box models are not very useful. It is rarely possible to measure or estimate the model's numerous parameters in a complex network environment. For a network designer, a model ought to be simple and meaningful in a particular network. It can relay on actual network measurements, and the result ought to be relevant to the performance and the operation of a real network.

For a long time, traffic models were developed independently of traffic data collected in real networks. These models could not be applied in practical network design. Today, the availability of huge data sets of measured network traffic and the increasing complexity of the underlying network structure emphasize the application of the Ockham' Razer in network modeling. (Ockham's Razor is a principle of the medieval philosopher William Ockham.) According to this principle, modelers should not make more assumptions than the minimum needed. This principle is also called the Principle of Parsimony and motivates all scientific modeling and theory building. It states that modelers should choose the simplest model among a set of otherwise equivalent models of a given phenomenon. In any given model, Ockham's Razor helps modelers to include only those variables that are really needed to explain the phenomenon. Following the principle, model development will become easier, reducing the possibilities for inconsistencies, ambiguities, and redundancies [52].

Structural models are presented, for instance, in [53] and [54]. The papers demonstrate how the self-similar nature of aggregated network traffic of all conversations between hosts explains the details of the traffic dynamics at the level generated by the individual hosts. The papers introduce structural traffic models that have a physical meaning in the network context and underline the predominance of long-range dependence in the packet arrival patterns generated by the individual conversations between hosts. The models provide insight into how individual network connections behave in LANs and WANs. Although the models go beyond the black box modeling methodology by taking into account the physical structure of the aggregated traffic patterns, they do not include the physical structure of the intertwined structure of links, routers, switches, and their finite capacities along the traffic paths.

In [3], the authors demonstrated that World Wide Web (WWW) traffic shows characteristics that are consistent with self-similarity. They show that transmission times may be heavy-tailed due to the distribution of available file sizes in the Web. It is also shown that silent times may also be heavy-tailed, primarily due to the effect of user "think time." Similarly to the structural models in [53, 54], this paper lacks analysis of the impact of self-similar traffic on the parameters of the links and the routers' buffers that ultimately determine a networks' performance.

The effect of self-similar traffic on queue length statistics for real asynchronous transfer mode (ATM) variable bit rate (VBR) traffic is studied in [55]. Making use of fractionally differenced ARIMA (1, d, 0) for the input process, the authors study the queue length process for a varying level of mean utilization. The results of the simulation model demonstrate that the increased buffer size does not significantly decrease cell-loss probabilities for long-range dependent processes. The models developed under the S+ package [56] focus on the queue length of a single-server queue. They do not simulate the combined, overall effect of the interrelated, individual components of a network, such as links, buffers, and applications' response times.

Our paper describes a traffic model that belongs to the aforementioned structural model category. We implement the M/Pareto model within the discrete event simulation package COMNET that allows the analysis of the negative impact of self-similar traffic on not just one single queue, but on the overall performance of various interrelated network components, such as link, buffers, response times, etc. The commercially available package does not readily provide tools for modeling self-similar, long-range dependent network traffic. The model-generated traffic is based on measurements collected from a real ATM network. The choice of the package emphasizes the need for integrated tools that could be useful not just for theoreticians, but also for network engineers and designers. Our paper intends to narrow the gap between existing, well-known theoretical results and their applicability in everyday, practical network analysis and modeling. It is highly desirable that appropriate traffic models should be accessible from measuring, monitoring, and controlling tools. Our model can help network designers and engineers, the ultimate users of traffic modeling, to understand the dynamic nature of network traffic and assist them in designing, measuring, monitoring, and controlling today's complex, high-speed networks in their everyday practice.

1.2.2. Implications of Burstiness on High-Speed Networks
Various papers [33, 50, 57, 58, 59] discuss the impact of burstiness on network congestion. Their conclusions are as follows:

- Congested periods can be quite long with losses that are heavily concentrated.
- Linear increases in buffer size do not result in large decreases in packet drop rates.
- A slight increase in the number of active connections can result in a large increase in the packet loss rate.

Results show that packet traffic "spikes" (which cause actual losses) ride on longer-term "ripples," which in turn ride on still longer-term "swells" [33].

Another area where burstiness can affect network performance is a link with priority scheduling between classes of traffic. In an environment where the higher priority class has no enforced bandwidth limitations (other than the physical bandwidth), interactive traffic might be given priority over bulk-data traffic. If the higher priority class is bursty over long time scales, then the bursts from the higher-priority traffic could obstruct the lower-priority traffic for long periods of time.

The burstiness may also have an impact on networks where the admission control mechanism is based on measurements of recent traffic, rather than on policed traffic parameters of individual connections. Admission control that considers only recent traffic patterns can be misled following a long period of fairly low traffic rates.

2. Model Parameters

Each transaction between a client and a server consists of active periods followed by inactive periods. Transactions consist of groups of packets sent in each direction. Each group of packets is called a burst.

The burstiness of the traffic can be characterized by the following time parameters:

- Transaction Interarrival Time (TIAT): The time between the first packet in a transaction and the first packet of the next immediate transaction.
- Burst Interarrival Time ($1/\lambda$, λ: arrival rate of bursts): The time between bursts.
- Packet Interarrival Time (1/r, r: arrival rate of packets): The time between packets in a burst.

2.1. The Hurst Parameter
It is anticipated that the rapid and ongoing aggregation of more and more traffic onto integrated multiservice networks will eventually result in traffic smoothing. Once the degree of aggregation is sufficient, the process can be modeled by Gaussian process [49]. Currently, network traffic does not show characteristics that close to Gaussian. In many networks, the degree of aggregation is not enough to balance the negative impact of bursty traffic. However, before traffic becomes Gaussian, existing methods can still provide accurate measurement and prediction of bursty traffic.

Most of the methods are based on the estimate of the Hurst parameter H-the higher the value of H, the higher the burstiness and, consequently, the worse the queuing performance of switches and routers along the traffic path. Some are more reliable than others. The reliability depends on several factors, e.g., the estimation technique, sample size, time scale, traffic shaping or policing, etc. Based on published measurements, we investigated methods with the smallest estimation error1. Among those, we chose the Rescaled Adjusted Range (R/S) method because we found it implemented in the Benoit package [60]. The Hurst parameter calculated by the package is input to our method.

2.2. The M/Pareto Traffic Model and the Hurst Parameter
Recent results in [49, 61] have proved that the M/Pareto model is appropriate for modeling long-range dependent traffic flow characterized by long bursts. Originally, the model was introduced in [61] and applied in the analysis of ATM buffer levels. The M/Pareto model was also used in [68, 69, 70, 71] to predict the queuing performance of Ethernet, VBR video, and Internet protocol (IP) packet streams in a single server queue. We apply the M/Pareto model not just for a single queue, but also for predicting the performance of an interconnected system of links, switches, and routers affecting the individual network elements' performance. We make use of some of the calculations presented in [49, 61, 68, 69, 70].

The M/Pareto model is a Poisson process of overlapping bursts with arrival rate λ. A burst generates packets with arrival rate r. Each burst, from the time of its interval, will continue for a Pareto-distributed time period. The use of Pareto distribution results in generating extremely long bursts that characterize long-range dependent traffic.

The probability that a Pareto-distributed random variable X exceeds threshold x is:

$$(1)\quad P(X > x) = \begin{cases} \left(\dfrac{x}{\delta}\right)^{-\gamma}, & x \geq \delta \\ 1, & otherwise \end{cases}$$

$$1 < \gamma < 2, \delta > 0.$$

The mean of X, the mean duration of a burst $\mu = \delta\gamma/(\gamma - 1)$ and its variance is infinite [68]. Assuming a t time interval, the mean number of packets M in the time interval t is:

$$(2)\quad M = \lambda \mathrm{tr}\delta\gamma/(\gamma-1)\text{, and}$$
$$(3)\quad \lambda = M(\gamma-1)/\mathrm{tr}\delta\gamma$$

The M/Pareto model is described in [68, 69, 70, 71] as asymptotically self-similar, and it is shown that for the Hurst parameter, the following equation holds:

$$(4)\quad H = (3-\gamma)/2$$

3. Implementation of the Hurst Parameter in the COMNET Modeling Tool

We implemented the Hurst parameter and a modified version of the M/Pareto model in the discrete event-simulation system COMNET [64, 65]. By using discrete event-simulation methodology, we can get realistic results in measuring network parameters, such as utilization of links and the queuing performance of switches and routers. Our method can model and measure the harmful consequences of aggregated bursty traffic and predict its impact on the overall network's performance.

3.1. Traffic Measurements

To build the baseline model, we collected traffic traces in a large corporate network by the Concord Network Health network analyzer system. We took measurements from various broadband and narrowband links, including 45 Mbps ATM, 56 Kbps, and 128 Kbps frame-relay connections. The Concord Network Health system can measure the traffic in certain time intervals at network nodes, such as routers and switches. We set the time intervals to 6,000 seconds and measured the number of bytes and packets sent and received per second, packet latency, dropped packets, discard eligible packets, etc. Concord Network Health cannot measure the number of packets in a burst and the duration of the bursts, as it is assumed in the M/Pareto model. Due to this limitation of our measuring tool, we slightly modify our traffic model according to the data available. We took snapshots of the traffic in every five minutes from a narrowband frame-relay connection between a remote client workstation and a server at the corporate headquarters as traffic destination in the format in *Table 1*.

The mean number of bytes, the message delay from the client to server, the input buffer level at the client's local router, the number of blocked packets, the mean utilizations of the 56 Kbps frame relay, the digital signal (DS–3) segment of the ATM network, and the 100 Mbps Ethernet link at the destination are summarized in *Table 2*.

COMNET represents a transaction by a message source, a destination, the size of the message, communication devices, and links along the path. The rate at which messages are sent is specified by an interarrival time distribution-the time between two consecutive packets. The Poisson distribution in the M/Pareto model generates bursts or messages with arrival rate λ—the number of arrivals, which are likely to occur in a certain time interval. In simulation, this information is expressed by the time interval between successive arrivals $1/\lambda$. For this purpose, we use the Exponential distribution. Using the Exponential distribution for interarrival time will result in an arrival pattern characterized by the Poisson distribution. In COMNET, we implemented the interarrival time with the function Exp $(1/\lambda)$. The interarrival time in the model is set to one second matching the sampling time interval set in Concord Network Health and corresponding to an arrival rate λ = 1/sec.

In the M/Pareto model, each burst continues for a Pareto-distributed time period. The Concord Network Health can-

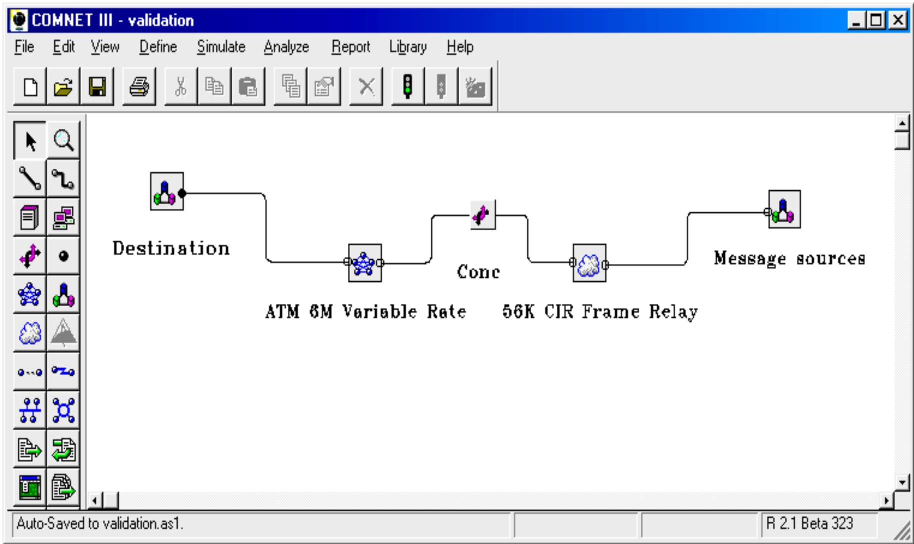
FIGURE 2

Part of the Real Network Topology Where the Measurements Were Taken



not measure the duration of a burst; hence, we assume that a burst is characterized by the number of bytes in a message sent or received in a second. Since the ATM cell-rate algorithm ensures that equal length messages are processed in equal time, longer messages then require longer processing time. So we can say that the distribution of the duration of bursts is the same as the distribution of the length of bursts. Hence, we can modify the M/Pareto model by substituting the Pareto-distributed duration of bursts with the Pareto-distributed length of bursts. We derive δ of the Pareto distribution not from the mean duration of bursts, but rather from the mean length of bursts.

The Pareto distributed length of bursts is defined in COMNET by two parameters: the location and the shape. The location parameter corresponds to the δ, the shape parameter corresponds to the γ parameter of the M/Pareto model in (1) and can be calculated from the relation (4) as

(5) $\gamma = 3 - 2H$

The Pareto distribution can have infinite mean and variance. If the shape parameter is greater than 2, both the mean and variance are finite. If the shape parameter is greater than 1, but less than or equal to 2, the mean is finite, but then the variance is infinite. If the shape parameter is less than or equal to 1, both the mean and variance are infinite.

From the mean of the Pareto distribution we get the following:

(6) $\delta = \mu * (\gamma - 1)/\gamma$

The relations (5) and (6) allow us to model bursty traffic based on real traffic traces by performing the following steps:

a. Collect traffic traces using the Concord Network Health network analyzer.
b. Compute the Hurst parameter H by making use of the Benoit package with the traffic trace as input.
c. Use the Exponential and Pareto distributions in the COMNET modeling tool with the parameters calculated as previously described to specify the distribution of the interarrival time and length of messages.
d. Generate traffic according to the modified M/Pareto model and measure network performance parameters.

The traffic generated according to these steps is bursty, with parameter H calculated from real network traffic.

4. Validation of the Baseline Model

We validate our baseline model by comparing various model parameters of a 56 Kbps frame-relay and a 6 Mbps ATM connection with the same parameters of a real network as the Concord Network Health network analyzer traced it. For simplicity, we use only the "Bytes Total/Sec" column of the trace, i.e., the total number of bytes in the "Bytes Total/Sec" column is sent in one direction only from the client to the server. The Hurst parameter of the real traffic trace is H = 0.55 calculated by the Benoit package. The topology is shown in *Figure* 2.

The "Message sources" icon is a subnetwork that represents a site with a token-ring network, a local router, and a client A sending messages to the server B in the "Destination" subnetwork (see *Figure* 3).

The interarrival time and the length of messages (see *Figure* 4) are defined by the Exponential and Pareto functions Exp (1) and Par (208.42, 1.9) respectively. The Pareto distribution's location (208.42) and shape (1.9) are calculated from formulas (5) and (6) by substituting the mean length of bursts (440 bytes from *Table* 2) and H = 0.55.

The corresponding heavy-tailed Pareto probability distribution and cumulative distribution functions are illustrated in the *Figure 5*. (The X-axis represents the number of bytes.)

The "Frame Relay" icon represents a frame-relay cloud with 56K committed information rate (CIR). The "Conc" router connects the frame-relay network to a 6 Mbps ATM network with variable rate control (VBR), as shown in *Figures 6* and *7*.

FIGURE 3

"Message Source" Remote Client

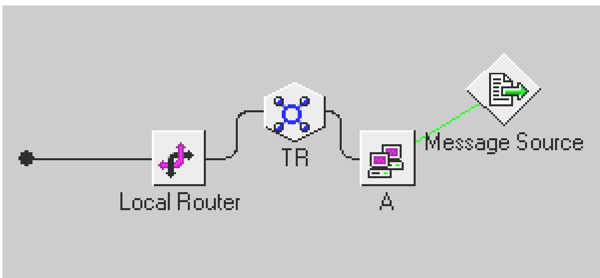


FIGURE 4

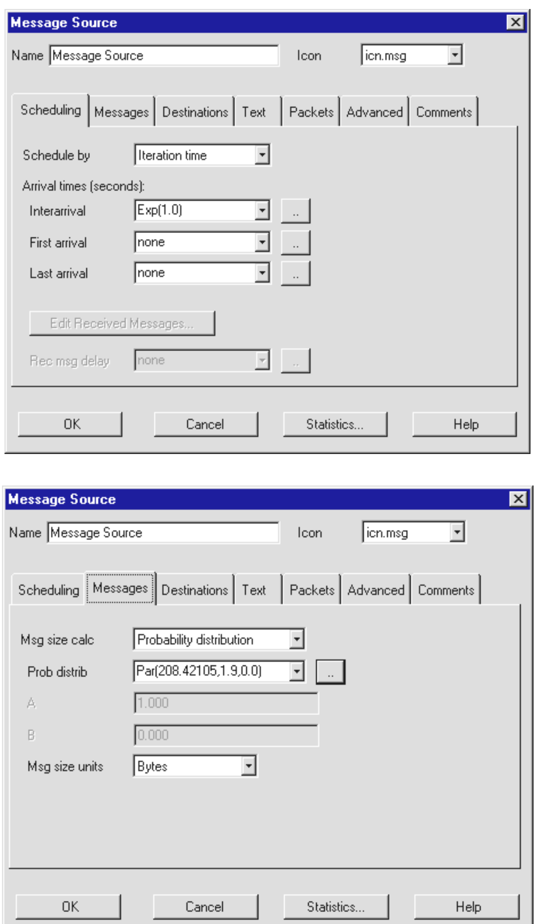
Interarrival Time and Length of Messages Sent by the Remote Client



The "Destination" icon denotes a subnetwork with server B (see *Figure 8*).

The results of the model show almost identical average utilization of the frame-relay link (0.035 ~ 3.5%) to the utilization of the real measurements (3.1%) (see *Figure 9*).

The message delay in the model is also very close to the measured delay between the client and the server (78 msec) (see *Figure 10*).

The input buffer level of the remote client's router in the model is almost identical with the measured buffer level of the corresponding router (see *Figure 11*).

Similarly, the utilizations of the model's DS–3 link segment of the ATM network and the Ethernet link in the destination network closely match with the measurements of the real network (see *Figure 12*).

It can also be shown from the model's traffic trace that for the model-generated messages, the Hurst parameter H = 0.56, i.e., the model generates almost the same bursty traffic as the real network.

Furthermore, the number of dropped packets in the model was zero, similar to the number of dropped packets in the real measurements. Therefore, we start from a model that closely represents the real network.

5. Consequences of Traffic Burstiness

To illustrate our method, we developed a COMNET simulation model to measure the consequences of bursty traffic on network links, message delays, routers' input buffers, and the number of dropped packets due to the aggregated traffic of large number of users. The model implements the Hurst parameter as it has been described in Section 3. We repeated the simulation for 6,000 seconds, 1,6000 seconds, and 18,000 seconds to allow infrequent events to occur a reasonable number of times. We found that the results are very similar in each simulation.

FIGURE 5

The Pareto Probability Distribution for Mean 440 Bytes and Hurst Parameter H = 0.55

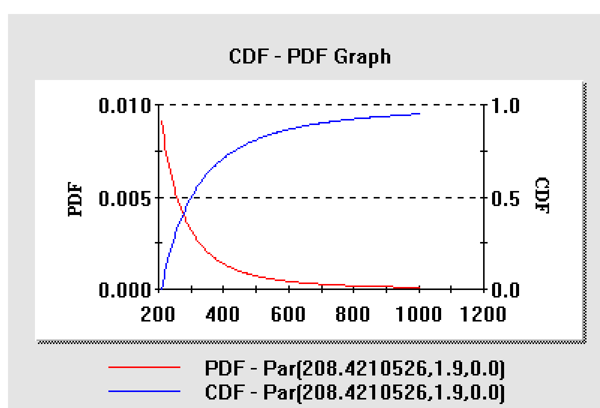


FIGURE 6

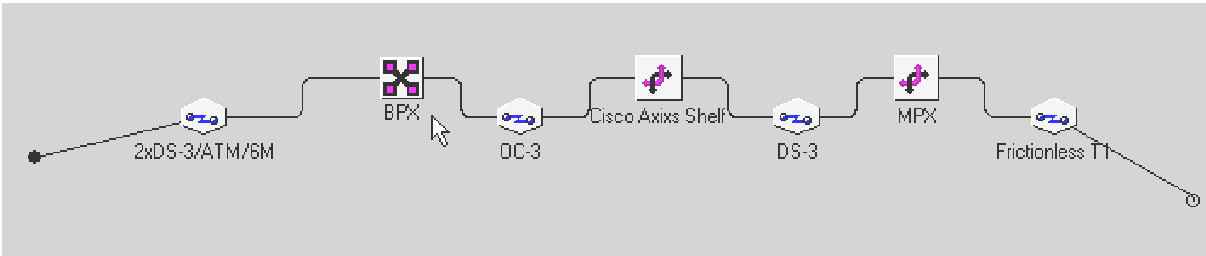
The Internal Links of the 6 Mbps ATM Network with Variable Rate Control (VBR)

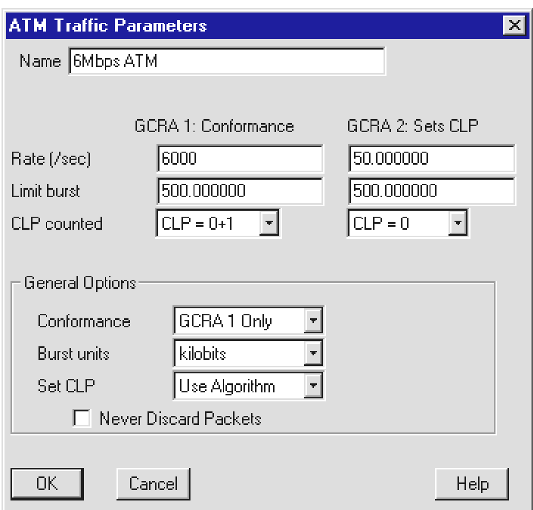


5.1. Topology of Bursty Traffic Sources

The "Message Source" subnetworks transmit messages as in the aforementioned baseline model, but with different burstiness: H = 0.95, H = 0.75, H = 0.55, and with fixed size (see *Figure 13*). Initially, we simulate four subnetworks and four users per subnetwork, each sending the same volume of data (mean 440 bytes per second) as in the validating model.

FIGURE 7

Parameters of the 6Mbps ATM Connection



5.2. Link Utilization and Message Delay

First, we are going to measure and illustrate the extremely high peaks in frame-relay link utilization and message delay. The model traffic is generated with message sizes determined by various Hurst parameters and fixed-size messages for comparison. The COMNET modeling tool has a trace option to capture its own model-generated traffic. It has been verified that for the model-generated traffic flows with various Hurst parameters, the Benoit package computed similar Hurst parameters for the captured traces.

Table 3 shows the simulated average and peak link utilization of the different cases. The utilization is expressed in the [0,1] scale, not in percentages:

The charts in the Appendix clearly demonstrate that even though the average link utilization is almost identical, the frequency and the size of the peaks increase with the burstiness, causing cell drops in routers and switches. We received the following results for response time measurements (see *Table 4*).

The charts in the Appendix graphically illustrate the relation between response times and various Hurst parameters.

5.3. Other Network Performance Parameters

In addition to the utilization of the individual frame-relay links carrying traffic with increasing burstiness, we can also

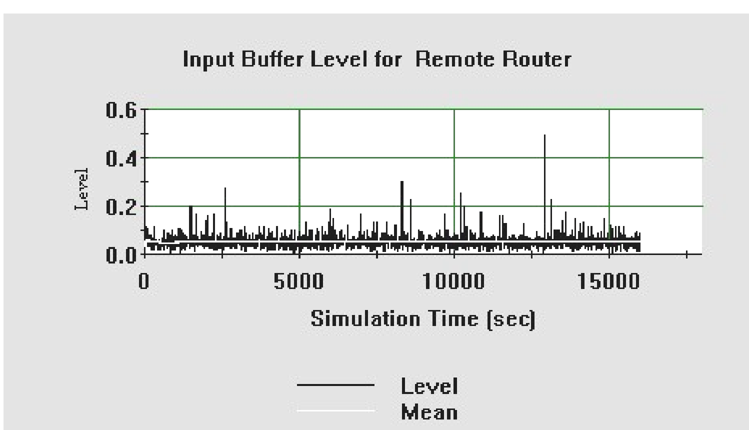

FIGURE 12

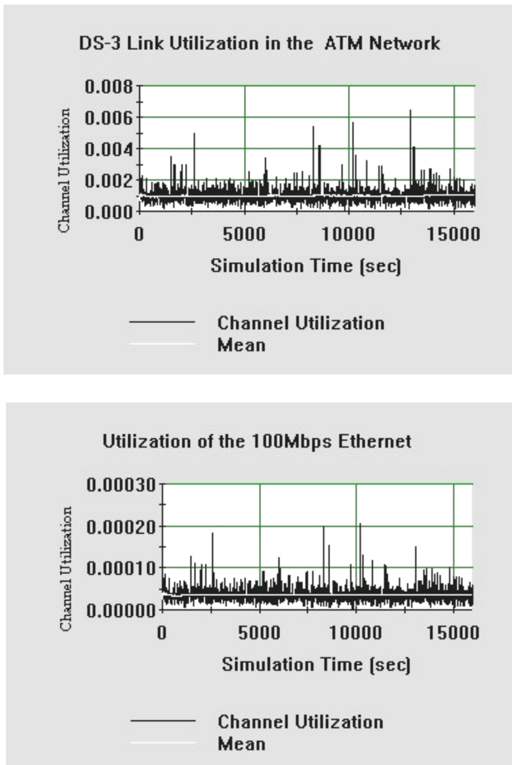
Baseline Utilizations of the DS-3 Link and Ethernet Link in the Destination



measure the impact of the combined traffic on various network parameters of the ATM network and the final destination network, such as link utilizations and input buffer levels. The charts in the Appendix depict these simulation results as well.

5.4. Input Buffer Level for Large Number of Users

We also measured the number of cells dropped at a router's input buffer in the ATM network due to a surge of bursty cells. We simulated the aggregated traffic of approximately 600 users, each sending the same number of bytes in a second as in the measured real network. The number of blocked packets is summarized in *Table 5*.

6. Conclusion

The paper presented a discrete event-simulation methodology to measure various network performance parameters while transmitting bursty traffic. It has been proved in recent studies that combining bursty data streams will also produce bursty combined data flow. The studies imply that the methods and models used in traditional network design require modifications. We categorize our modeling methodology as a structural model [51, 53] contrary to a black box model. Structural models focus on the environment in which the models' data was collected, i.e., the complex hierarchies of network components that make up today's communications systems. Although black box models are useful in other contexts, they are not easy to use in designing, managing, and controlling today's networks. We implemented a well-known model, the M/Pareto model, within the discrete event-simulation package COMNET that allows the analysis

of the negative impact of self-similar traffic on not just one single queue, but on the overall performance of various interrelated network components as well. Using real network traces, we built and validated a model by which we could measure and graphically illustrate the impact of bursty traffic on link utilization, message delays, and buffer performance of frame-relay and ATM networks. We illustrated that increasing burstiness result in extremely high link utilization, response time, and dropped packets and measured the various performance parameters by simulation.

The choice of the package emphasizes the need for integrated tools that could be useful not just for theoreticians, but also for network engineers and designers. Our paper intends to narrow the gap between existing, well-known theoretical results and their applicability in everyday, practical network analysis and modeling. It is highly desirable that appropriate traffic models should be accessible from measuring, monitoring, and controlling tools. Our model can help network designers and engineers, the ultimate users of traffic modeling, to understand the dynamic nature of network traffic and assist them in their everyday practice.

Appendix

Measurements for Link Utilization

The following charts (see *Figures 14* through *17*) demonstrate that even though the average link utilization for the various Hurst parameters is almost identical, the frequency and the size of the peaks increase with the burstiness causing cell drops in routers and switches. The utilization is expressed in the [0,1] scale not in percentages.

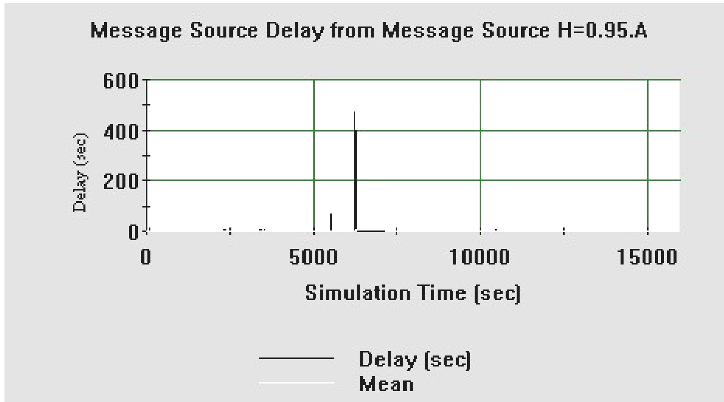
Message Delay for H = 0.95 (Extremely Long Response-Time Peak)



Measurements of Other Network Performance Parameters

We also measured the impact of the combined traffic on various network parameters of the ATM network and the final destination network, such as the DS–3 link utilizations, the 100 Mbps Ethernet, and input buffer levels of the Cisco-7500 and the BPX switches. The following charts (see *Figures 22* through *25*) depict these simulation results.

Abstract

In this paper, we show how the workfllow-oriented, library-based test-design and execution environment presented in [8] fulfills the promise of enabling efficient integrated system-level tests of complex industrial applications. We exemplify on the basis of a concrete case study (Siemens' HPCO Application, a complex call-center solution) how test engineers can now work with the integrated test environment (ITE). Efficiency measurements in the field document an average performance gain in the execution of functional regression tests of factors beyond 30: Setting up the test scenario is now the most expensive activity!

1. Introduction

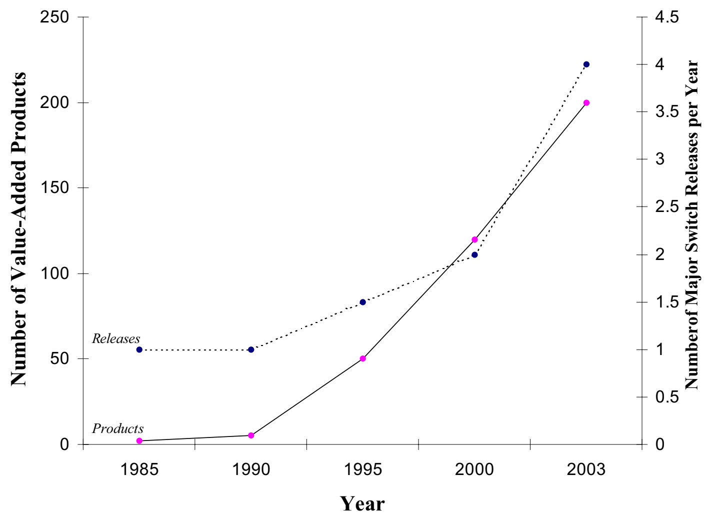
The world of telecommunications has rapidly evolved during the last 15 years, modifying in this process its focus. In 1985, a telephone switch was used "only" as a telephone switch. Additional components, either hardware or software, were gradually developed to bring additional functionality and flexibility to the traditional switch, e.g., in the initial days, voice-mail or billing systems. Today, not only are single functionalities added at a quick pace, but the switch is also mutating its role into the central element of complex heterogeneous and multivendor systems: It is nowadays integrated into whole business solutions, e.g., in the field of hotel solutions, call centers, and unified messaging applications. Technically, whereas in the earlier days the interaction between the switch and the applications was almost exclusively implemented via proprietary interfaces, today the definition of open standards—such as the computer-supported telecommunication applications (CSTA) protocol [1,2], which specifies the command sets and the data structures needed at the application layer, or the telephony application programming interface (TAPI) [6], which defines the programming interface for telephony applications—pushes the field toward the development of new, system-level applications.

Figure 1 (left Y axis) documents the trend toward increased product integration in terms of the augmentation in the number of value-added applications that work on average with or on a switch. As one can see, the integration factor has been rapidly increasing since 1995, and this trend points in the direction of even larger value-added product ranges.

A parallel but concurring aspect is the increasing number of major switch releases per year (see *Figure 1*, right Y axis). This trend is driven mainly by the convergence between the classical telecommunications technology and the modern Internet protocol (IP) technology, i.e., voice over IP. Modern

FIGURE 1

Trends in the Development of CTI Systems—(left Y axis) Growing Product Integration and (right Y axis) Faster-Paced Switch Releases



switches are themselves complete complex systems, and they experience the accelerating evolution pace of hardware and software in combination!

In this rapidly evolving scenario, the need for efficient automated regression testing is evident. Whenever a release arises—either of the switch or of (a subset of) the application programs that cooperate with it, and either singularly or, increasingly often, in collaborative combinations—the correct functioning of the new configurations must be certified again.

Altogether, testing complex telephony solutions is a multidimensional task that demands automation via adequate system-level tool support. The complexity lies in the interaction between the components as well as in the short innovation cycles and the great number of possible combinations between the private branch exchange (PBX) and the value-added applications. Therefore, an adequate environment must focus on structuring, efficiency, and abstraction.

In summary, systems-under-test have become composite (e.g., including computer telephony integrated [CTI] platform aspects), embedded (due to hardware/software codesign practices), reactive, and run on distributed architectures (e.g., client/server architectures). Complex subsystems affect each other in a variety of complex ways, so mastering today's testing scenarios for telephony systems demands an integrated, open, and flexible approach to support the management of the overall test process, i.e., specification of tests, execution of tests, and analysis of test results.

In [8], we presented an automated testing environment for CTI systems capable of handling their structural complexity. Our approach offers a coarse-grained testing environment, realized in terms of a component-based test design on top of a library of elementary but intuitively understandable test-case fragments. The relations between the fragments are treated orthogonally, delivering a test design and execution environment enhanced by means of lightweight formal verification methods.

Now, one year later, we summarize our practical experiences in the use of this environment at Siemens, where the ITE has been used in a production environment. In this paper, we show on the basis of a concrete case study (Siemens' HPCO Application) how test engineers now work with the ITE. Measurements in the field have exceeded our expectations, documenting an average efficiency improvement in the test execution of functional regressions of complex call-center solutions and of several other CTI applications of factors beyond 30: As mentioned, setting up the test scenario is now the most expensive activity.

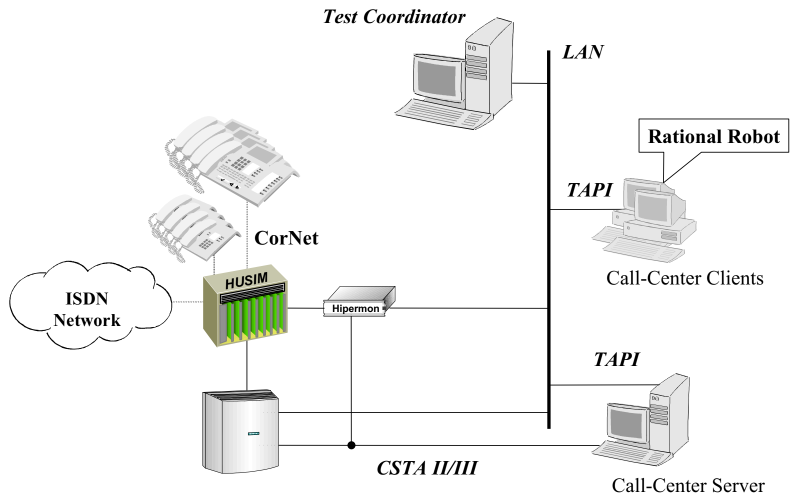
In the rest of the paper, we first describe in Section 2 the concrete industrial application (regression test of a complex call-center solution), then we detail in Section 3 the process followed to integrate the call-center solution into the ITE. Section 4 presents our field results, concerning in particular the concrete measured speed-up of the test execution, and Section 5 imparts our conclusions and some perspectives.

2. Regression Test of a Complex Call-Center Solution

A typical example of an integrated CTI platform is a call-center solution, as illustrated in *Figure 2*, where the switch is connected to the integrated services digital network (ISDN) telephone network, or, more generally, to the public switched telephone network (PSTN), and acts as a "normal" telephone switch to the phones. Additionally, it communicates directly via a local-area network (LAN) or indirectly via an application server with call-center client/server applications that are executed on personal computers (PCs). Like the phones, these CTI applications are active components; they may stimulate the switch (i.e., initiate calls), and they also react to stimuli sent by the switch (i.e., notify incoming calls). Therefore, in a system-

FIGURE 2

Test Setting for a Complex Call-Center Solution



level test scenario, it is necessary to investigate the interaction between such subsystems.

Even the relatively simple scenario of *Figure 2* demonstrates the complexity of CTI platforms from the communications point of view, because there are several (internal) protocols involved. For example, the telephones communicate via the corporate network protocol[1] with the PBX, whereas the PBX communicates via the CSTA Phase II/III protocol [1,2] with the application server. On the application server, a TAPI service provider performs a mapping of the CSTA protocol to the TAPI protocol [6], which is the communications protocol between the application server and its clients.

2.1. The Integrated Test Environment

The ITE (see [7, 8] for a more detailed discussion) is based on an existing general-purpose environment for the management of complex workflows, METAFrame Technologies' Agent Building Center (ABC) [11], which contains built-in features concerning test coordination and test organization. The test coordinator constitutes the test-management layer of our environment and includes an application-specific specialization of the ABC for the domain of system-level regression testing of telephony systems.

To communicate with different test tools, a flexible common object request broker architecture (CORBA)/remote method invocation (RMI)–based architecture has been developed. The test coordinator executes integrated test cases by controlling several test tools, each managing its own subsystem. The extensibility of the environment by additional test tools is the key of the approach.

3. Integration of the Call-Center Solution into the ITE: The Process

To be able to handle regression testing of the call-center solution within the ITE, the following steps have to be performed:

- Integration of test tools
- Identification and implementation of testblocks
- Test-case design and execution

These steps, which must be taken whenever a new system-under-test is integrated into the ITE, are discussed in detail in the following subsections.

3.1. Integrating the Test Tools

3.1.1. How to Integrate

The ITE offers a generic CORBA interface to communicate with the different test tools that comprise the basic methods (e.g., getName, getVersion) that all test tools have to support. Specific features (e.g., input and output commands for testing a special component) can be added as need by extending the interface. The specific methods of the test tools are accessed via test-tool–specific basic functionalities (testblocks).

The integration process consists of two main activities:

1. Integration of the interface provided by the test tool into the test coordinator
2. Implementation of the interface functionality by the test tool

If the interface is not implemented in the test tool by the vendor, there are different ways for integration.

Plug-In Approach: If the test tool supports customization via loading plug-ins or libraries, the interface can be integrated by implementing such a plug-in, including the CORBA object request broker (ORB).

Separate Server Process: If a test tool offers remote access via an interface of its own (e.g., COM, DCOM, or CORBA), a separate server process can communicate via this interface with the test tool. Then, the special server implements the interface or its derivation and communicates with the test coordinator—i.e., it can be seen as a relay between the test coordinator and the test tool.

3.1.2. What to Integrate
Two different test tools are used in the call-center scenario:

1. A proprietary protocol analyzer (Hipermon [5]), which is connected to a telephone simulator (Husim) and to the connection between the switch and the application server
2. A graphical user interface (GUI) test tool (Rational Robot [10]), which is used in several instances—i.e., for every considered call-center client

Hipermon/Husim: The required interface to the ITE is implemented in the Hipermon/Husim directly by the vendor. It provides the tester with full access to the whole functionality of a telephone as well as to the underlying protocols, i.e., corporate network (CorNet) protocol and CSTA II/III. The Hipermon is able to decode CorNet/CSTA messages and to deliver the attached data to the ITE for further processing.

Rational Robot: The Rational Robot does not provide a CORBA implementation itself. Here we followed the plug-in approach: We implemented an external library that provides the CORBA functionality and brings the Rational Robot into an interpreter mode, which allows us to send Robot Scripts to the Rational Robot for execution. Furthermore, it is possible to use generalized scripts, which use variables where the concrete values are requested at run time from the ITE.

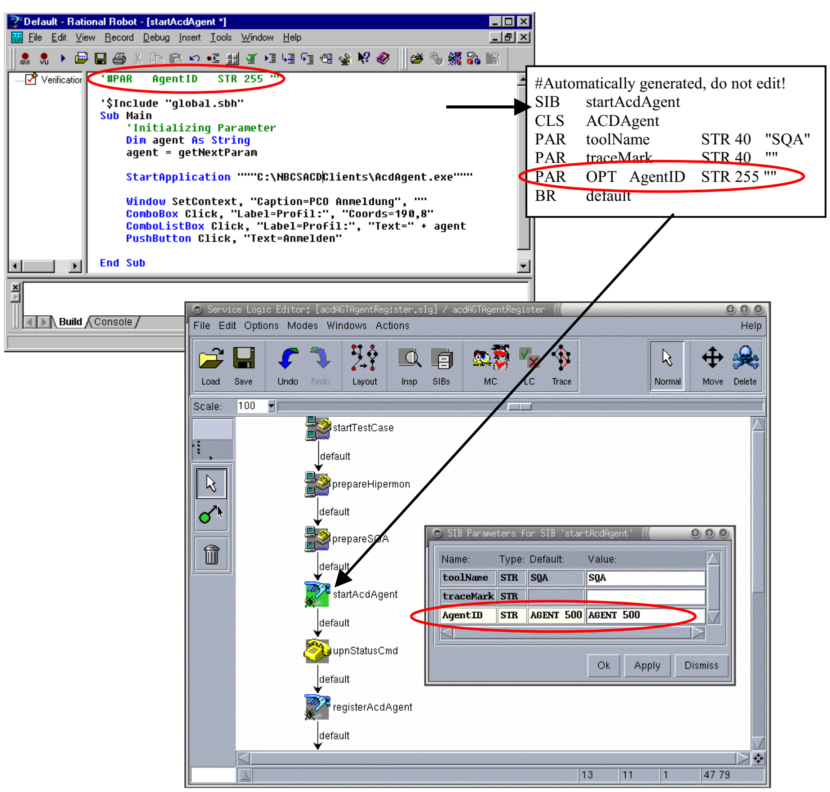
3.2. Identification of Suitable Testblocks
Several classes of testblocks had to be provided to test the call-center solution:

- *Testblocks for the User Interfaces:* The user-interface layer concerns the functionality of the features that constitute the user interfaces of the single subsystems, such as telephone devices (e.g., the hook switch, display, and lamps of a telephone set) and software applications (e.g., the buttons, check boxes, and text fields of an application's GUI).
- *Testblocks for Communication between the Switch and Telephone Devices*: Devices, both simulated and real, communicate with the switch according to the CorNet protocol.
- *Testblocks for Communication between the Switch and Call-Center Server*: The CSTA protocol [1, 2] specifies the command sets and the data structures needed for this application layer.

3.2.1. Defining Testblocks for the User-Interface Layer
Generally, tests of GUIs are performed by means of "recording and replaying" tools, which capture events and effects and allow storage of them for later execution. The Rational Robot [10] has been made available in the ITE in a flexible way for driving an application's GUI. A testblock is generated automatically for each Robot Script, which is, in turn, either recorded or programmed. As shown in *Figure 3* (top left), the code of a Robot Script is enriched by special keywords that

FIGURE 3

Automatic Generation of Test Building Blocks



specify the parameters of the script. These parameters are essential for the test coordinator in order to instruct the Rational Robot during the test execution.

This solution enabled the test engineers at Siemens to provide more than 80 different test blocks for a call center (i.e., log-on/log-off of an agent) in a short time by simply recording the actions on the GUI.

3.2.2. Defining Testblocks for the CorNet Communication Layer
Messages exchanged between switch and device according to the CorNet protocol:

- Are used to modify the display lines, brightness, and color of lamps or the ringer mode and ringer pattern.
- Initiate calls, indicate incoming calls, or terminate calls.
- Activate or deactivate specific features of the switch.

Such messages are collected by the Hipermon, which decodes them into a format appropriate for a further evaluation within the ITE.

In this context, testblocks are needed that either test the current state of a device or simulate the functionality of a device toward the switch.

3.2.3. Defining Testblocks for the CSTA Communication Layer
CSTA defines a telephony process model for applications and a computing process model for the switch. An implementation of CSTA consists of CSTA services and the CSTA-protocol. By means of the protocol, an application accesses the CSTA telephony services from the switch or provides CSTA computing services to the switch. Each model consists of a set of objects and rules to change the states of the objects. Examples of telephony objects include the following:

- *A device object*, representing anything that allows users to access telecommunications services. It can be either a physical device (buttons, lines, and stations) or logical devices (a group of devices, an automatic call distribution [ACD] group). A device has attributes, including *device type, device identifier*, and *device state* that can be monitored and manipulated by an application.

  In the CTI system of *Figure 3*, a special CSTA device (agent) is used. An agent represents the association and the activities of a physical device with an ACD group. An agent—i.e., the physical device—becomes associated with a specific ACD group by a process of logging on. The agent's state describes the current relation of the agent with the ACD group (logged-on, ready to accept calls, busy, working after call).

- *A call object*, describing the logical session among calling and called parties. The call behavior—i.e., its establishment and release—can be observed and manipulated by an application. A call object representing a call session has attributes such as *identifier* and *state* and offers operations such as *make* or *clear*. One or more devices may be involved in a call in different phases.

- *A connection object*, representing a relationship between a call and a device. It is characterized by attributes such as *identifier* and *state* and by operations such as *hold* or *clear*. Many CSTA services, such as hold-call, reconnect-call, or clear-call, are made by operating on connections comprising a call.

Basically, CSTA services consist of a request and a response, both possibly parameterized. A monitor service can be activated to track control and other activities and to receive notification of all changes of the switch. Starting a monitor indicates that an application, be it a component of the system or an external observer, wants to be notified of changes that occur in calls, devices, or applications as well as device attributes managed by the switch. Examples of changes include arrivals of a call at a device, answering a call, and changing a device by modifying features such as "forwarding." Event reports are sent to the monitor-requestor. For the test of CTI systems it is necessary to have access to the CSTA events for validation.

3.2.4. How to Identify and Implement Testblocks
To design system-level test cases, it is necessary to know which features and functions the system provides, how to operate the system in order to stimulate a feature, and how to determine whether the features work. This information is gathered for each key component of the system and each functional area, resulting in a set of stimulation actions and verification actions that form the basis for the design of test cases in terms of so-called testblocks. These are specified by means of the following three steps:

1. *Classification:* A testblock name is identified and organized relative to a hierarchical classification scheme. In the call-center application, we have classes for each subsystem and each layer.
2. *Parameterization:* A set of formal parameters is defined to enable a more general usage of a testblock.
3. *Connectivity:* To steer the control flow during test execution, each testblock possesses a set of outgoing branches representing the different possibilities for continuation.

3.3. Design and Execution of Testgraphs

Once the libraries of testblocks are available, we are ready to design executable test cases. As described in detail in [8] and shown in a very simple case in [9], designing test cases consists of a behavior-oriented graphical combination of testblocks. Icons representing testblocks are graphically stuck together to yield testgraph structures that embody the test behavior in terms of control. A macro technique allows the encapsulation of a section of a testgraph into a new testblock to support a hierarchical design of test cases. Parameters of testblocks that are used in a macro can be specified as parameters of the macro.

The design of test cases is controlled by validation techniques that enforce essential technical frame conditions and guarantee the key features of the underlying test purpose, as illustrated in detail in [8]. There we showed how critical consistency requirements, including version compatibility and frame conditions for executability, are formulated and how consistency of test cases is fully automatically enforced via model checking and error diagnosis.

In the ITE, testgraphs are immediately executable by means of ABC's tracer module. Starting at a specified testblock of a testgraph, the tracer proceeds from testblock to testblock. The actions associated with each testblock are performed, i.e., stimuli and inspection requests are sent to the corresponding system's component, and the responses are received and evaluated. The evaluation results successively determine the selection of the next testblock.

4. Evaluation

To evaluate the economic impact of the ITE introduction, we must first identify the cost factors that pertain to testing CTI systems. *Table 1* identifies the macroscopic cost factors that arise along the test-process life cycle together with their frequency of occurrence.

Test planning and specification, and the definition and set-up of test scripts, occur only initially, when an experimental scenario (i.e., the testing of a specific CTI system) is set up. The planning and specification phases are not (yet) affected by the ITE. The usual collection or programming of test scripts, which in a manual setting directly constitute the elementary testblocks, is in the ITE supported by a largely automated generation of reusable testblocks that fit with the overall ITE architecture.

The main focus of the ITE in this first phase is the reduction of costs for the repetitive phases of CTI testing. Primarily, we addressed test execution, the former bottleneck (see *Table 2*), in combination with the automatic creation of test reports and (in the near future) advanced support of the analysis of test results.

Table 2 documents the measured improvement of the test-execution costs due to the introduction of the ITE. The systems under test considered in each row are composed by the PC client/server application listed in column 1, which cooperates with the HICOM switch along the configuration pattern illustrated in *Figure 2*. The second and third column report the measured effort (in man hours) of one regression cycle for the system under test when performed manually (column 2) or with the ITE (column 3). The improvement is dramatic: speed-up factors of about 30 for each regression-cycle execution! Indeed, the personnel is now completely freed from manual test execution; the test cases run in batch mode, e.g., at night or while the test engineers work on further test-case definitions or on setting up a different test scenario. The automated protocol facility allows them to just look off-line at the test cases that ended up with errors or warnings, providing, in this case, detailed information.

The shift toward an automated test-execution environment brings additional benefits that go beyond the pure savings in manpower. In particular, the test-design activities during the test planning and specification phases have shifted from largely programming to a more conceptual modeling and generation approach. This has effects on the organization and the maintainability of the test suites (there is a high-level model of the test cases), on the documentation of the test runs (if all goes well, few data are stored), on their repeatability (the configurations, etc., are well documented and automatically managed), and on the error diagnosis, where the testgraph provides an intuitive guide when looking for causes of misbehavior.

The full automation of test execution is for the moment not yet feasible, since some manual steps—such as system set-up and configuration (e.g., physical connection of the components, installation of the software on the machines)—are still needed. While in a manual execution, setting these steps represented about 20 percent of the effort for a regression cycle.

TABLE 1

Regression Test Cost Factors

Task	Without ITE	With ITE	Frequency
Test Planning	Manual	Manual	Once
Test Specification	Manual	Manual	Once
Test Scripts	Manual	Manual	Once
Test Execution	Manual	Automated (Batch)	Recurrent
Test Protocol	Manual	Automated	Recurrent
Test Analysis	Manual	(Selected Cases)	Recurrent

TABLE 2

Test-Execution Effort in Hours per Regression

System-under-Test	Manual	With ITE	Speed-Up Factor
Hotel Solutions	10.0	0.5	20
Call-Center Solutions	43.0	1.0	43
Analog Voice-Mail	23.0	0.5	46
Digital Voice-Mail	20.0	0.5	40
Call-Charge Computer	19.0	0.5	38
Total	115.0	3.0	ca. 38

Now, due to the test-execution speed-up introduced by the ITE, they are responsible for more than 80 percent of the total effort! We are therefore currently aiming at reducing (or, ideally, automating) the configuration process [4].

5. Conclusion

In this paper, we have shown on the basis of a concrete case study (Siemens' HPCO Application) how test engineers can now work with ITE in their daily regression testing activities. The workfllow-oriented, library-based test-design and execution environment presented in [8] has proved to fulfill the promise of enabling efficient integrated system-level tests of complex industrial applications in real-life usage. The field experience gathered over the last year has shown that the use of ITE has brought a new dimension of efficiency (with measured speed-up factors of greater than 30 for the test-execution phase) for regression testing of large CTI systems together with an improved test-design methodology and test-process organization. A global cost-benefit calculation thus shows that the additional investment for the ITE is well able to pay off in a short period of time if extensively adopted. The ITE, in fact, dramatically reduces the recurring cost factors almost without impairing the remaining positions that concern the basic effort that still has to be spent along the whole test life cycle (test planning, manual configuration of the test settings, etc.) and the necessary upfront investments (e.g., license fees for test tools, hardware, etc.). In fact, we believe that we will be able to also cut down on the required basic effort in the near future.

Recovery Techniques in Generalized Multiprotocol Label Switching

Robert Haim
Senior Product-Marketing Manager
Polaris Networks, Inc.

Abstract

Generalized multiprotocol label switching (GMPLS) is the evolution of the multiprotocol label switching (MPLS) suite of protocols that extends the control-plane operation used in packet-based networks to optical networks. The basic functions of GMPLS include expediting traffic forwarding on traffic-engineered end-to-end paths (label switched paths, or LSP), creating differentiated services (DiffServ), efficient utilization of the discreet optical bandwidth levels (e.g., optical carrier [OC]–48/192), and dynamic fault-management of LSPs or tunnels. In essence, GMPLS is considered as the common control plane for both electrical and optical networks.

A major factor in the acceptance and successful deployment of GMPLS is its ability to carry out intelligent fault-management. Not only does GMPLS need to provide a more granular level for protection, it must address performance levels that are comparable to SONET protection/restoration schemes (50 ms or better).

While GMPLS uses the synchronous optical network (SONET) protection scheme as a benchmark, it does not have to be bound to the strict "all or nothing" scheme of SONET that gives away 50 percent of available bandwidth for protection. In this paper, GMPLS' varying degrees of protection and restoration schemes are explained.

Brief Primer on GMPLS

The suite of protocols that comprises MPLS is used to speed up packet forwarding and to provide for traffic engineering in Internet protocol (IP) networks. Therefore, the connectionless operation of IP networks become more like a connection-oriented network, where the path between the source and the destination is pre-calculated based on the application's required quality of service (QoS) level. To speed up the forwarding scheme, an MPLS device uses *labels* rather than address matching to determine the next hop for a received packet. To provide traffic engineering, tables are used that represent the levels of QoS that the network can support. The tables and the labels are used together to establish an end-to-end path called a *label switched path* (LSP). Extensions to traditional IP routing protocols (open shortest path first [OSPF], intermediate system–to–intermediate system [IS–IS]) and to the existing signaling protocol, i.e., resource reservation protocol (RSVP), and/or the new signaling protocol, i.e., constraint-based routing–label distribution protocol (CR–LDP), comprise the suite of MPLS protocols.

GMPLS extends MPLS suite of protocols to provide the control plane (signaling, routing, and management) for devices that switch in packet, time, wavelength, and fiber domains. This common control plane promises to simplify network operation and management by automating end-to-end provisioning of connections, managing network resources, and providing the level of QoS that is expected in the new sophisticated applications. To provide a variety of QoS levels that is required by different applications, GMPLS protocols also address network fault-management. For example, link management protocol (LMP) is a new protocol that includes provisions for fault-management in GMPLS.

High-Availability Models for GMPLS

The basic premise of the GMPLS suite of protocols can be viewed as the convergence of control-plane operations for both electrical and optical switching devices. This implies that an end-to-end path (LSP) can be established through different types of networks to carry a variety of services with differentiated levels of QoS. To date, packet switching devices have carried data on a best-effort basis, while SONET–based optical networks have carried highly reliable voice traffic. However, recent applications such as voice traffic over IP, virtual private networks (VPNs), and other multimedia applications have modified the reliability requirements necessary for end-to-end connections. As these types of traffic travel through different optical segments, the protection levels that are available today are not granular enough to satisfy these applications efficiently.

Figure 1 shows a three-segment GMPLS network. The access network(s) support traffic from end-users, such as enterprises, or multi-tenant dwellings, and pass their aggregated multiservice traffic on to metro SONET transport rings. The end users have different QoS–level requirements depending on their service-level agreements (SLAs) with their "access" providers. The equipment in the metro, such as add/drop multiplexers (ADMs) and digital cross-connect systems (DCSs), groom and switch the traffic to the long-haul network, which will further transport the traffic, e.g., via wavelength-based transmission equipment. The deployment of GMPLS in each network segment provides the establishment of end-to-end traffic-engineered LSPs that span all of these segments. And more importantly, it is capable to provide multiple levels of reliability in protecting and restoring services that are specific per end-user application.

SONET protection schemes have been available for some time now and have been proven to provide highly reliable time division multiplexing (TDM) networks that carry voice traffic. These schemes stand as benchmarks for GMPLS. SONET protection schemes are reviews in *Table 1*. We will examine how GMPLS addresses these protection/restoration schemes.

High Availability in GMPLS

Survivability refers to the network's ability to absorb and process deterministic and non-deterministic *changes* while maintaining the level of service that was promised for an application. These *changes* affect network topology, either through planned expansions or unplanned, unforeseen problems. Topological changes and, therefore, network-capacity degradation could also occur when a card, a node, or a line goes down for a variety of reasons. To accommodate network changes in a timely manner, the equipment must have built-in intelligence to assure uninterrupted traffic flow, e.g., via automatic network discovery and dynamic new routes to provide multiple levels of protection and restoration. This intelligence allows seamless operation of the network and bypasses its problems to continue its service. GMPLS–based protection and restoration schemes attempt to provide this intelligence while taking into account that LSPs may span multiple dissimilar network types, e.g., packet or TDM/SONET. Therefore, the main goal for GMPLS–driven reliability is, for a given LSP, which carries a certain QoS–level based on the application's SLA, to identify an *efficient* approach that will maintain the promised QoS based on two "failure" probabilities:

P_{nf} = Probability of nodal failure
P_{lf} = Probability of link failure

For an LSP that spans N nodes and N-1 links, the following can be deduced:

$$P_{lspf} = 1 - (1 - P_{nf})^{N} * (1 - P_{lf})^{N-1}$$

where P_{lspf} is the probability of LSP failure. For simplicity, the formula assumes uniform failure probability for every node and every link that comprise the network. For example, assuming that $P_{nf} = 1 \times 10^{-5}$ and $P_{lf} = 1 \times 10^{-9}$ for a 10 node network, P_{lspf} becomes about 1×10^{-4}. Naturally, P_{lspf} increases and lowers the availability of an LSP, with each additional and/or link. To maintain a given level of QoS in a GMPLS–based network, the following issues have been considered in the industry:

- Must consider that an LSP may traverse a variety of equipment in which the times of LSP set-up may vary greatly from each other, e.g., a high-speed router and a digital cross-connect. The former does not take as much time as the latter does to find an output port for incoming data on an input port.
- GMPLS operates in a multilayer environment where packet-based data is transported by optical cross-connects (OXCs) that are in turn transported by wavelength division multiplexers (WDMs) on a fiber layer. This requires that the layer that is closest to where a

FIGURE 1

End-to-End GMPLS–Based Networks

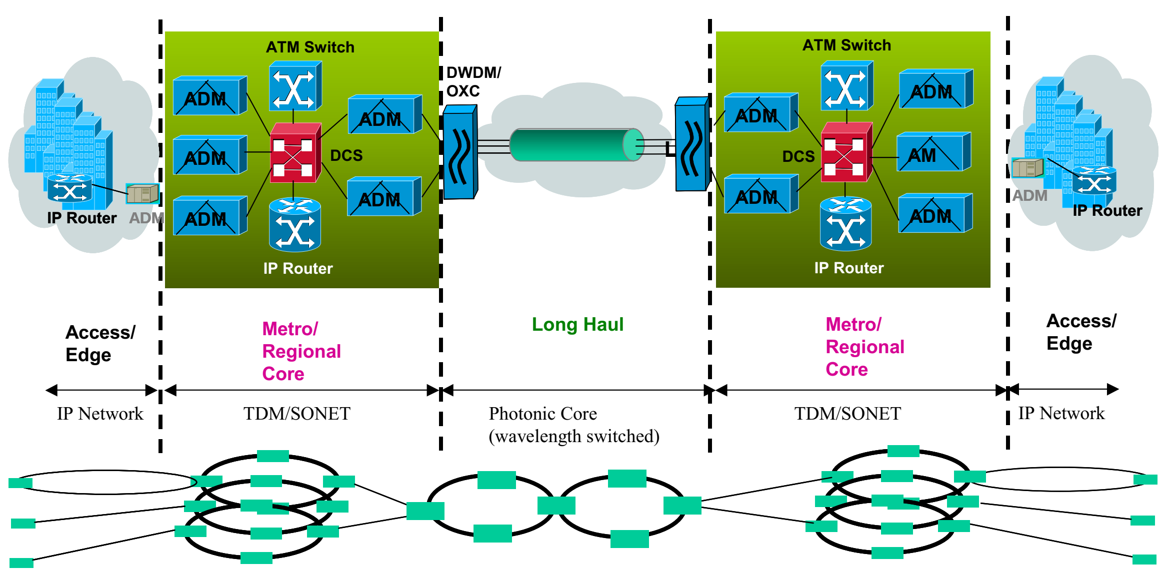

TABLE 1

SONET Protection Schemes

Protection Scheme	Architecture	Level of Protection	Mode of Operation	Usually Used in	Restoration Time
Automatic Protection Switching (APS)	Point to point; only two-line terminating equipment; [Protection provided at line level]	1+1	Signals travel on both working and protection fibers	Access/feeder rings	50 ms or better
		1:N; 1:1	Allows other interruptible traffic to flow on the backup		
Unidirectional Path-Switched Ring (UPSR)	Ring: two fibers [Protection provided at the SONET STS–N path level]	1+1	Does not allow for interruptible traffic to flow on the backup lines	Access rings	50 ms
Bidirectional Line-Switched Ring (BLSR)	Ring/mesh: four fibers [Protection provided at the SONET STS–N path level]	Effectively, 1:1	During normal operation, traffic flows through the four-fiber BLSR on the *working fiber pair*. The *protection fiber pair* is either idle or carrying interruptible traffic during normal operation.	Metro, regional, or long-haul networks	50 ms

fault has occurred must be able to detect it. A recovery action in one layer should not trigger recovery action in another layer.

- Extra, spare capacity must be built into the network but must be used efficiently, i.e., be able to allocate resources, e.g., bandwidth, for protection in such a way that it can be used to carry other traffic when the required QoS allows it.
- Must be able to assign two or more different routes for the same LSP, having end-to-end protection when required by its QoS level.
- For those services that require the highest availability, SONET's 50 ms target time is a sound goal. A good example is a mission-critical application such as real-time distance medical imaging or financial transactions.
- If voice traffic is to be carried on a GMPLS–based LSP, users' call-drop tolerance time of less than two seconds must be taken into account.
- Must also be able to support applications with lower levels of QoS requirements, e.g., e-mail or Web browsing, which require best effort to other real-time services, such as enterprise VPNs, which may require higher levels of QoS than best effort.

GMPLS not only must be capable of providing protection mechanism that are similar to SONET, but it also must be flexible enough to provide more granular protection methods for those applications that do not require it. In the next section of this paper, different protection and restoration schemes that are currently proposed in GMPLS are discussed. For completeness, a brief explanation of protection and restoration is given, since it is important to distinguish between the two schemes.

Protection/Restoration Schemes

The main differences between these two schemes can be summarized as *protection* having a faster operation but being less efficient in use of resources, while *restoration* is slower but uses resources more efficiently. Protection switching requires pre-allocated resources similar to the SONET schemes given in *Table 1*. This means that alternate path(s) must be pre-calculated and established (with or without signaling). Restoration, on the other hand, refers to dynamic allocation of resources, i.e., signaling and establishment of backup paths after the occurrence and detection of fault. Both of these schemes are used in GMPLS to offer different QoS levels to satisfy different application requirements.

Basically, two major linear protection schemes are used: 1+1 and M:N. This is the same as discussed in the SONET protection schemes in *Table 1*. In the former, data is simultaneously transmitted via two distinct paths, called *working* and *protection*. The receiver then autonomously decides which of the two carries the healthier signal. In the 1+1 scheme, the backup path always transports a mirror image of the primary path data while the primary path is operational. This makes the 1+1 scheme less efficient in bandwidth utilization but more robust. For M:N scheme, M pre-allocated backup paths are used to support N primary paths. In the M:N scheme, the backup paths do not transport backup data at the same time while the primary paths are in operation—only in case of failure do the backup paths become active. The M:N scheme has two special cases: 1:N and 1:1, in which only one dedicated backup path is used to support N or 1 primary path, respectively. The 1+1 scheme is more common for TDM networks. A side effect of M:N protection scheme is that other types of traffic, which do not require high availability, can be placed on the backup link and preempted when needed for the application that was assigned to the protection link.

For restoration, two approaches are proposed in the industry: local repair and global repair. Local repair is applied to a single LSP at path level when a link or node failed. The problem with a link is worked around by *patching* the path in the area where the fault has occurred. In this case, the adjacent node(s) takes action to "detour" the LSP around the failure without the end-to-end re-route. Global repair, on the other hand, provides for a brand new end-to-end backup path. Local repairs are more appropriate for larger networks where fault notification propagation can slow down the recovery time.

Providing High Availability in GMPLS

A key attribute of GMPLS suite of protocols is the ability to enable automated fault-management in network operation. A fault in one type of the network must be isolated and resolved separately from other networks. This is a very important feature for end-to-end LSPs that are tunneled in other LSPs that require higher degrees of reliability along the hierarchy.

In general, four distinct actions are taken to completely resolve a fault:

1. *Fault Detection*, which has to be handled by the layer that is closest to the fault, for example, loss of buffer space for reception of data at the IP layer.
2. *Fault Localization*, which determines exactly where the failure has occurred. The LMP, which runs between two neighboring nodes, includes procedures to localize link-level failures. This is possible because GMPLS allows physical separation of the data bearing channels and control (signaling/routing/management) channels. Specifically, LMP uses the "ChannelFail" message for this purpose, which can be used in pure optical or mixed opto-electrical networks.
3. *Fault Notification*, which takes place once the fault has been localized. It will be up to the node to determine whether a fault requires path recovery. Fault notification is achieved by sending "Notify" messages in RSVP–traffic engineering (RSVP–TE) protocol extensions. This message is sent to the head-end label-switched router (LSR) to perform a global repair or an LSR along the LSP to carry out a local repair.
4. *Fault Resolution*, which takes place either by a switchover to a healthy pre-calculated, pre-assigned protection path or by creation of a new path. This is covered in more detail next.

GMPLS Protection Scheme

GMPLS provides protection against a failed channel (or link) between two adjacent nodes (*span protection*) as well as end-to-end protection (*path protection*). The OSPF and IS–IS extensions for GMPLS advertise the "link-protection type" parameter to include span protection while the route is being computed. After the route is computed, signaling is carried out via RSVP–TE or CR–LDP to establish the backup paths. In constraint-based shortest path first (CSPF), each traffic-engineered (TE) link includes a protection type that can be configured, e.g., unprotected, 1:1, 1+1. The protection type for a given TE link is advertised along with other TE parameters and also stored in the TE database on each node in the network. When an LSP request is received, it includes the "protection type" parameter, which has one of the values, e.g., 1:1. During the CSPF procedure, the routing module performs a TE database lookup to try to find the matching TE links for the protection type requested.

For span protection, 1+1 or M:N protection schemes are provided by establishing secondary paths through the network and using signaling messages to switch from the failed primary path to the secondary path. This kind of protection attempts to emulate SONET's APS, shown in *Table 1*. Recovery time of 50 ms or less is the target.

For end-to-end path protections, the primary and secondary paths are computed and signaled to indicate that the two paths share reservations. End-to-end protection requires that the notification signals travel to the egress node, which will then provide the switchover to the backup path. Since the propagation delay may prove to be too large for some applications, a more localized repair scheme must be utilized to bypass a failure along the path.

Shared risk link group is an optional mechanism that allows establishing backup LSPs that have none or minimal links in common with the primary LSP. This is achieved in the routing extension of OSPF/IS–IS.

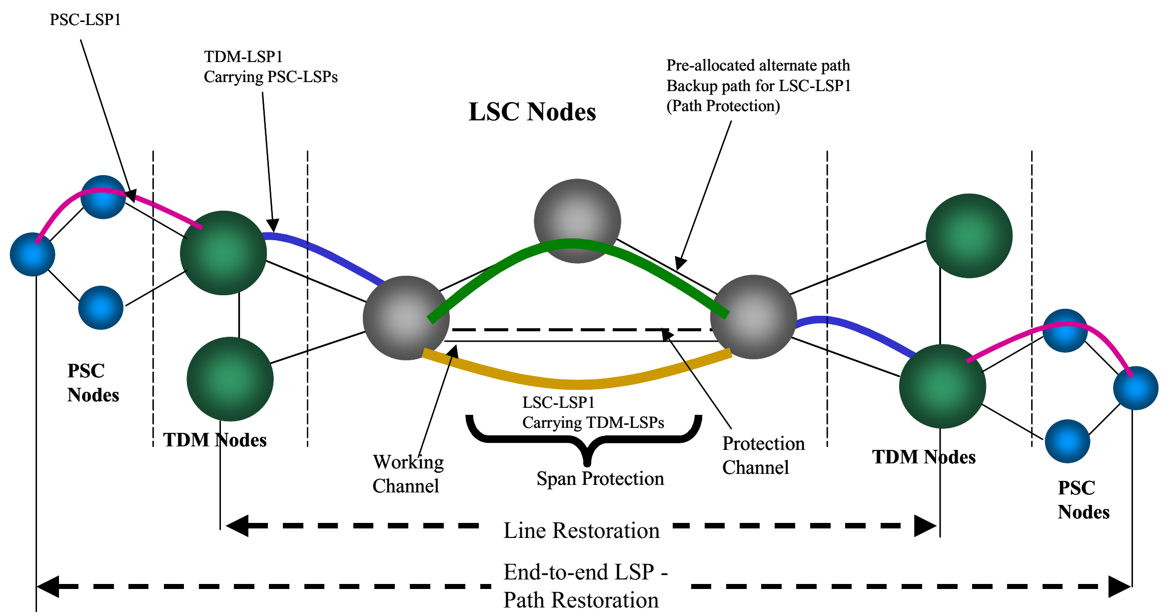
GMPLS Restoration Scheme

As mentioned, *restoration* of a failed path refers to dynamic establishment of a backup path. This process requires dynamic allocation of resources, which in turn requires route calculation and signaling for the new path. Two different restoration methods are given: line and path. Line restoration finds an alternate route at an intermediate node. Path restoration is initiated at the source node to route around a failed path anywhere within the path for the specific LSP. As mentioned earlier, they are also referred to as local and global repair, respectively. In addition, backup paths can be pre-calculated or computed after a fault has occurred. The choice depends on the level of QoS that is required by the application. *Figure 2*[1] provides a snapshot of the possible protection mechanisms that could be used in a mixed network.

To expedite GMPLS restoration, recent Internet Engineering Task Force (IETF) drafts provide the notions of

FIGURE 2

Protection and Restoration in GMPLS



"fast reroute," "detours," and "bypass" [6, 8] in which backup routes are pre-calculated and detours are used along the path of an LSP to remedy a fault by extending the RSVP–TE signaling protocol. The use of a "detour" parameter allows the nodes to differentiate the main LSP from the *detour* LSP. Reference [8] provides a method for unsignaled backup paths.

Both, "detour" and "bypass" LSPs require that the ingress LSR include the "FAST_REROUTE" parameter and use two flags that indicate the need for local protection in the SESSION_ATTRIBUTE object in the RSVP–TE PATH message. This allows the nodes on the primary LSP, which support either "detour" or "bypass," to know that the primary path requires protection.

Currently, there are several proprietary GMPLS LSP protection/restoration/fast reroute drafts that have been recommended to the IETF. The problem is that none of them cover the computation of maximally disjoint backup paths. There are, however, many methods to achieve this. Reference [12] provides a generic method for this calculation, in which the main objective of the given algorithm is to exploit sharing of backup LSPs to reduce the total amount of bandwidth that is consumed by the LSPs.

It is important to note that while the backup path is calculated, there is no guarantee that it will be available once needed, as it could have had failures itself. This could be detrimental to devices that may require a significant order of time to set up their internal switching mechanism, such as a DCS. To remedy this shortcoming, one solution could be having the CSPF to periodically compute the backup path at the egress node to make sure of its availability to reduce restoration time.

Conclusion

The suite of protocols that comprise GMPLS promise to bring true network automation to a variety of dissimilar networks, electrical and optical. Protection schemes are an integral part of GMPLS operations. These schemes use the widely available SONET protection methods as a benchmark but go beyond that to provide a more granular protection level for those applications that do not require very high availability levels. GMPLS' capability to provide SONET–like protection as well as restoration, via dynamic backup path establishment, allows for highly efficient utilization of network resources. Service providers will be able to provide various levels of QoS to their customers and consequently increase their revenue base.

Service Integration: Marrying SLAs to Service-Provider Business Applications

Joel Halpern
Co-Founder and Chief Technology Officer
Longitude Systems

The Service-Provider Crisis

Service providers are under continuous pressure to offer the most competitive services and to attract and retain customers. Both, however, cost considerable time and money. Adding to service providers' bottom-line issues are infrastructure costs that are rising faster than revenue, an inability to differentiate service offerings, marginally integrated operational environments, and service-introduction delays. Service-level agreements (SLA) are being proposed as a method of increasing revenues. Unless they are resolved, these problems will increase costs even faster. This paper discusses the issues of information inconsistency in the SLA–focused environment.

The Promise of Win-Win SLAs

One goal for service providers is to create SLAs that benefit both them and their end customers. A win-win SLA offers service providers the following:

- A foundation for new value-added service offerings
- Strong services differentiation
- Significant new revenue opportunities

A win-win SLA offers end customers the following:

- Reliable operation of mission-critical applications
- Higher employee productivity
- The opportunity to introduce new business models

Why the Promise Is Unfulfilled

Every service provider wants to attain these goals, but many are not succeeding. They have the tools needed to thrive, but they lack the appropriate mixture and use of these tools. Point solutions are very important; without them a provider cannot deliver the SLAs. But it is not enough. A service provider must tie together SLA monitoring, SLA delivery techniques, ordering techniques, billing, and provisioning. An enterprise-oriented solution is needed to work with all these aspects. Without that, providers have true operational inefficiency rather than true operational efficiency.

For instance, the following example of swivel-chair management inside a major Internet service provider (ISP) describes one inefficient operational environment. The provider has contracts with customers and is trying to make sure that billing is enabled at the right time and that the provisioning of routers is done at the right time. Then the provider adds proactive service monitoring, service enforcement, and service maintenance mechanisms. The provider must notify all these systems of the right things at the right times. This would require one employee to sit at two or three terminals, trying to cut and paste and reenter the correct data. Perhaps understandably, the employee gets it wrong. If ISP data in the current environment is only 80 percent accurate (and 80 percent is considered a generous estimate for the accuracy of an ISP), imagine what will happen when providers try to roll out these kinds of additional services.

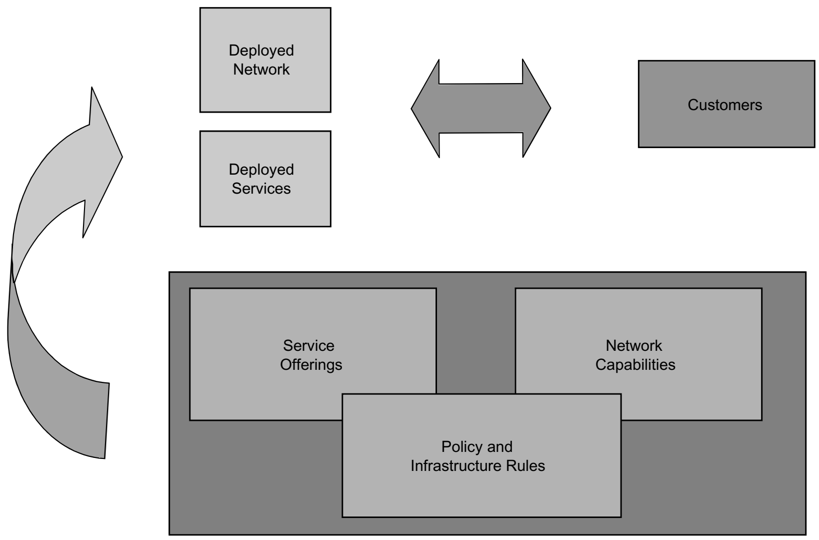
Service providers must deliver SLAs, but they need an environment in which they can deliver them. They must be able to enforce network and business rules, achieve data integrity, and—most important—scale. In other words, to be able to deliver and monitor SLAs service providers must move to an environment that can tie together the service offerings, the network capabilities, and the business and network rules they have in place (see *Figure 1*).

Service Integration

A service provider needs something that can detail the kinds of service offerings it has as well as its network capabilities. The provider then must relate that to what it actually has deployed so that when it rolls out another kind of service, the network understands which of these SLA monitoring and enforcement techniques must be notified so that all the pieces can come together. The system must know

FIGURE 1

Service Integration Model



what network infrastructure is available, how to provision the service, when it is correct to notify billing, and so forth. A service provider needs an operational model that is not only a data repository, but that can also tie the operational behavior together so that it becomes a truly intelligent service integration, bringing together the network engineering processes with all other activation and monitoring processes (see *Figure 2*).

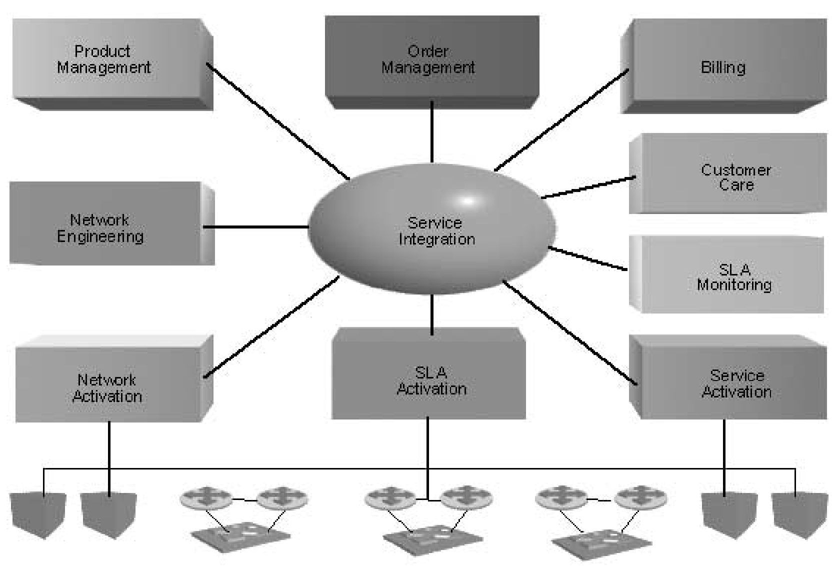
However, this does not cover all the functional areas necessary for a service provider to operate successfully. Many other operations support systems (OSS) have evolved (e.g., order entry, billing, and customer care, to name a few) that must be integrated to deliver the kinds of services and SLAs that customers expect.

Total SLA Implementation Solution

Service providers must be able to define SLA–based services independent of their network. They need to deliver those services efficiently and effectively, but they also must integrate them with the rest of their business process. A

FIGURE 2

SLAs in the Operational Environment



provider's services must tie into billing, customer care, order entry, provisioning, etc.

Services must evolve because the key to success is the ability to innovate and introduce new services continuously. Any service a provider introduces next week—even if it is really innovative—will, in turn, be introduced by a competitor in six months. A provider should be able to introduce the next one after that and to change its business processes either as new components become available or as they offer new services. Successful service providers must evolve continuously, while maintaining data integrity.

For example, when ISPs began buying Juniper routers, many stored the data in the Cisco router table. Why? Because that was the table they already had. This meant they were losing information before they even started because the two are not interchangeable.

In fact, service providers need to take advantage of such differences to gain and maintain competitive advantages. They need a system that lets them greatly improve data integrity, operate efficiently, and scale. No company wants to be a small operation. Any organization in the service-provider industry wants to be a major player because that is how it gets traction. Many providers lament that it is difficult to deliver SLAs when it is over another organization's network. Yet, if a provider has a bigger network, it can control more, and that requires scaling up and growing. The endgame is possessing an operational environment with the intelligence to drive the business processes to achieve efficiency and customer satisfaction.

Call Control in the New Public Network: An Overview of Network Elements and Signaling Protocols

Andrew Hendry
Product-Marketing Manager
Oresis Communications

Introduction

The monolithic circuit switches of the traditional public switched telephone network (PSTN) are well known. There are more than 19,000 Class-5 switches deployed in central offices (COs) and more than 500 Class-4 tandem switches deployed in regional offices across the United States alone. While the annual growth rate of these voice switches has recently been slow and steady, the traditional voice switching architecture will soon undergo an evolution similar to that of the computing architecture in the early 1980s, in which advanced personal computer (PC) workstations running third-party software replaced vertically integrated proprietary mainframes.

Carriers have begun to migrate to next-generation packet-switched voice networks because of intensifying competition, significant cost efficiencies, and new service revenue opportunities. Multiple vendors, both new and incumbent, that specialize in switching hardware, call-control software, and new applications software are beginning to offer a dizzying array of different solutions. Nevertheless, astute choices can be made to optimize the performance of the packet voice solution and the return on investment (ROI) of the purchase decisions.

The Softswitch Architecture

In an environment of intensifying competition for customers among incumbent and competitive carriers, next-generation packet-switched voice networks offer several fundamental benefits: significantly reduced capital and operation costs, less reliance on overlay networks, simplified service provisioning, and new services creating additional revenue and differentiation.

As shown in *Figure 1*, the four key elements in the softswitch architecture are as follows:

- Media gateway
- Softswitch (or media gateway controller)
- Signaling gateway (functionality may be integrated in softswitch)
- Application server

Media Gateway

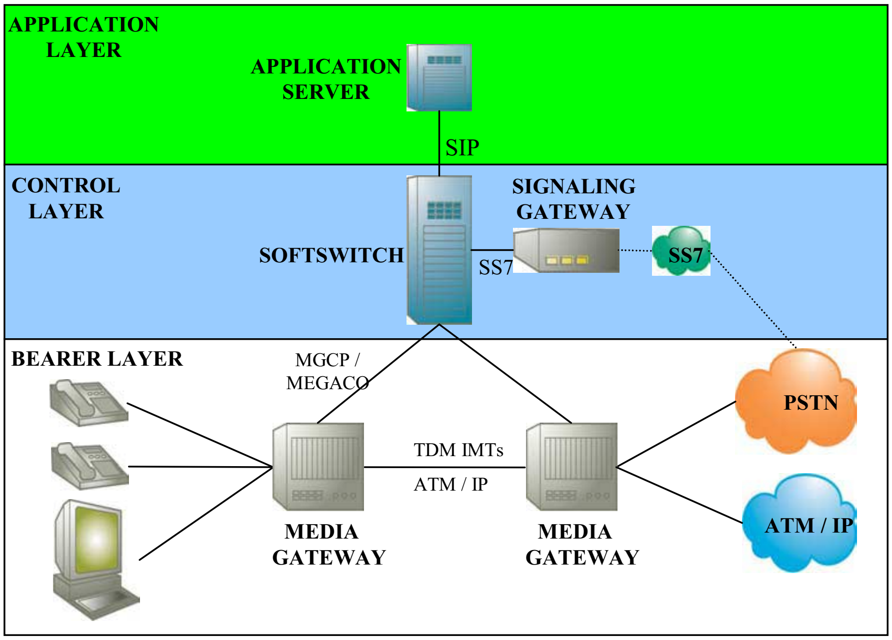
The media gateway is an access/trunking switch that converts and switches time division multiplexing (TDM) voice traffic and packet voice traffic and provides interworking between the two types of interfaces. The packet voice traffic can be either Internet protocol (IP) or asynchronous transfer mode (ATM), depending on the capabilities of the media gateway and the carrier requirements. The media gateway should be capable of providing interworking between multiple access protocols: for example, any pair of TDM, ATM, and IP.

Important factors for media gateways are as follows:

- *Scalability:* Media gateways must accommodate current traffic as well as future growth. Media gateways currently range from 2 to 20 gigabits per second (Gbps) switching capacity. Port capacity for a Class-4/5 switch typically ranges from 10,000 to 100,000 digital signal (DS)-0s.
- *Reliability:* Media gateways must be highly reliable, usually exceeding five-nines availability (99.999%) to be considered carrier-class. This type of reliability requires superior components, quality manufacturing processes, and rigorous product testing. Full fault-tolerance and redundancy are critical to service availability assurance. NEBS Level 3 Certification is required and OSMINE compliance may be required depending on the carrier.
- *Interworking and Interoperability:* Carriers may use media gateways and softswitches from multiple vendors; as a result, interoperable media gateway control protocol (MGCP)/media gateway control (MEGACO)/session initiation protocol (SIP) protocols are necessary. Bearer

FIGURE 1

The Softswitch Architecture



interfaces (TDM, ATM, IP) and signaling protocols (private network-to-network interface [PNNI], bearer independent call control [BICC]) interworking are also essential.

- *Footprint:* The media-gateway footprint drives occupancy costs. More scalable products will accommodate denser modules and typically reduce occupancy costs.
- *Cost:* Carriers deploying media gateways will always consider a cost-per-port comparison. Density is typically an important factor in lowering cost-per-port.

Most media gateways have been developed initially to transport voice using either ATM cells or IP packets. While many industry analysts think that carriers will migrate to IP/multiprotocol label switching (MPLS), for now most carriers rely on ATM to provide the carrier-class quality of service (QoS) required to deliver packet voice services. Either way, a media gateway that meets industry standards is critical.

Softswitch

The softswitch, or media gateway controller, provides the intelligent call control for the voice network. The softswitch also provides another essential function in the context of packet networks: It provides the interworking between the different signaling on the TDM and on the packet portions of the network, e.g., integrated service digital network user part (ISUP) and MGCP protocols. The softswitch may have a Class-4 and/or Class-5 feature set, depending on its role in the network.

Important factors for softswitches are as follows:

- Feature Set: The number and type of Class-4 and/or Class-5 features provided.
- System Capacity: Voice processing capability, typically measured as voice calls per second or busy-hour call attempts (BHCAs), per system.
- Internetworking: Softswitches must support and interwork multiple signaling protocols to provide more flexibility to the carrier deploying its system of choice.
- Reliability: Softswitches must provide carrier-class reliability. Full fault-tolerance and redundancy is critical to service-availability assurance. Fault tolerance between the softswitch and the media gateway is also essential.
- Interoperability: Softswitches must interoperate with a wide range of other network elements, especially other softswitches, because their role is central to the functionality of the packet voice infrastructure. Carriers view interoperability as the top concern in the purchasing decision for new equipment, as seen in *Figure 2*.

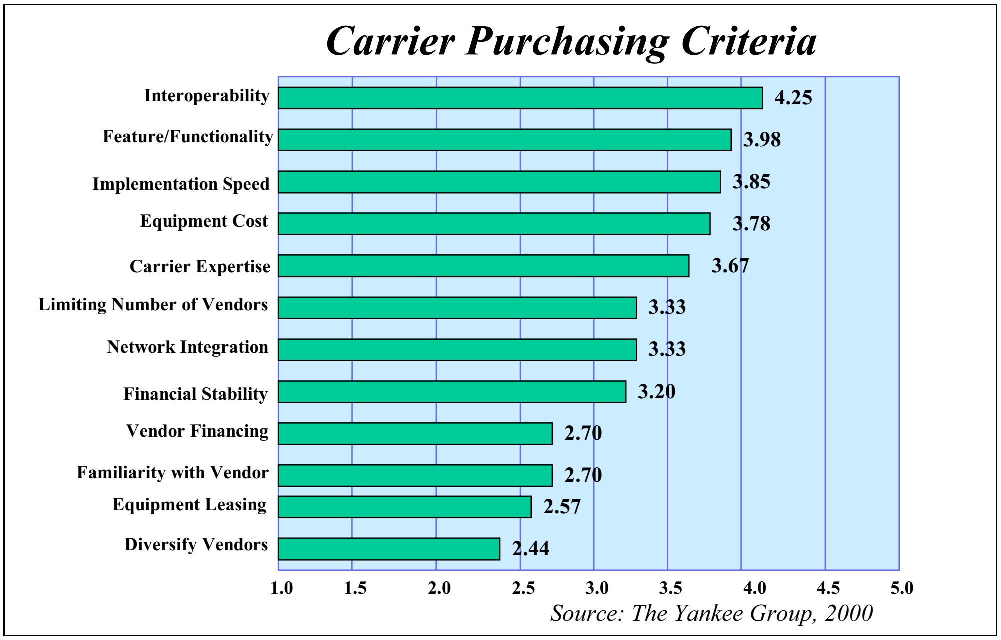
The softswitch can be either physically separate from or physically integrated with the media gateway. In the former, a general-purpose server platform such as the Sun Netra or Compaq PCI server provides call control, and, in the latter, an optimized module fits within a standard slot on the media-gateway chassis.

Although most vendors use external server platforms, a few vendors use the optimized softswitch modules. Physically integrated softswitches provide multiple advantages over these general-purpose platforms: simpler interoperability, higher call capacity, smaller footprint, better redundancy, lower cost, and more efficient operations.

Another important feature of certain softswitches is the capability to provide call control for multiple media gateways distributed across the packet voice network. While solutions from many vendors require co-location of a

FIGURE 2

Interoperability Tops Carrier Concerns for Next-Generation Equipment



softswitch with every media gateway, a more efficient and cost-effective approach is for remote softswitches to control bearer voice traffic on multiple media gateways located in separate COs.

Signaling Gateway

The signaling-gateway function communicates directly with the signaling transfer point (STP) in an signaling system 7 (SS7) network via SS7 signaling messages in order to provide authorized services and route voice traffic through the bearer traffic network. In some vendor solutions, the signaling gateway is a separate network element but ideally is integrated into the softswitch, which offers lower-cost, simpler operations and a smaller footprint.

Application Server

The application server is a product that provides enhanced services that may include "follow me" roaming, automatic language-translation services, and data-driven voice services. Until now, carriers have relied heavily on the feature set of the traditional circuit switch. In a softswitch environment, however, carriers will have the flexibility to offer new services without replacing or updating the entire packet voice platform.

Alphabet Soup: Signaling Protocols

How the primary network elements in a softswitch architecture communicate with each other is not an easy discussion, because there is a plethora of standards-based and proprietary protocols. Nevertheless, the total number of used protocols is shrinking and can be segmented based on the specific interfaces, as seen in *Table 1*.

PNNI is the standards-based protocol used by media gateways and ATM switches to share routing and signaling information to establish and maintain real-time voice and data connections. The BICC signaling protocol, which is a modified SS7 ISUP protocol, correlated with ATM and PNNI signaling, is used as a signaling interworking function.

TABLE 1

Common Signaling Protocols

Network Elements	Signaling-Protocol Options
Media Gateway–Media Gateway	PNNI, BICC
Media Gateway–Softswitch	MGCP, MEGACO (H.248)
Softswitch–SS7 Network	ISUP, TCAP
Softswitch–Softswitch or Application Server	SIP

MGCP is the signaling protocol between the media gateway and softswitch used until now for carrier deployments. Most vendors' MGCP implementations are proprietary. MEGACO (H.248) is the compromise International Telecommunication Union-Telecommunication Standardization Sector (ITU-T) communications protocol that will eventually replace MGCP. MEGACO is still under development by most vendors and has not been widely tested for interoperability. Consequently, MEGACO is still too new for carrier deployments.

ISUP is a SS7 protocol for signaling the parameters and procedures to set up and tear down circuit-switched voice calls between a softswitch/signaling gateway and an STP. Transactional capabilities applications part (TCAP) is used to exchange control-related messages between a softswitch/signaling gateway and application databases (service control point [SCP]).

SIP is an Internet Engineering Task Force (IETF) protocol for transporting call control, authentication, and other signaling messages among softswitches and other devices through an IP network.

Conclusion

The migration to packet-switched voice networks will be an evolution, not a revolution. The most likely scenario is for carriers to pursue a "cap and replace" strategy for Class-4 tandem switches, followed later this decade by Class-5 switch replacement. With so many emerging network elements and communications protocols, the vision of the new public network can be somewhat daunting. But similar to the revolution from mainframes to PC workstations, significant capital cost and operational savings will prove to spur carriers and service providers to make the migration. With the range of packet voice infrastructure products currently being developed and launched, this segment is definitely one of the most exciting in telecommunications.

APPENDIX

Purchase Recommendations

Media Gateway	*Purchase Recommendation:* Select a media gateway that offers scalable port density, has a high initial non-blocking switching capacity, offers multiple physical interfaces, has proven reliability, has proven interoperability with external softswitches, occupies a small footprint, and begins with ATM while supporting IP/MPLS longer term.
Softswitch/Signaling Gateway	*Purchase Recommendation:* Select a softswitch that can meet call-processing capacity; has a desired feature set; has proven reliability; has proven interoperability with media gateways, other softswitches, and application servers; and incorporates the signaling gateway functionality. A physically integrated softswitch capable of supporting call control with multiple distributed media gateways offers distinct performance and value advantages.
Application Server	*Purchase Recommendation:* Select an application server that provides attractive new services, scales to meet customer needs, and has proven interoperability with other softswitches and application servers.

Operationalizing Voice over Broadband: Integrating the Operations Support System

Razi Imam
Vice President, Marketing and Business Development
CoManage Corporation

This paper focuses on the challenge of ending the fragmentation problem in the United States for voice over digital subscriber line (VoDSL) and rethinking the operations support systems (OSS) architecture.

The Challenges

OSS fragmentation is a significant issue for today's service providers. Providers currently take too long to set up, provision, activate, and offer services. Other considerations include how network convergence will affect the next-generation services and how service providers can leverage and deliver high-margin services on this new infrastructure. Finally, providers must determine how to address customer expectations, decide which management functions need to be integrated, and deliver the quality of service (QoS) required for next-generation voice services.

Network Element Convergence: The Collapsing Infrastructure

In the OSS fragmentation picture today (see *Figure 1*), service providers are dealing with multiple types of networks, such as asynchronous transfer mode (ATM) core networks, Internet protocol (IP) networks, or synchronous optical network dense wavelength division multiplexing networks (SONET DWDM). These networks are made up of multiple boxes connected independently. Each box employs its own proprietary technologies. Each box has its own method of being managed, whether through simple network management protocol (SNMP) transaction language 1 (TL1), common object request broker architecture (CORBA) or proprietary element management system (EMS). From an OSS perspective, this situation creates a nightmare because operations personnel have to deal with different types of networks and equipment when they are setting up services. Using Telnet (a command-driven, text-based interface) to manage these boxes and set up services becomes a very difficult challenge, given the multitude of different equipment types found in a typical carrier's network.

The OSS Fragmentation Problem

Until now, the solution employed by many has been to acquire various software to perform individual network management tasks (see *Figures 2* and *3*). Order management software is purchased to create a link between the customer- and network-facing tasks. Providers attempt to reduce activation bottlenecks with provisioning and activation software that physically talks to the equipment and creates an end-to-end service. They buy provisioning and fault-monitoring software to know if faults occur and to create trouble tickets. Performance-monitoring software is especially necessary if the provider is selling guaranteed service-level agreements (SLA). In all, providers are purchasing a multitude of costly software applications just for network and service management. Many carriers also invest in other customer-facing and operations applications, such as billing, inventory management, interconnection, workforce management, and trouble ticketing.

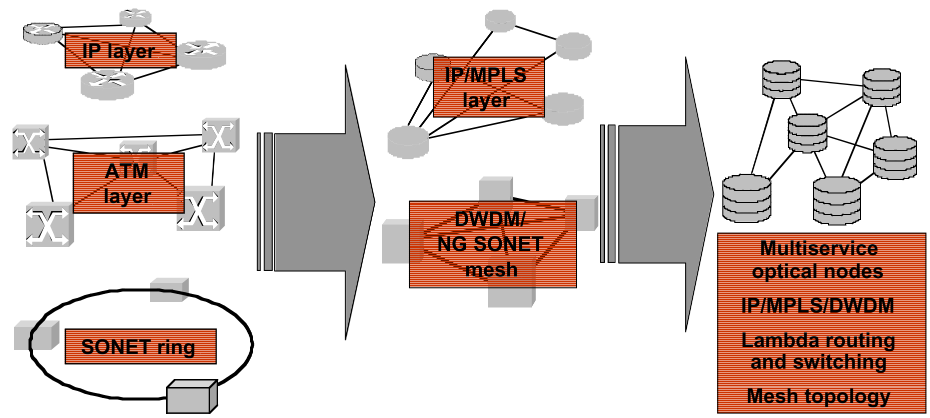
Every piece of equipment in the network has its own way of being managed. Software providers all publish unique applications programming interfaces (API), if at all. Database schemas are not only different, but often obscure. And no standards have ever been agreed upon to unify data within OSS software.

Many software applications are required to activate a single service. On Canadian service provider studied can take 35 to 40 days to activate a transparent local-area network (TLAN) service because it is necessary to Telnet into 30 to 40 different boxes to set up the service. With such complexity, many services are error-prone and never get completely activated in about 50 percent of activation attempts. The reality is that the activation process is extremely fragmented.

Real problems occur when the above reality is coupled with customer expectations. Customers want fast service turn-up. They want accurate billing. Other customer expectations include service quality, application-driven QoS, greater

FIGURE 1

Network Element Convergence—The Collapsing Infrastructure



service-provider responsiveness, and proactive customer relations in the event of outages. Customers evaluate service providers in these terms. Meeting customer expectations is the impetus for customer-aware service management.

The Converging OSS

One solution is the convergence of OSS (see *Figure 4*). Some companies have begun to develop the next-generation VoDSL services or similar broadband services—but instead of maintaining their legacy systems, these providers are considering software applications that have been designed from the ground-up to help provide these services faster. For example, a single application could give the provider the ability to discover the network, provision the network, and activate the services. The same application that monitors the services also monitors the network, providing a unified view. A unified view is important because it builds a network knowledge base within a single application.

A single application allows providers to be proactive. If a fault occurs on a certain port, it is possible to determine what services and customers are affected by the fault. The provider can connect to the trouble-ticketing packages and the customer-billing packages to report that the fault has occurred. Similarly, if a new service is activated, the application can direct billing applications to start charging for the new services.

Customer-Aware Service Management

Customer-aware service management has four requirements:

1. Awareness and management of the customer's equipment, including all edge and core gear.
2. Awareness and management of the customer's services. The provider must have end-to-end views and control of individual connections and overall QoS.
3. Awareness and management of the customer's problems to permit rapid responses and reduce customer churn.

FIGURE 2

Converging Management Systems

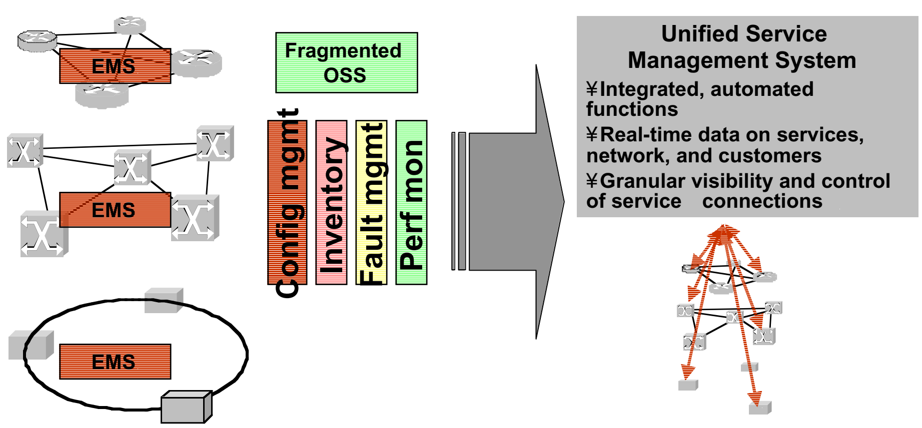


FIGURE 3

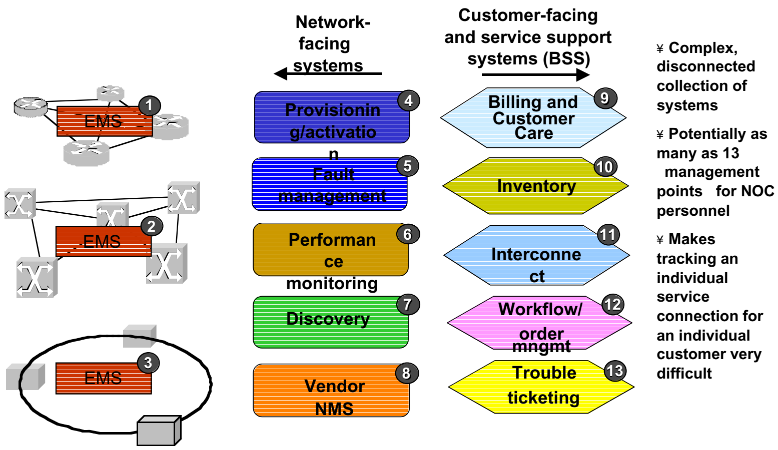
The OSS Fragmentation Problem



4. Awareness and management of the customer's service quality to offer meaningful SLAs and required QoS.

Building the Customer-Aware OSS

To address these four requirements and fully leverage the network infrastructure, a network-facing OSS must have several characteristics. It must have integrated functionality. It must have tight coupling between QoS, SLAs, and individual service-control functions. Because the DSL infrastructure is composed of a wide variety of equipment from multiple vendors, it must provide multivendor support.

Creating a unified OSS architecture is complex. Hardware vendor solutions are robust but typically only manage their own equipment. Software solutions from third-party vendors tend to be generic and only address one aspect of network or service management. The new goal for service providers should be to buy the best-of-breed hardware to set up the network and then buy a single application to manage the network.

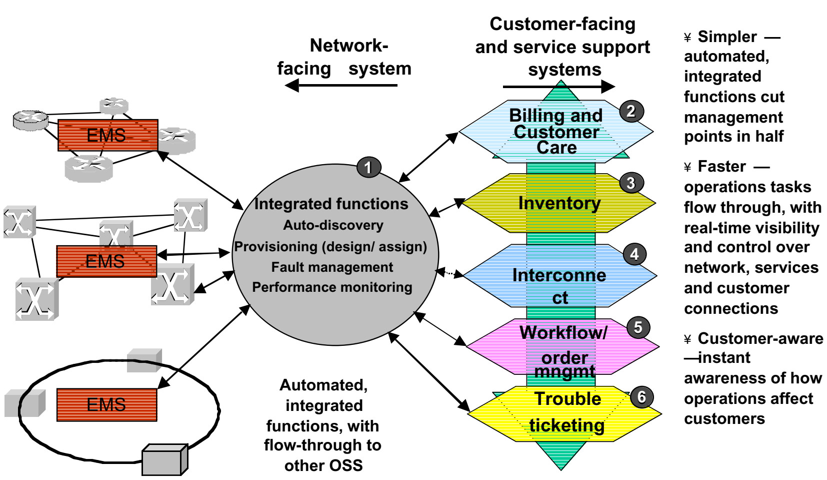
Integrated Functionality

A research study done two years ago with approximately 40 different service providers asked them to identify the functions that could drive operations costs down, the functions that could help them reach profitability faster, and the preferred method of delivery for these functions.

First, the providers wanted to integrate. They wanted a single application, and one of its principal components should be discovery. Providers should be able to discover not only their boxes, but also the ports and the cards and how are they interconnected. The providers wanted to be able to see a topological view of the entire network. In addition, because these are next-generation boxes and services, the application should discover all the services that are currently running on

FIGURE 4

The Converging OSS



the network so the providers know exactly how much of the total network capacity being used, and what resources are available to activate new services. Discovery was identified as the principal means of reducing operations costs because of the information it can provide. Providers did not want to buy new boxes if they are not required—information that only a robust, real-time discovery system can provide.

Providers also wanted a simple provisioning function that would allow them to select different profiles and offer different levels of service and SLAs. They wanted to be able to click icons to provision and activate those services.

The final components identified by carriers were fault management and performance management. Carriers wanted to know when a fault occurs. They did not want to learn about the fault at a later time, but wanted to be informed by the application when a fault occurs in the network. Ideally, the OSS should be able to identify not only faults in the physical network, but also in the logical or service layer of the network, which is critical to proactive customer service.

In performance management, service providers wanted the ability to understand how services are performing for individual customer at any given moment. This is important for making sure customers' services are meeting SLAs and enabling upsell possibilities.

The key to function integration is knowledge integration. Knowledge integration requires a unified database structure

FIGURE 5

Knowledge Integration Example

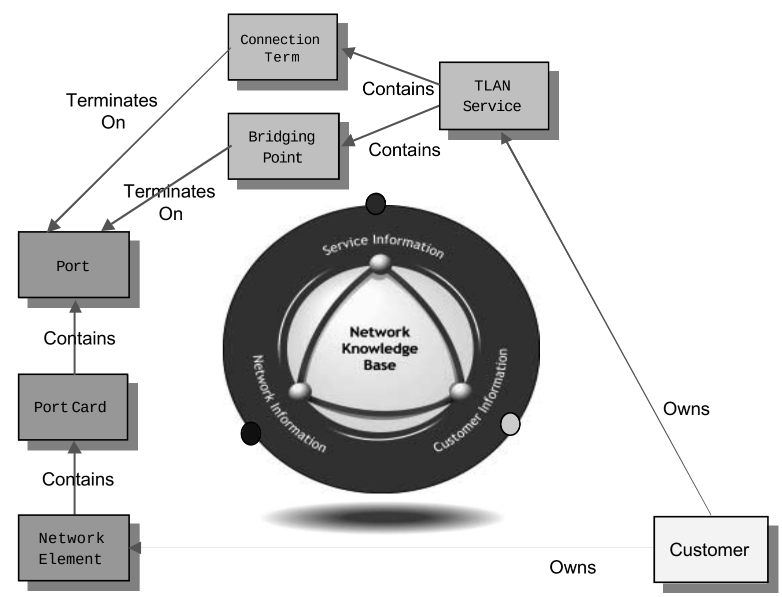


FIGURE 6

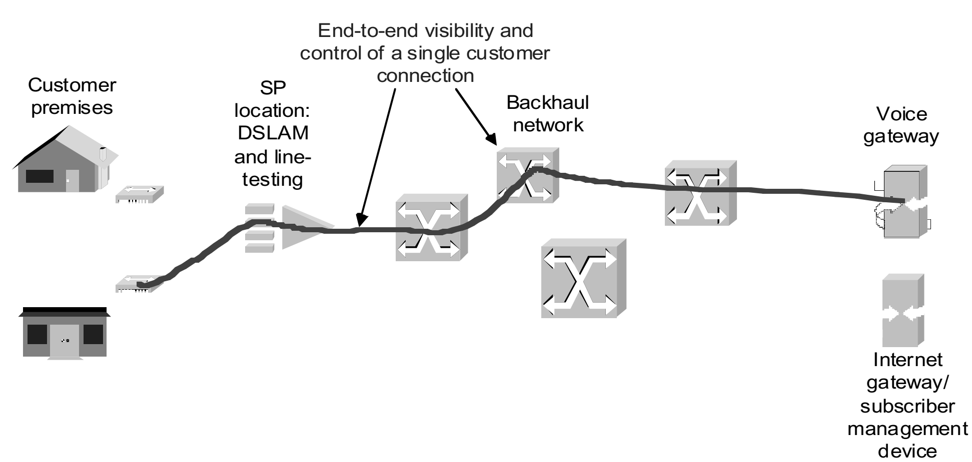
Benefit: Single Service/Customer Management for Complex Services



with detailed information on the network, the service, and the customer.

An Example of Knowledge Integration

These four fundamental applications were a prerequisite for offering next-generation data services. Developing this application led to a unified network knowledge base, a database characterized by a correlation that was never possible in the past. *Figure 5* shows all network cards and ports correlated to all services and all customers using those services and ports. This kind of correlation can only happen via a single application with a unified database. If a port goes down, the providers not only know which box it is so they can roll the truck and fix that port, but they also know exactly where it is because of the discovery capability. They know which ports are not functioning, what services are running on those ports, and which customers have been affected.

Such capability gives service providers a competitive advantage because they can call their customers to acknowledge that services are down but are being repaired. This kind of proactive customer service is unheard of in the current market.

Benefit: Single Service/Customer Management for Complex Services

The bold connecting line in *Figure 6* represents all the service elements that comprise a service topology. This figure, an end-to-end example of voice-over-broadband (VoBB) or VoDSL, also shows the hardware components that build the network topology and the customers in the network knowledge base. A single application provides a view from the integrated access device (IAD) to the voice gateway. Providers can provision all of the elements throughout the entire network—the DSLAM, the backhaul network, the voice gateway, and the IAD. Providers can monitor faults on these elements and manage performance over the entire end-to-end service because management is provided by a single application.

Key to Integration Success: Automation

Automation is the key to integration success. Automated discovery provides real-time awareness of network resources, provisioned services, and customers. Automated provisioning has a one-touch service design with simplified QoS assignment and automatic design, activation, and flow-through. Automated fault management starts immediately upon service turn-up, triggering predetermined protection and fail-over processes and speeding root-cause analysis. Automated performance monitoring instantly flags performance issues related to QoS requirements and SLAs, permitting proactive resource allocation to meet traffic demands.

Flow-Through Service Provisioning: QoS/SLA Service Profiles

Providers must be able to easily offer any variety of services to gain a customer's business. The single software application on a next-generation network would allow the provider to pick a service profile that would satisfy the customer or to change the service profile when necessary (*Figure 7*).

For example, a customer may want a gold service profile, which is point-to-point DSL, but wants to upgrade the max-

FIGURE 7

Example of Service Profile

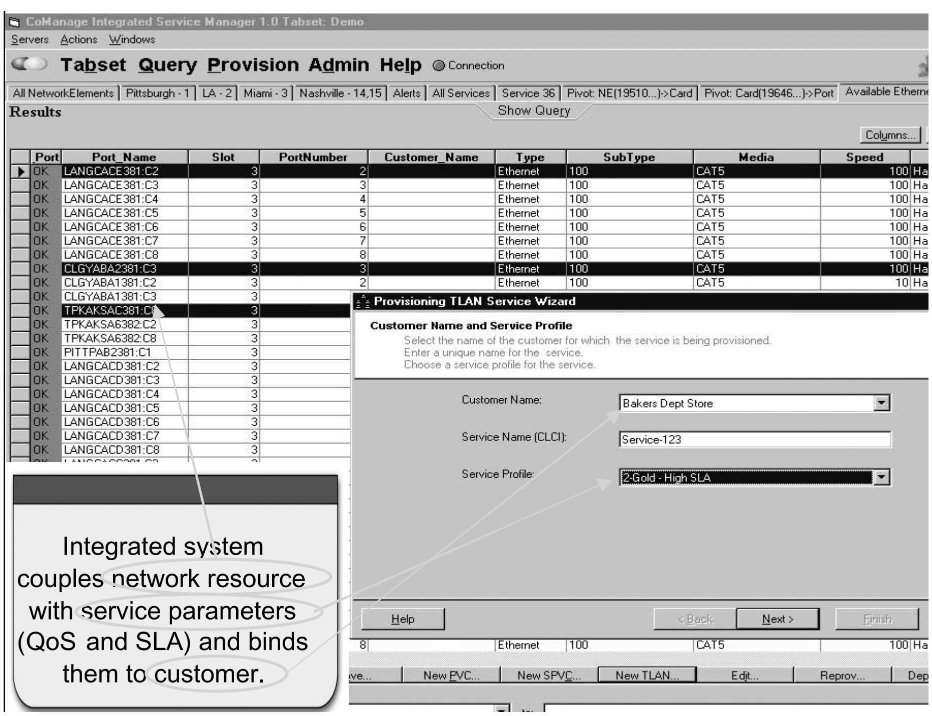


FIGURE 8

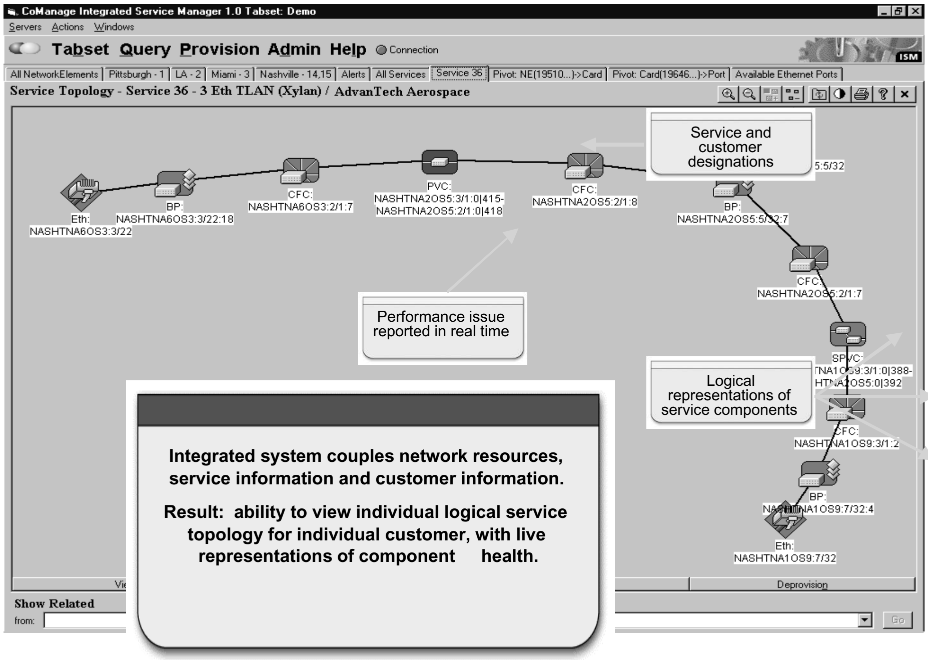
Example of Service Topology



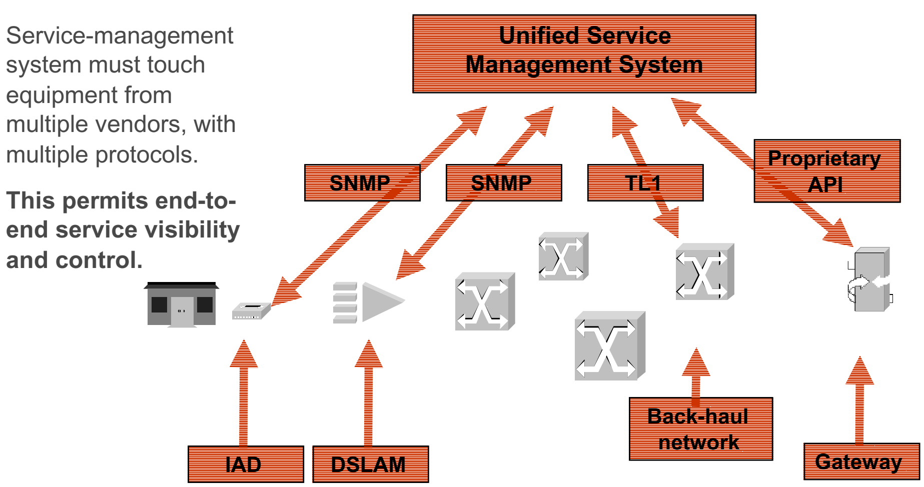
imum bandwidth to 1.2 megabits per second (Mbps). The provider can easily accommodate the request because the software permits real-time modification of these profiles to customize what the sales and marketing staff may sell. Providers then have the flexibility and capability to tell the sales force that although they could only sell one type of service in the past because it took a considerable amount of time to set up the service, the new integrated software solution allows them to sell whatever services can gain the customer's business.

Figure 8 shows a service-topology view of the services. Once the network knowledge base is in place, the provider is able to discover, provision, and fault-monitor the network and performance-manage services.

From a service standpoint, these are next-generation services. The benefit of next-generation service management is

FIGURE 9

Multivendor Support



the ability to monitor SLAs and faults and immediately identify customers that are adversely affected quickly and easily. If a customer has a VoDSL service or a transparent LAN service, the provider can see what part of the logical layer has broken down and then fix it or route around it.

Anyone trying to integrate five different vertical applications—especially the network-facing applications such as discovery, provisioning, fault management, and performance—will find that the integration process never stops. It never stops because applications change and versions change. Integration is a continual work in progress. Network-facing applications should be unified into a single application because it provides the maximum benefit of building the network knowledge base, without ongoing systems integration expenditures.

Multivendor Support

Multivendor support allows providers to choose what equipment suits their budgets and needs and to be able to build a network through a multivendor setup (see *Figure 9*). Providers can select best-of-breed DSLAMs and voice gateways without concern for operation support interoperability.

Conclusion

To take advantage of next-generation services, providers need to simplify. Networking-equipment innovations are collapsing the network infrastructure, so service management systems must simplify as well—especially for managing complex DSL infrastructures. The integration of key functions must take place to end OSS fragmentation in these complex environments. Solutions are available that are specifically designed to get providers running on these next-generation services quickly.

Moreover, providers need to enhance the customer experience by giving customers what they want. Service provisioning and assurance systems must be able to associate strong QoS guarantees with specific SLAs and specific customer needs, particularly for toll-quality voice.

Finally, customer awareness is the key to unlocking the power of the next-generation network. To be a more customer-centric service provider, the network-facing applications should contain customer information. The information does not need to be exhaustive, but it should have a correlation of the customer information embedded right at the core of operations. That information gives a provider a tactical, competitive advantage.

Service Assurance: Empowering Operational Excellence

Norman Kincl
Chief Architect, Integrated Service Management
Hewlett-Packard

Introduction: What is Service Assurance?

A service provider will have many different business processes that together define their business. Some of these will be generic processes that any company can be expected to have. Others will be very specific to communications service providers.[1]

Though aspects of this paper may be applicable in other environments, the focus of this paper is service providers. Using the TeleManagement Forum (TMF) definition, service providers are "companies who provide communications and/or data services as a business. Service providers may operate networks, or they may integrate the services of other providers to deliver a total service to their customers."

The TMF has identified three end-to-end business processes that are specific to a service provider:

- Service fulfillment (also called service delivery)
- Service billing (also called service usage)
- Service assurance

In addition, we consider customer-relationship management (CRM) as a separate process. Though not unique to service providers, it is critical.

Figure 1 shows the TMF processes and how they break down into customer-focused activities. Typically, a service provider uses a collection of systems and manual steps to implement these business processes. This collection of systems is often referred to as the operational support system (OSS).

Within the end-to-end process, the TMF defines "service assurance" as the collection, analysis, and processing of network state information correlated with customer assets to ensure that the offered services to the customer have met and exceeded the required quality of service (QoS) and to provide information for recovery action if otherwise.

Two things need to be made clear about service assurance. First, service assurance cannot be considered in isolation of the broader end-to-end process. As shown above, it is an integral part of a larger set of processes and systems. Second, there is value in looking at and focusing on service assurance apart from the other processes. Even though no two people will decompose a system into the same set of functionality, the larger systems, such as an OSS, need to be decomposed if we are to understand the problems and requirements and be able to build a solution.

What Makes a Service?

Looking at service assurance, one question that immediately comes to mind is this: Exactly what are the services we are assuring? This should be defined from the end customer's perspective: a service is something (in this case, communication- or data-related) that the customer is willing to purchase. This could be as simple as a point-to-point leased-line connection or as complex as a complete Internet protocol (IP) virtual private network (VPN) together with a set of hosted applications, such as sales-force automation and unified messaging.

Each service could be composed of different service elements (SE). For example, in the VPN example above, the service provided to the customer could be composed of the following SEs:

- IP access network
- IP VPN
- Unified messaging
- Sales-force automation application service

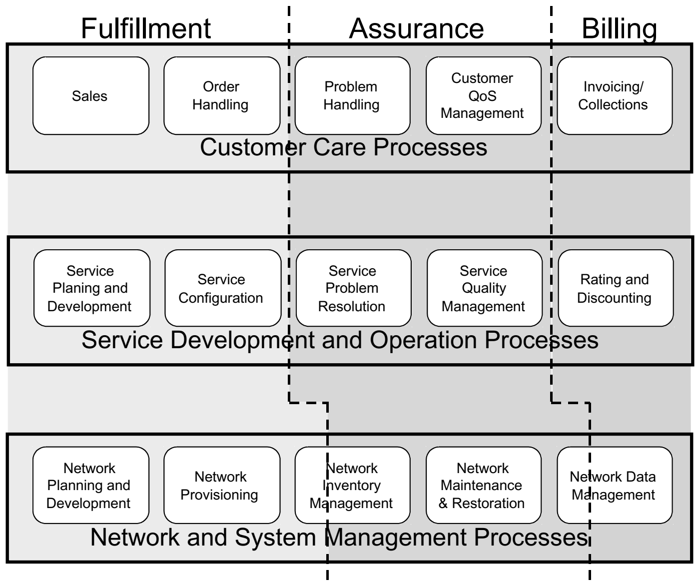
A products and services catalog defines how the SEs come together to form a service offered to customers. This catalog is a component that needs to be shared across all the service provider processes. The services offered and SEs used will depend on the business model of the service provider.

Figure 2 shows an example of how a service could be composed of several SEs. Each SE is implemented by a component. These components could be:

- Network components, such as traditional network elements (NE) and their contained components
- Platforms, including servers and basic networking utilities, such as domain name server (DNS), dynamic host configuration protocol (DHCP), etc.

FIGURE 1

End-to-End Process Breakdown



- Applications that provide specific functionality to the customer

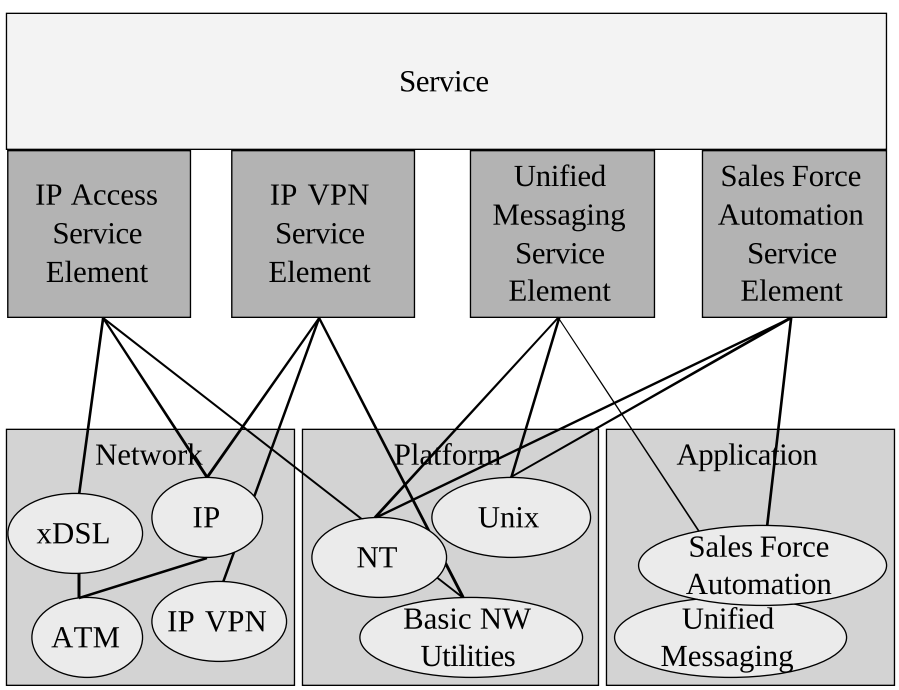
The specific categorization of the components is not significant. The important thing here is to understand the potential complexity and variety of the underlying components that implement the SEs.

Merging Models

As the Internet has been growing and becoming an important part of a service provider's business, two cultures have been clashing—the world of the traditional telephony and that of the Internet. This is manifest in many ways, not the least of which is the terminology used in each world. The

FIGURE 2

Example Components of a Service



traditional telephony world has a vocabulary that has come out of years of standardization efforts in organizations, such as the International Telecommunication Union (ITU). The Internet world also has a rich heritage, stemming from its academic origins and its "open" approach to development and growth. And just as it began to look like we would have these two groups able to understand each other's vocabulary and communicate, a new complexity arises.

There is now a third set of models, vocabulary, and way of looking at things coming into the fray. As ASPs become part of the service-provider landscape, the culture developed in the information technology (IT) organization also becomes important. In this world, standards, such as the IT infrastructure library (ITIL), define a different vocabulary.

This paper uses concepts and terminology that try to speak to the mixed environment of traditional telephony and the Internet world. The important task of bringing these two cultures together with the IT management culture has not yet been attempted. This should not be interpreted to mean, however, that the concepts outlined in this paper do not apply to service providers focusing on applications or other services that have a traditionally strong IT tie.

Why Service Assurance?

The heavy push throughout all industries and regions into a reliance on electronic commerce (e-commerce) is placing increasing demands upon service providers. It is no longer merely inconvenient if a communications or data service is slow or unavailable. Any disruption in the communications services can have a significant impact on the bottom line of a company.

To address this, companies are increasingly requiring service-level agreements (SLA) from their service providers. Though low cost is always attractive, it is becoming far more critical for a service provider to be able to provide differentiated levels of service.

SLAs

An SLA is a contract between the service provider and its customers, the service subscribers. The SLA defines the service-level aspects of the service contract.

SLAs provide value to both the service provider and the service subscriber. Benefits to the service provider include the following:

- Differentiating service offerings from other providers
- Ensuring that customers have a clear understanding of service expectations
- Providing a clear specification of what workload the providers can expect for the customers
- Defining a common language that can facilitate discussion and resolution of service-related problems
- Faster identification of service problems leading to better service
- Satisfied customers

For the customer, the benefits include the following:

- A guaranteed QoS
- An unambiguous understanding of the guarantees
- A mechanism for auditing the performance of a service provider and holding them accountable when guarantees are not met
- The ability to compare the service quality of various providers and make price-performance tradeoffs
- The opportunity to shift the task of managing and maintaining the service-delivery infrastructure to a provider

Some of the topics an SLA will typically cover are related to the components. These include such areas as availability, throughput, mean time between failure (MTBF), and mean time to repair (MTTR). Since these are directly related to the components supplying the service, they are referred to as component-related SLA parameters.

An SLA can also refer to service-related parameters, such as the time required to provision a new service. Finally, an SLA could also contain customer-related parameters. These could include the amount of time the customer is on hold waiting for a customer-service representative (CSR) or how a customer is notified of service-related problems.

In order to support these SLAs, service providers need to have a system that allows them to monitor and manage the level of service you are providing—a service-assurance system.

What is a Service-Assurance System?

A service-assurance system is a system that allows a service provider to manage the processes and information required for service assurance. They are typically considered part of the OSS. As described in fuller detail later in this paper, a service-assurance system needs to share information with the other systems.

Service assurance takes the view that a service is composed of component pieces. And these component pieces could be provided by the following:

- Some dedicated components, such as a line card or a digital subscriber line (DSL) modem
- Shared components, such as a router or a mail server
- Services outsourced from another service provider, such as a local loop or an IP network

To manage the service, the service provider needs two things. First, they need to manage the individual service components. This typically will come together in a network-management system (NMS). The network view will show the general health of the components (and outsourced services).

Second, the services they provide to their customers need to be managed. The service provider achieves this by putting the status of the component, as discovered by the network view, together with the understanding of how the components work together to provide a service. By combining these, they can view the status of each service provided to their customers. By bringing together customers' expectations as defined in the SLA with the component-, service-, and customer-related SLA parameters, a service provider can manage their customers' satisfaction with their services.

Different Views

A service-assurance system will provide different views of the information to the service provider: namely, network, service, and business views. It is important to understand that, though these views are based on the same underlying data, they each have very different purposes:

- The network view[2] provides a technology-centric view
- The service view looks at things from the perspective of the services offered
- The business view focuses on how well the business is running

In addition, the service-assurance system needs to provide a customer view that provides the service provider's customer with a logical view of the services that they are purchasing.

Network View

The network view provides an understanding of how well all the components that make up services are working. These typically have been provided through an NMS. Currently, these primarily address managing the network components, with some extending into managing platforms. Application management (and much of the work around platform management) has generally been in the domain of IT management. Only recently have these been achieving the scalability or robustness required by service providers.

There are two primary purposes for the network view. First, it indicates problems or trends that could become problems, allowing the service provider to repair them before the customer complains. Second, it provides a strong foundation for building the service view.

Though it is possible, and sometimes beneficial, to use a small number of independent NMSs, the number of systems should be kept to a minimum. Certain activities, such as correlation, become very complex across independent systems.

NMSs have been the focus of many standards. The primary standardization effort has been in the view that the NMSs have of the NEs. There are two primary areas of standardization:

The first area involves the protocols to communicate with the NEs or element managers. SNMP and common management information protocol (CMIP) are the primary standards for communication with network equipment. Other standards, such as transaction language 1 (TL1), as well as proprietary systems are also still widely used.

The second area is the model the network manager has of the NEs. The ITU object model (as defined by the Guidelines for the Definition of Managed Objects [GDMO]) and the SNMP management information base (MIB) are the primary standards. As with protocols, much of the equipment in use today still relies on older models.

Though the telecommunications management network (TMN) model suggests an element-management layer (EML) underneath the network-management layer (NML), this does not always make business sense. Element managers are highly desirable when the NEs are complex, or where the number and diversity of similar NEs provide economic value in creating an abstraction layer. However, when the NEs are very simple or small in number, an element manager may not make sense.

Though a full NMS could include many more areas, we will look at those that fall within the domain of service assurance.

Business Benefits

The service provider can expect a variety of benefits from implementing a service-assurance system that adequately addresses the network view. Among these benefits are the following:

Reducing the cost of operations by doing the following:

- reducing the number of required tasks
- concentrating supervisory activities in a national center during off-hours
- instituting an ability to provide follow-the-sun operations
- maintaining control of the key business processes while allowing outsourcing of others

Maximizing operational efficiency by doing the following:

- allowing operators to monitor and control a larger number of components
- enabling reduction of data coming from the network into only the critical information
- providing network status information to the right people at the right time
- introducing preventive maintenance functions

Maximizing the usage of infrastructure by doing the following:

- monitoring usage capacity
- avoiding congestion through traffic control and load balancing

Managing the capital investment in the infrastructure by doing the following:

- using trend analysis to project future capacity
- understanding utilization of resources

Fault Management

Fault management is the cornerstone of service assurance. It provides the collection and correlation of alarms and other relevant events to provide an accurate view of the health of the network. There are several major functions that need to be addressed by fault management, and they are described in the following sections.

Alarm Collection

Alarm collection is the function of collecting information from the NEs or systems to determine their health. For most modern components, the primary form of alarm collection is to listen for events and map those that correspond to error conditions into alarms.

However, not receiving any error events does not necessarily mean that the NE or system is properly working. For example, a component may suffer a "silent death."[3] There are also some components that may not be able to emit events. Because of this, a robust alarm collection system must be able to poll various devices to ascertain that they are still operating properly.

Not all events will come directly from the NEs or systems. For example, one of the responsibilities of performance management is to provide threshold alarms when specific performance parameters are exceeded. Alarm collection must be able to deal with these as if they were coming directly from the system component.

The final function of alarm collection is to put the alarms into a canonical format. A canonical format allows upstream systems, such as those that provide correlation or service mapping, to process the alarms without needing to understand the details of the component emitting the alarm.

Event Correlation

A complex network can generate a massive amount of alarms. Event correlation reduces this to a manageable level by allowing the operator to focus only on those alarms that represent actual problems. Event correlation should not just reduce the number of alarms; it should also have the capability to increase the information content of the alarms.

The first aspect of event correlation in an NMS should be the ability to eliminate or reduce repeated alarms and transient alarms. This type of correlation should be performed as close to the source of the alarms as possible.

Repeated alarms occur whenever a component emits the same event many times in succession. Two separate processing options should be possible for repeated alarms. First, only the first occurrence is transmitted and all subsequent events are suppressed. Second, the first n occurrences are suppressed, with an alarm being generated only after n+1 events.

Transient alarms compose a set of events occurring within a certain time interval of each other (typically seconds) that indicate a problem and its resolution. Transient alarms are generally completely suppressed. A separate "excessive transients" alarm could be generated if the number of transient alarms exceeds a pre-defined rate.

The second aspect of event correlation is correlating individual alarms into problem conditions. A problem condition is a set of alarms that relate to a single problem. In its most basic form, this will simply present an alarm and the clear for that alarm as a single problem condition. Rather than having two separate alarms displayed, the operator would see one problem condition indicating the current state of the component.

However, problem conditions can become a much more powerful concept with more advanced event correlation tools. For example, as event correlation determines that a set of alarms are all related, with one alarm being the root cause and the rest being related alarms, a problem condition will focus attention on the root-cause problem.

The final aspect of event correlation is its ability to increase the information content of alarms. This is done implicitly in the first two aspects (e.g., an alarm indicating that n+1 events have occurred or a problem condition with a root cause and its related alarms have richer information content than the individual alarms). Robust event correlation should also allow you to explicitly increase the information content. For example, for certain alarms, additional information from a configuration database could augment the event information generated by the component.

Problem Management

Problem management allows operators to act on problems. The minimal function it needs to provide is a display of the problem conditions. This can range from simple text-only displays to comprehensive graphical displays. The critical function is to allow the operators to quickly recognize problems. A highly desirable feature is to provide an indication of the impact of a problem.

The ability to display problem conditions, coupled with the operator's ability to discharge those that have been solved, is often sufficient functionality to address those problems that can be directly resolved by the operations staff. The resolution could be to ignore the problem (e.g., ascertaining that the problem is caused by a thunderstorm affecting the microwave transmission) or to take an action that is of relatively short duration (e.g., sending a reset command to a component).

When the problems involve more people or longer duration, problem management should provide additional support. This support can come in one of two forms. The first, and more traditional option, is integration with a trouble-ticket system. The second option is integration with a process engine.

A trouble-ticket system generally provides support for primarily manual steps. The business processes implemented by a trouble-ticket system are relatively static. Typically, the trouble-ticket system would implement an escalation process. Some trouble-ticket systems will provide assistance to the people solving the problem by allowing them to search for how similar problems were solved.

A process engine is better suited for automating the problem resolution, including automatically performing part of the problem-resolution functions. For example, if a fault indicated the failure of a card, a card-replacement process could be initiated in the process engine. This process could do the following:

1. Enable a backup route, if one exists
2. Verify inventory for the replacement card
3. Order additional cards if inventory is low
4. Ship the card where it is needed
5. Schedule a technician to meet the card
6. Schedule downtime on the equipment
7. Test the replacement card
8. Re-establish the primary route

Process engines possess some distinct benefits, including the following:

- They can allow easy modification of the processes as new insight is gained.
- They can maintain metrics on how the processes are working.
- They can be easily integrated with applications required to solve the problem.
- They can provide for manual steps within a process.

A process engine and a trouble-ticket system are not mutually exclusive. Though there is some overlap in functionality, the overlap is not complete—it may make business sense to have both. For example, the process engine could automatically handle known problems, while a trouble-ticket system could provide the support for problems that have not been understood enough yet to have their resolution automated.

Performance Management

The lack of faults does not necessarily mean that the network or systems are running properly. Though the equipment may be functioning, it may not be performing—the load on it may be such that it is just being asked to do too much. This is where performance management comes in.

Most performance data collected is associated with a "network level" component—an NE, system, or application. In some cases, the performance data could be associated with a service or service component, such as asynchronous transfer mode (ATM) permanent virtual circuit (PVC).

There are two major foci for performance management: real-time (or near–real-time) monitoring and trend analysis. Both are supported by a data-collection function.

Data Collection

Performance-data collection is analogous to alarm collection. Typically, NEs or systems are polled on a regular basis for the performance data. As with alarms, this data needs to be converted to a device-independent format.

It is important to provide a balance in the frequency of the polling for performance data. If the component is polled too frequently, then collecting the performance data will affect the performance. However, not polling frequently enough may not detect developing performance problems until it is too late.

Real-Time Monitoring

The purpose of real-time performance monitoring is to identify performance problems as they occur. For example, the load on a mail server may reach a level where it can no longer service user requests in a timely manner. By comparing current performance values against pre-set thresholds, the performance-management system can determine if there is a problem. When it detects a threshold violation, the performance-management system will raise an alarm and send it, on behalf of the component, to the fault-management system.

In reality, the monitoring is not real time but is subject to the polling interval defined by the data collection. This interval should be in the range of 5 to 15 minutes.

Trend Analysis

The function of trend analysis is to project future system performance based on past performance data. As the data is collected, the trend analysis system analyzes and reduces the data, determining any trends. By projecting the trends outward, the service provider can determine when the system will run out of capacity.

The trend analysis data is often also used in the planning and service-creation portions of the service-delivery processes. Rather than just relying on current trends to project capacity, the service provider can use projections from planned service introductions or system expansions to augment the trend data.

Recovery Management

The primary objective of recovery management is to restore the service components after a failure. Part of this process includes testing and diagnosing the components. To accomplish this, recovery management will involve actions, responses, and pre-planned activities.

These actions and activities could take one of several forms:

- Manual actions are directly selected by the operator and usually used in ad hoc situations or when the complexity of automating a process cannot be justified by its complexity.
- Semi-automatic actions are presented to the operator as suggested actions but are not executed until the operator verifies that the situation warrants the suggested action.
- Automatic actions are automatically executed by the system in response to a pre-defined set of events that has a well-known response associated with it.

Recovery management focuses on restoring failed components. However, it also plays a crucial task in providing service-level restoration. This topic is discussed further in the "Service Problem Resolution" section.

Command Abstraction

A properly designed recovery management system will provide a certain level of abstraction of the components. The commands required to reset or test a component may be complex. It is very likely that these commands will differ between manufacturers, or even releases, of the components.

Abstracting the commands has several major benefits:

- It reduces training requirements.
- It is simpler to introduce new equipment or versions.
- It minimizes operator error.

The third point here should not be taken lightly. A significant percentage[4] of problems occur because of operator error. Situations of operators typing a comma instead of a semicolon and causing a major switch to crash are not unheard of.

It is not the goal of recovery management to fully model every component into an abstract version. Rather, the goal is to implement the "80/20 rule": that is, implement the 20 percent of the commands that are used 80 percent of the time.

Restoration

Depending upon the nature of the fault, restoring the equipment may involve physical changes (e.g., replacing a faulty board) or logical (e.g., issuing a reset command).

When physical tasks are required, a proper trouble-ticketing, workforce-management, or process-flow system needs to track and manage the service restoration process. Though part of the broader restoration process, these systems are not strictly part of recovery management since they play a critical role in so many other processes.

Recovery management deals with the logical parts of the restoration process. Where the restoration tasks can be automated, the value is clear, allowing components to be restored significantly faster than would be possible manually. However, by abstracting the user interface across multiple components, it brings value even if the tasks cannot be (or the service provider does not wish to have them) automated.

Testing

Testing is used to verify the proper operation of a component. Testing may be performed at different times—upon initial commissioning of the component, upon service activation, or during operation to verify its proper function. The first two of these happen during the service-delivery processes and are not discussed in this paper. The later is in the domain of service assurance.

Testing may be initiated for one of several reasons. First, it may be initiated to verify that the component did not suffer a "silent failure," failing without emitting an alarm. As with collecting any management information from the components, a balance needs to be made between querying for management information and allowing the component to perform the task it is supposed to.

Second, other components may indicate that there might be a problem with the component.

Finally, a reported service problem could trigger tests on some or all of the components that provide that service.

Diagnosis

Sometimes a fault indication, such as an alarm, does not sufficiently define where the problem is or what action needs to be taken to restore the component to service. Diagnostics help pinpoint the cause of the fault.

When the diagnostics, but not the recovery, can be automated, it is beneficial for the operator to have the results of the diagnostics "attached" to the problem condition. Sometimes diagnostics can help during the correlation process to help determine if an alarm indicates a new problem, correlates with other alarms, or is not a problem.

Inventory and Configuration Management

Within the service-assurance processes, inventory and configuration management provides a variety of services.

System Details

Often the operators will require details of an NE or system that go beyond those kept by the fault-management system for its purposes. By providing a direct link from the fault-management system to the network-inventory system, the full information kept becomes available. The types of detailed information include the following:

- Decomposition beyond the fault-management containment tree
- Hardware revision levels
- Software revision levels
- Physical location
- Contact information
- Tracking information (e.g., a serial number)

Topology Information

To properly be able to correlate and display fault information, the fault-management process needs to understand the topology of the network and system components. Ideally this information should come directly from the network-inventory system. This is especially important for those components that do not support the concept of auto-discovery.

Auto-Discovery Reconciliation

Some component technologies lend themselves to auto-discovery—it is possible to automatically discover the current existence of resources and their configuration and topology. For these types of resources, the network-inventory system can provide a way to reconcile between the way the network is and the way it was designed to be. This can help detect incorrect configurations, whether done accidentally or maliciously.

Service Mapping

To provide for the service view, a clear mapping between the services and the components that implement those services must exist. This mapping is provided by the network-inventory system.

Spares Inventory

If a failure requires replacement of a hardware component, the recovery process will need to know the availability of spares (with compatible revision levels). This information should come from the network-inventory system.

Traffic and Load Management

The service assurance processes are responsible for the dynamic aspects of providing the services. Beyond recovering from faults (see the "Recovery Management" section in this paper), this dynamic management may include modifying the configuration to improve throughput. With the communications service components, this is generally referred to as traffic management or traffic engineering. With service components that comprise applications or platforms, this is usually referred to as load management or load balancing.

The service-delivery processes are also responsible for a level of traffic and load management. However, during service delivery, static choices are made to determine the best resources to allocate to the service. During service assurance, these choices are modified, within parameter limits set during the delivery processes, to dynamically optimize throughput.

Traffic or load management closely links real-time performance analysis with necessary controls that maximize throughput. The performance parameters measured may be those collected by the performance-management system. However, sometimes the traffic- and load-management systems need to augment the performance-management data collection to meet their specific requirements.

In some cases, such as with an ATM network, this level of control is provided through the NEs and element managers. Even in these situations, it may be desirable to have a higher-level traffic-management system. Such a system would augment the functionality of the lower-level traffic manager in two ways:

- It would provide an independent view into the element manager to provide a view into the decisions being made by the lower-level system.
- More importantly, it would provide the ability to exercise network-level controls that allow traffic and load to be balanced across a broader set of resources.

Service View

The service view helps service providers understand how well they are serving their customers. It looks at the services in total rather than at the components that makes up the service.

In the past few years, many things have been put forth as providing a service view. Though many of these do address some of the aspects required for a service view and do add value, most are ad hoc solutions rather than strong foundations for a new way of doing business.

Probably the most important thing that should be present in a solution implementing the service view is an automatic linkage with the service-delivery processes. Requiring the service-assurance system to be separately configured to monitor the service provided to customers is almost a guarantee that the information will be out of date. Any specific service information required by service assurance should automatically come from the service-delivery processes.

Business Benefits

The benefits provided by the network view primarily focus around cost reduction and operational efficiency. In contrast, the service-view benefits have a more direct impact on the service provider's ability to server its customers. Some of the benefits that the service provider can expect from a service-assurance system that implements a service view include the following:

Improved customer satisfaction and reduction in churn, through an ability to do the following:

- communicate timely and accurate information to customers about their service status
- consistently follow a customer's problems throughout the organization
- prioritize actions based upon the number or importance of customers affected

An ability to offer to customers additional service options, such as the following:

- differentiated service levels
- guaranteed service levels

Service Monitoring

The most basic service-level functionality is service monitoring. Service monitoring takes the network fault and performance information and presents it by service and customer. For example, rather than being told that a particular line card is down, a service-monitoring system could inform the service provider that circuit SJCPA023 for ACME Co. is down.

Instead of equipment alarms and problem conditions provided by the network view, service monitoring provides service alarms and service conditions.

The service-monitoring system needs to be notified of new or modified problem conditions. Whenever the problem condition indicates that it is service affecting, then the service-monitoring system determines which services are affected. It does this by looking at the inventory- and configuration-management information. From this, it determines the affected services and creates service alarms against them. These service alarms correlate into the service condition.

The reverse process should also be possible. When a customer calls a service representative reporting a problem, there is often no way to correlate the reported problem with possible equipment malfunctions. The service-monitoring system should also use the inventory- and configuration-management information to decompose a service into the network components that provide it. The NMS can use this list to test for proper operation.

Two things are critical for service monitoring to succeed. The first is being properly notified by the NMS of the service-affecting faults. The second is an accurate mapping between the service and the components providing the service. The easiest way to maintain this information is by accurately and automatically recording it as the service is created or modified. This is why it is crucial that these service-assurance processes be closely linked with the service-delivery processes.

Service Problem Resolution

Service problem resolution goes beyond simple service monitoring in that it allows the service provider to react to and resolve service problems. This involves two different types of activities.

Resolving service problems consists of fixing the problem with the service. If a failure of a component affects a service, usually the easiest way to restore that service is by fixing that component, a topic discussed earlier in the "Recovery

Management" section. However, if the MTTR for the component will be long or will cause the SLA to be violated, the service provider may need to employ other service-recovery methods. Typically, this will involve activating backup resources or provisioning alternate routes. This is discussed further in the "Service Restoration" section.

Reacting to service-level problems consists of the ability of the service provider to do more than just fix what is wrong. It may include having operations notify customer care of the problems, updating status displays for customers, etc. Generally, this means executing on a pre-defined business process that defines exactly how the service provider wants to react to service problems.

SLA Monitoring

A well-defined SLA needs to be measurable. It needs to be clear to both the service provider and the customer what constitutes acceptable service. This is defined through a set of service-level objectives (SLO). An SLO is a combination of one or more component measurements to which constraints are applied. In addition, the SLO will have an operating period over which it is valid. For example, a set of SLOs defining the performance aspects of an SLA could look as follows:

- service response time < 85 ms between 8:00am and 5:00pm, Monday–Friday
  AND
- service availability > 99.95 percent between the hours of 8:00am and 8:00pm
  AND
- overall compliance > 97 percent over a period of a calendar month
  VALID FOR
- transaction workload < 100 transaction/sec

SLA monitoring is monitoring the service for compliance with these objectives. Rather than just raising an alarm because the response time exceeded 85 ms, an SLA–monitoring system may not raise an alarm when it notices that it is late at night and the response time is allowed to deteriorate. Rather than just reacting to problems (as a simple fault manager might force you to do), or reacting to service problems (as service monitoring might have you do), SLA monitoring allows the reactions to be based on contracts and expectations set with the customer. This allows the service provider to offer his customers differentiated service levels. Instead of having to react the same way in all situations, the service provider reacts appropriately to the service level the customer is paying for.

The SLA–monitoring system could be set up to react before the SLA is violated. By defining a threshold value, the SLA–monitoring system could provide an alarm before the SLA is violated. This would allow the service provider to work proactively to avoid a potentially costly SLA violation.

It is important to note that SLAs define service objectives that go beyond jus the performance or reliability of the service. Some of the objectives will pertain to areas beyond the service components. For example, an SLO may state that calls to customer service will be answered by a CSR in < 10 seconds between 8:00am and 8:00pm, Monday through Friday. Similar SLOs could be created regarding time required to provision a new service or change service parameters.

SLA Management

More is required than just knowing when a SLA has been (or is about to be) violated. Two separate aspects come into the more comprehensive type of SLA management: support for reacting to SLA violations and support for defining and managing SLAs.

Reacting to SLA Violations

The service provider should have an ability to automatically react to SLA violations[5]. Typically, when an SLA is violated, a number of actions need to be taken. These could be defined in terms of the business processes that need to take place.

The process that needs to take place could affect many different systems. Depending on the nature of the violation and the contract in place, it may be necessary to

- Reconfigure the service to restore proper operation
- Raise the priority of the network problems that are causing the violation
- Notify the customer of the violation
- Notify the customer's sales representative of the violation
- Notify the billing system for the customer to receive any credit due

Whatever the actions, these should be defined as a process in a process engine. When a violation does occur, the service-assurance system can then spawn an instance of the appropriate process.

Defining an SLA

The second part of managing an SLA is defining it. Though part of this process is a legal and contractual process that falls outside the scope of service assurance, there is a critical portion that needs to be addressed here.

Service-level objectives are what make it possible to measure SLAs. A critical portion of defining the SLA is defining the SLOs. These SLOs need to be well defined. It is important that the definition include the following three elements:

- The measurements—this involves determining what will be measured (e.g., the time it takes to complete one sales transaction)
- The conditions—this involves determining what constitutes an out-of-bounds measurement (e.g., transaction time over 500 ms)
- The method—this involves determining how the measurement will be made (e.g., a test transaction originating on a remote node will be measured every 10 minutes)

If these three variables are well defined for each SLO, then there should be no arguments between customer and service provider about meeting or not meeting the SLA. As ambiguity comes into these definitions, however, uncertainty and inconsistency between customer expectations and service-provider expectations stemming from the SLA will increase. Such uncertainty and inconsistency will often result in unsatisfied customers.

Clearly, once the SLOs have been defined, the service-assurance system needs to be set up to measure and report on them.

Business View

The business view allows the service provider to see how well their business is running. Rather than looking at individual services sold to particular customers, it looks at a service offering across all customers.

The business view links the service-assurance process with the other processes, along with the broader financial picture, to define cost accountability. The typical service provider has no good way to determine the cost of providing and operating individual services or types of services.

This paper presents the business view as part of service assurance. In reality, though, this view needs to cross all four of the business processes. It could equally well be described as fitting in service delivery, service usage, or CRM.

Service-Offering Management

Service-offering management provides the service operator with a business view across all instances of a particular service. Rather than just focusing on a service provided to a single customer, looking at a service from the business view allows the service provider to get answers to questions falling under the following topics:

- ***Return on investment (ROI) and profitability of service:*** Is the service offering getting us the ROI expected by our investors?
- ***QoS offering:*** Is the service offering meeting the quality standards that our customers expect from us?
- ***Ability to meet SLAs:*** Are we generally meeting our SLA commitments?
- ***Customer satisfaction and retention:*** What is the level of satisfaction of our customers for our service offering?
- ***Cost accountability:*** Are the proposed costs in line?

This is an area where only rudimentary work has been done.

Customer View

While the other three views provide information to the service provider, the customer view is information for the customer. There are three major functional aspects that need to be provided:

- Status update
- Trouble reports
- Service reconfiguration

In some ways customer views appear to be identical to service views. However, there are some important distinctions that benefit from it being considered as a different view.

As soon as access to parts of an OSS becomes available to outside users, security and access control to information need to become a primary architectural driver. For customer views into a service-assurance system, this translates into ensuring that the following security issues are addressed:

Protection between customers—customer A should not be able to see anything about customer B (their existence, the services they use, the amount of traffic they generate, etc.); this is even the case when the services provided to customer A and customer B share the same equipment (e.g., an edge router)

Abstraction of the network—customers should not be able to see the details of how a service is provided; they should only see the abstraction the service provider wants to present to them; this needs to be detailed enough for the customer to understand and control their service, yet abstract enough to allow the service provider flexibility to make changes and protection of their proprietary ways of providing a service.

Status Update

The first service-assurance aspect that customers want from a service provider's system is a view of the current status of their services. The customers need to be able to see their "logical network" where such a view is applicable, as well as to see overall service levels and service levels relative to their SLA.

Because of the security issues addressed above, it is generally desirable to keep the details of the customer view at a service or service-element level. Even so, it is generally not sufficient to simply provide the customer with a feed to the service monitoring or SLA monitoring information. Since these are geared as internal systems, they may not have the proper abstraction level or filtering of information to adequately protect the information of either the customer or the service provider.

Trouble Reports

The second aspect of the customer view is the need for customers to be able to submit trouble reports and track the progress of resolution. There are three considerations that become important.

First, though the customer needs to be able to track the progress of the trouble reports, there will be much information in the trouble report that may be inappropriate for the customer to see. The service provider could consider things like names of technicians, actions taken, or details of the service implementation as proprietary information.

Second, the customer should also be able to track the progress of select trouble reports that relate to the customer's service. If the service provider has already detected a problem, it should not be necessary for the customer to create a new trouble report just to be able to track the progress to resolution.

Finally, a well-architected system will allow for a mapping from the service on which the customer is reporting a problem to the components in the network providing the service. This will allow automatic testing of the components.

Service Reconfiguration

Finally, if we look at service assurance as the ongoing operational support of a customer's service, it also includes customer ability to reconfigure profiles and service parameters.

As systems implementing policy-based management (see the "Policy-Based Management" subsection within the "Future Directions" section for further discussion) become prevalent, the customers will want to change some of the policy parameters that apply to their service.

Process Integration

As pointed out before, the service-assurance processes should not be viewed in isolation of the other processes. This section provides examples of some of the interactions that should be expected (see *Figure 3*)

Meeting Service-Level Objectives

Since the service-assurance systems are responsible for ensuring that the contracted service levels are being delivered, all processes need to feed information to the service-assurance system about meeting or not meeting specified service-level objectives. As described in the "SLA Monitoring," SLOs can address such things as hold time while waiting for a CSR or time to provision new services. This information needs to be made available for a comprehensive view of SLA compliance to be possible.

Service Delivery

The service-delivery processes include all systems and steps related to the process of implementing a new customer account and activating a new service subscription. Actual service delivery is the result of a chain of activities that starts with a service request to a central point and ends with providing the requested services. Typical process steps in between include the following:

- Confirming the service request
- Identifying the type of requested service
- Checking if the required facilities are available
- Informing the billing system
- Activating the service
- Registering the subscription

Three specific areas of integration between these processes and service assurance deserve elaborated discussion:

- Network inventory
- Testing
- Service restoration

Network Inventory

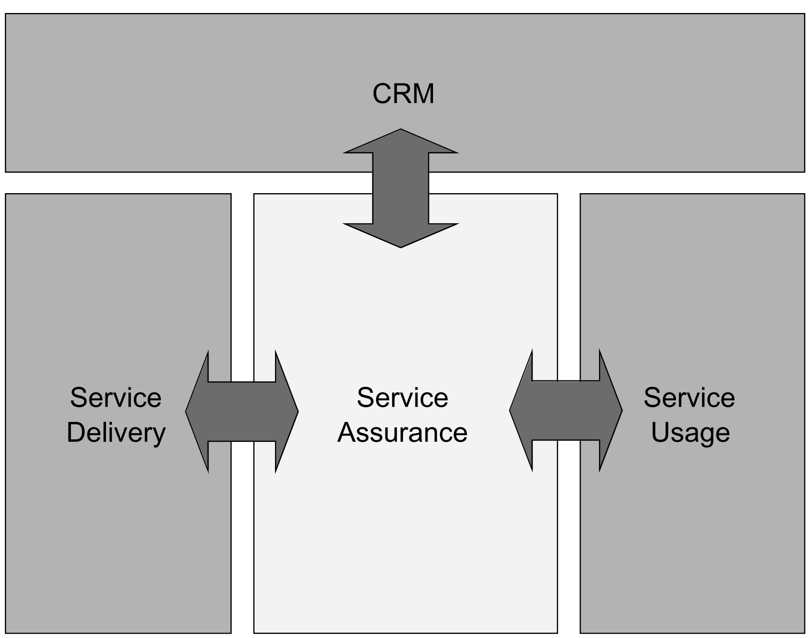
Inventory and configuration management is an area that spans the service-delivery and service-assurance processes. In broad terms, the service-delivery process uses inventory management to understand what resources are available, plan the set of resources that will be needed to provision a service, and allocate the resources to the service.

Within the service-delivery processes, the network-inventory system has that knowledge and supports the following functionality:

- Equipment—the description in data format and graphical format of the physical layout of an NE (rack, sub-rack, cards, spares, etc.), allowing the service provider to plan and grow the equipment as needed to meet the requirements for new services
- Physical connectivity—the description of the physical connectivity between NEs, both in the central office (CO) and outside (connectivity to and from digital distribution frame)

FIGURE 3

Integrated OSS Solution



- Logical connectivity—the description of the logical connectivity; allocation of signaling channels, traffic channels, and operations, administration, and maintenance (OA&M) channels; and bandwidth allocation
- Services—the association of the physical and logical connectivity to the end-to-end services offered to customers as well as the association with the customer data

For service assurance, the inventory- and configuration-management function has been outlined earlier in the "Inventory and Configuration Management" section. This strong overlap should be addressed by a consistent system that addresses the needs of both service assurance and service delivery.

This consistency is more than just using one system for both processes. Creating the consistency is complicated because neither of the processes can be considered as the ultimate "master." Though the service-delivery processes are the ones that primarily create and modify much of the data in the inventory, the service-assurance processes can also modify it. In particular, as the service-assurance processes discover new components, they need to be able to reconcile the "as-is" network with the "as-designed" network.

Testing

Both service assurance and service delivery require a testing facility. Within service delivery, testing is used to ensure that the provisioned service works. It may also be used to determine if it is possible to provision a service (e.g., checking the line condition before provisioning a DSL circuit).

Service assurance uses testing to diagnose components and to verify components are operating properly.

Service Restoration

There are two scenarios for how service restoration can work. Both require the service-delivery processes to cooperate with the service-assurance processes.

First, the service could be configured with backup components. If this is the case, then service restoration principally consists of activating the backup components. For this to work, the service-delivery processes need to assign backup components and communicate them to the service-assurance processes.

However, in some situations it may not be desirable to assign backup components. In such situations, service restoration is still possible. However, instead of simply activating backup components, the service-assurance processes would need to request the service-delivery processes to re-provision the service using different components. For this to work, two things are necessary. First, there needs to be a way for the service-assurance processes to initiate a re-provisioning request. Second, there needs to be a way for the service-assurance processes to inform the service-delivery processes which components have failed and should not be used.

Service Usage

The service-usage processes deal with the collection of usage information from the network and its application to billing, call-behavior analysis, and other systems that can utilize this information. Systems that support these processes include the following:

- Billing mediation
- Billing
- Usage analysis

Two areas in which service usage interacts with service assurance are examined below.

Call Data Records Monitoring

Call data records (CDR) are records produced by the components in the network to detail the usage of the network. The initial purpose of CDRs was to allow the service provider to bill their customers on usage. However, since CDRs capture how the network is being used, they can provide additional valuable information.

In particular, by monitoring and analyzing the CDRs for predefined patterns, it is possible to generate alarms that indicate possible problems. For example, it is possible to identify a sudden drop in call-completion rates or an increase in congestion.

For this type of detection to be possible, the service-assurance systems need real-time access to the CDR information collected as part of the service-usage processes.

SLA Violation Credit

Often times, an SLA will contain penalty clauses that call for the service provider to credit the customer in cases of noncompliance. It is also conceivable that an SLA could be written that calls for a bonus to be paid if certain service-level objectives are exceeded. From a process and integration perspective, this involves a service-assurance process detecting the SLA violation (or exceeding the SLO) and requesting a credit be issued (or a bonus payment charged) through the service-usage processes.

CRM

The CRM processes involve those processes that provide the contact between the service provider and its customers. The goal of CRM is to allow service providers to better identify, attract, serve, and retain customers by managing customer interactions across multiple channels. Included within these processes are both traditional and new types of systems:

- Traditional call centers
- Sales-force automation
- Web call centers
- Web-based self service

Service and SLA Information for CSR

For CSRs to have the ability to successfully provide support to the customers, it is imperative that they have access to the right information. For a service provider, one of the critical pieces of information is the status of the customer's service.

The CSRs do not need to know the detailed status of the service components. The right level of information is the service status and the SLA status of the customer's service. Rather than expecting the CSR to utilize a different system to access this information, it should be supplied to them through their CRM system. This requires the service-assurance systems to communicate the information to the CRM systems.

Portal for Customer Views
To be successful, CRM needs to have complete understanding of the interactions between the service provider and the customer. The service-assurance customer view provides customers with an understanding of their services. It, therefore, stands to reason that the service-assurance systems need to provide the customer view through, or under the control of, the CRM systems.

Having a single portal from the customer into the service provider would provide this. One of the pieces of information available through the portal would be the service and SLA status.

Verify Service
Sometimes the customer might perceive a problem with their service when there is no indication that there is a service problem. This could either be because the problem is with the customer's equipment or because a service component failed without reporting a problem.

In either case, the customer or the CSR may wish to verify the service. Service verification provides a link from the CRM systems into the service-assurance systems. It allows the CRM systems to request that a service, or a set of service components, be tested to ensure that everything is functioning correctly. Though the request comes from the CRM systems, the actual tests need to be under control of the service-assurance systems.

Future Directions

Policy-Based Management
Policy-based management is an evolving technology that will allow components to adjust their functions based on pre-set policy. Initially intended for the IT environment, these policy-based systems, as they evolve, will begin to address important aspects of the service provider's infrastructure.

Policies, in one form or another, have been used for a long time to manage networks and systems. Policy-based management is developing new tools and systems to automate many of the tasks. A significant difference of these new policy-based–management systems is a centralized repository of the policies. This allows all components and management systems to share a consistent set of policies.

The policy-based systems are imbedded into the NEs, service components, or element managers. They allow the operator to define a set of policies to govern the behavior of the component.

Rather than eliminating the need for service-assurance systems, however, policy-based management has the potential for complicating service assurance. When everything is working properly, then the customer should be receiving the contracted-for service level. However, service-assurance systems are not as valuable when everything is working—they earn their keep when things go wrong.

Policy-based management will simplify some of the processes of SLA monitoring, but it will also introduce an additional failure point—the policies. As policy-based–management systems evolve, it will be necessary for service-assurance systems to evolve with them.

Federated Management
In today's world of complex communications services, a service provided to a customer is often composed of SEs purchased from another service provider. The TMF defines this as the layered-service concept, as illustrated in *Figure 4*.

In *Figure 4*, a customer obtains a service with one or more service access points (SAP) from Service Provider 1. Service Provider 1 integrates various SEs to create the service. One of these SEs is a service that Service Provider 1 obtains from Service Provider 2.

Two conflicting issues complicate these types of layered services. First, service management and diagnosis require an end-to-end view of the service. Service Provider 1 needs to have management-information flow across the boundary with Service Provider 2.

Second, business requirements restrict the sharing of information across administrative boundaries. Though in this particular case the two service providers are partnering in providing the service to the customer, they may also be competing in other areas.

Interconnection gateways that provide controlled access to ordering and trouble-ticketing systems are beginning to show up. These will need to be extended to provide a more complete solution. In particular, there need to be standard ways to do the following:

- Selectively share management information across administrative domain boundaries
- Derive measurable aspects from the legal SLA documents
- Provide recommendations and policies to define metrics and their bounds for service compliance

Notes

1. In this paper, the term "service provider" is used to refer to communications service providers (CSP) or data service providers (DSP), including those providing value-added services, such as application hosting, unified messaging, etc. The acronym xSP can also be used to refer collectively to CSPs, ISPs, application service providers (ASP), etc.
2. It is called "network" view to match the well-known TMN model. This, however, is an unfortunate naming since it seems to exclude non-network components, such as platforms and applications. This is not the intent.
3. This is where the component fails without sending any notification of its failure.
4. Reported numbers range from 20 to 60 percent or more.
5. This, of course, could include automatically reacting at some threshold before an SLA is violated.

The OSS Integration Quandary

Ryan Licari

Independent Telecommunications and OSS Consultant

Introduction

Communications service providers (CSPs or carriers) are no longer measured by their billion-dollar investments in high-speed networks, but rather by operational excellence and customer profitability. Profitability, not the number of cities lit, or hitting the next subscriber target levels will keep carriers in business. How does a carrier then create an organization and operations that can sustain profits? The path to profitability hinges on a combination of differentiated service offerings and operational excellence—with automation and flow-through integration being the key to operational excellence. Fully integrating key components of a carrier's operations support system (OSS) is the most critical factor. The end goal is to drive manual interaction to next to zero. Carriers tend to underestimate the true size of a complete integration effort with dozens of systems, a number of business processes, and even more customer and transaction data. This paper addresses all types of carriers including incumbent local-exchange carriers (ILECs), competitive local-exchange carriers (CLECs), interexchange carriers (IXCs), metropolitan-area network (MAN) carriers, Internet service providers (ISPs), and broadband network operators such as digital subscriber line (DSL), fixed wireless, and cable operators. The paper provides and overview of the OSS environment today, an analysis of the true size and challenges of typical OSS integration, and an overview of the popular integration approaches utilized today.

Overview of Today's OSS Environment

To understand the true magnitude of the integration challenges facing carriers today, we must first gather an understanding of what a typical OSS looks like. It may be easier to look at greenfield carriers and more mature carriers, such as regional Bell operating companies (RBOCs), separately, since the integration elements will be substantially different. Analyzing the OSS elements of a greenfield carrier first, you will find the luxury of a small number or even no legacy systems in place. To start, these carriers will most likely evaluate and purchase a packaged customer-care and billing system from a vendor such as Amdocs, Convergys, Lucent Technologies, Portal Software, or CSG Systems. Billing tends to be the obvious first choice, because if you cannot bill a customer, a carrier will not be in business too long. Next comes order management and provisioning systems. These systems provide true measures of operational efficiency, enabling carriers to streamline their service fulfillment and service-assurance processes. Packages such as MetaSolv Software, Cramer Systems, and Sigma Systems for order management, and Syndesis, CoManage, and 3Com for provisioning are the common vendors mentioned in this category. Customer-relationship management, or CRM, tools soon follow. These systems enable easy management of a carrier's service offerings and the overall customer ordering and acquisition process. Siebel Systems is the lead horse in this race followed by PeopleSoft. The final primary tier purchase is usually fault management. It is essential for carriers to be able to easily identify network outages or problems. Failure to adequately do so can result in very costly customer churn from abnormal and lengthy network outages. Micromuse is the category killer here.

The next set of purchases usually involves what many carrier's consider as "nice to haves," selected in the second tier of OSS buildout. These areas include interconnection gateway, service-level agreement (SLA), and performance-management tools. In the interconnection gateway space, NightFire Software, Quintessent Technologies, Telecordia Technologies, and Accenture's Launch Now solution all compete. Interconnection gateway solutions enable carriers to streamline the provisioning process of circuits that reside off their own network. For example, a carrier may need to obtain a local loop, port, or frame-relay circuit from another carrier to fulfill a service request. Interconnection gateway software intelligently validates and automates these orders, eliminating errors and speeding customer turn-up. Service-level management solutions are often addressed through a variety of packaged and custom reports generated from other OSS packages. This approach may provide a certain level of monitoring and SLA management, but it is a very manual intensive and somewhat crude process. There are some companies, such as the European-based joint venture between Verizon and Telecom Italia called Sodalia Solutions, that are starting to successfully position their SLA management tool in larger accounts from wireless carriers to long-distance providers. By probing for data on the network and throughout other OSS systems and meshing this data with easily defined SLAs, this tool monitors, manages, and alarms SLA infractions in real time. Again, this can often be viewed as a "nice to have," but the benefits to the customer from proper implementation of these tools can be quite powerful.

Let's now move from the greenfield to the more complex scenario—the OSS components of larger carriers such as the

RBOCs that have been in business since the time when long-distance service was actually a money-making proposition. Telecordia Technologies and the big integration companies, such as the former Andersen Consulting and Price Waterhouse Coopers, have built from scratch enormous systems to support the expansive business requirements of RBOCs. Some of these systems are on record as being the largest systems ever created. Even the names of theses systems can be complex: CABS, CRIS, SPC SOS, and FlexCab. Because these systems cover incredible amounts of business functions, they tend to require constant code changes and updates to user interfaces. They are much more dynamic and expansive systems than the "off-the-shelf" solutions typically implemented by the greenfields. In addition, because the carriers have been in business for longer, they support a larger number of service offerings, each of which may have its own billing, customer-care, order-management, and inventory systems. The number of custom systems can grow exponentially.

The Magnitude of Integration

This section outlines a number of elements that make creating and maintaining successful integration a substantial effort. First, the number of systems alone can be daunting. The greenfield integration scenario appears to be more straightforward versus the integration tasks of more mature carriers' systems, but the number of systems requiring integration in either case can be staggering. The greenfield scenario must have a minimum of four and upwards of a dozen disparate OSSs to run their business, but the legacy carriers' can have hundreds. Let's consider a "killer" consumer offering: local, long distance, DSL, and a fax line all on one bill. Nice offering, but legacy carriers need to tie together the CRM, order-management, and provisioning systems to ensure an accurate service order and fulfillment. All of the services must then be tied together from multiple billing systems to be placed on a single bill. That is consumer only, not even mentioning the exponentially more complicated business offerings.

An additional complexity involved with integration is the actual method available to migrate data into and out of systems. The off-the-shelf packages have a leg up in this area. Off-the-shelf packages tend to design and build application programming interfaces (APIs) that allow for the export and import of critical information. These APIs were designed and built as part of the initial product development, which makes for better throughput and easier integration points. These APIs are intelligent and can massage information into the format required by the system, and they also inherently know how to update the systems to keep consistency and integrity within the application.

Unlike the packaged software solutions, the custom systems of the legacy carriers do not come equipped with readily built APIs to exchange critical data, requiring additional custom work to extract and input information directly into the systems core, usually with direct database writes. This method comes complete with risks. The systems are so complex that a single transaction posted from another system may require tens of table updates and database trigger modifications.

Looking at the type of data that needs to be exchanged can further help us to understand the complexity involved in systems integration. Some examples of information that needs to travel back and forth between systems, while maintaining integrity, include the following: customer information, billing information, service information, order information, and usage information. The most simple on the list is the customer information. This information is usually relatively standard across systems, so getting name, address, and contact information between systems is relatively simple. Billing information adds the complexity of payment type, terms, rates, and conditions involved with a customer's bill. Making a broad leap to the next level of complexity, one quickly encounters service information. Service information is stored in a product catalog. Sounds simple? Hardly. The billing, CRM, and the order-management systems all have their own product catalogs with information stored in a variety of different formats. One of the largest challenges in the OSS world today is to enable timely and accurate updates of a service change through a number of product catalogs. Order information presents a different level of complexity. The issues here are two: 1) What is the database of record for an order, and 2) orders can be extremely data intensive entities. These orders can be customer-to-carrier orders or carrier-to-carrier orders. For carrier-to-carrier orders, such as local service request (LSR) or access service request (ASR), the order information is traditionally entered into an order-management systems, but the information must be integrated and transferred through an interconnection gateway solution, where the order is transmitted to the receiving carrier. The database of record should be the order-management system, but what happens when an error occurs either with the gateway or the trading partner? The error information must be relayed back to the order-management system to maintain data and order integrity. This is another integration point that is very dynamic and data intensive. If a carrier executes 10 types of orders to eight different trading partners, that is 80 different interface points that must be maintained. Each interface, and ASR order for frame-relay service to BellSouth, for example, can contain as many as 10 message types, 20 forms, and hundreds of fields each. Keep in mind that all of these interfaces are not static, but rather change frequently.

Another key element to consider is the constant updates made to both off-the-shelf and customer applications. Packaged software packages tend to produce at least one major release upgrade per year, as well as a number of minor releases and bug defects on a consistent basis. Each change in a software package causes the potential for an integration change. Along with the potential code changes to integration components, carriers must also execute a new suite of integration tests to ensure that the systems are still compatible. As depicted, the versions and transaction data are never static and the wealth of data that needs to be migrated throughout systems can be daunting.

Looking at a real-life example can help to put the complexity in perspective (see *Figure 1*). A small business places an order for virtual private network (VPN) service between its headquarters and all of its remote sales offices from a local CSP. A customer-service representative (CSR) enters the order into a CRM package, where the account is created and pricing is negotiated. The service and billing information must be transmitted form the CRM to the billing and order-management systems, which breaks the order into its components. One of the sales office locations is in Washington, D.C., but the carrier taking the order currently lacks network capacity in that region. The network capacity was determined by transmitting order information from the order manager to the inventory system for validation and back. Satisfying this order now requires the carrier to order circuit capacity in Washington. The off-network circuit request comes in the form of an ASR entered in the order manager and sent through and interconnection gateway and on to the Washington, D.C.–area trading partner for provisioning. The responses from the trading partner must flow back through the gateway and on to the order manager. Now the order manager sends service and provisioning information to the provisioning and activation systems to turn up the service. The complete VPN service can now be turned on, leaving the fault-management system to transfer usage data and faults back to the order manager.

Potential Integration Approaches

We have now seen the business requirements and goals of a carrier driving the need for a number of integrated support systems, and we have discovered that integration itself is no lay-up—its time to explore the potential solutions of how integration occurs:

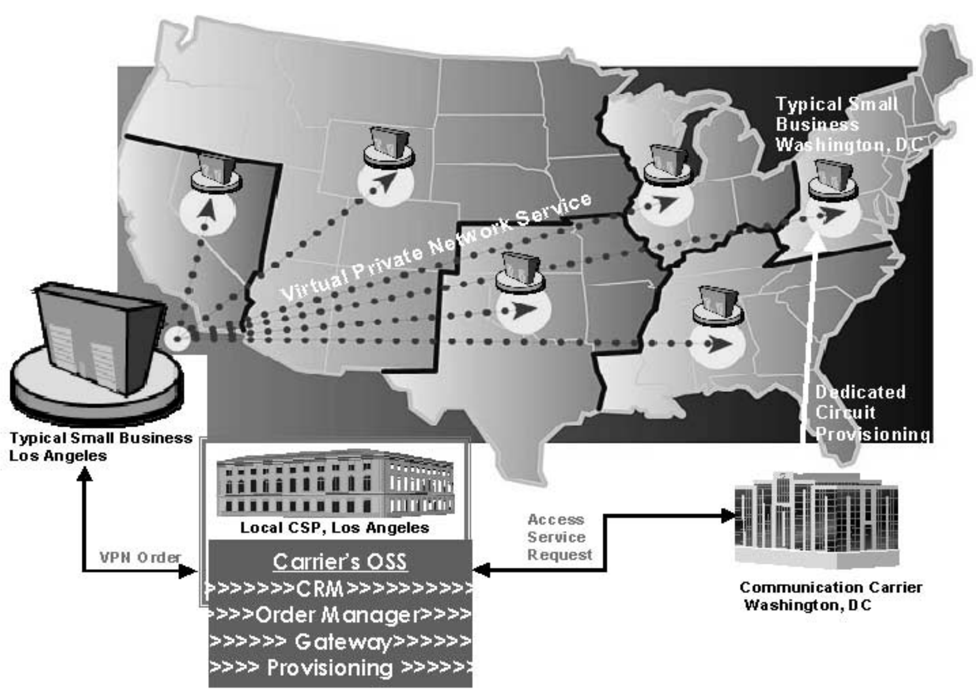
1. Multiple Data Entry
This option should not even be discussed. It's basically ignoring technical integration and using manual double entry. Carriers implementing this approach are asking for large-scale errors and service delays. The risks, challenges, and excessive expenditures surrounding this approach are obvious.

2. Custom Integrations
Custom integrations involve contracting with a systems integration firm to build "messaging tools" between systems to move data around the OSS. Custom integrations have typically been long, arduous processes, with no guarantees of success. This approach is shrinking in popularity.

3. Enterprise Application Integration (EAI)
Often referred to as middleware, EAI solutions offer tremendous functionality to automate business processes between systems, with very powerful tools to create and map critical business processes. This approach has been quite popular among carriers, but actual field implementations have yielded less than adequate results. EAI solutions can add a great deal of additional complexity to the integration, including adding another dynamic system that must be integrated and the need to maintain experts on whatever EAI tool you may choose.

Giving carriers, integrators, and vendors a great deal of credit by learning from their experiences of the boom time in telecom, a concerted effort is being made to create a hybrid integration solution that holds promise. It's a hybrid of the custom integration option, the EAI option, and a third option that will be discussed next: the point-to-point adapter. This solution provides carriers with the tools that EAI packages provide, along with a set of pre-packaged components and methods that will enable communications between selected packaged OSS software solutions. For example, webMethods offers pre-packaged components that enable Siebel System's APIs with Portal Software's APIs, but the specific data elements that require transport are not included. This leaves the need for continuous customization of the components using the EAI tools to meet

FIGURE 1



the needs of the carriers' specific business processes. EAI vendors are also going a step further in some cases by offering not only package-to-package components, but also a set of business processes or transactions to meet specific business requirements. For example, Vitria Technologies provides a set of customizable process flows and transactions to enable broadband service fulfillment processes. The systems integrators have taken a liking to this type of offering, creating large practices in a number of EAI technologies. The integrators have realized that integration using the EAI tools is more manageable and reusable that a straight custom approach.

4. Point-to-Point Adapters

Off-the-shelf, point-to-point adapters that connect and manage the communication of transactions between systems are starting to be offered by independent software vendors (ISVs) themselves. Point-to-point adapters offer carriers an additional, more headache-free option that helps to avoid the custom-integration pitfalls. These off-the-shelf, proven, integrated solutions can truly help carriers to achieve the data flow-through for which they are searching. Point-to-point adapters completely package integration. They contain specific messaging and process elements to manage specific processes between applications. The adapters also release a number of different versions to maintain productized support for updated versions of the packages themselves, as well as any changes in the data content or process flows between the systems. This sounds like a brilliant solution, but it is not one without downfalls. Chances are that ISVs will not offer productized connectors between all of the applications that you need to integrate. This approach also requires the ISV maintaining the adapter to become an expert and to establish incredibly close ties to the ISV to which it has built an adapter. This is an option to keep an eye on in the quarters to come.

5. One-Stop Shopping

The final option for carriers makes the finance department ecstatic because it's easy on the budget. However, the operations people may frown on the less than complete functionality. Companies such as BlueSpring Software, Wisor, and Telution are building all-inclusive solutions that address a carrier's billing, customer-care, CRM, order-management, and provisioning needs all in one. This option eliminates the need for integration and usually can be procured for a fraction of the price of buying the best-of-breed solutions in each area. The pitfall here is that the functionality of these packages may be more limited than the category killers.

Conclusion

Today's telecommunications climate is like a summer in San Francisco—changes are frequent and sometimes drastic. OSS components need to keep up with these changes. As we have seen throughout this paper, integrating solutions can provide carriers with powerful flow-through automation, enabling the ultimate in operational excellence. However, the path to utopia is a minefield. Although there are many different approaches that carriers can choose to integrate their systems, a few things are certain. Whatever integration method a carrier may select, an appropriate solution must be "future-proof"—i.e., technologically advanced enough to quickly adapt to change. Carriers should also be aware of, understand, and prepare for the magnitude of proper integration.

Defining "Carrier Grade"

Clyde Miller
Vice President
Nortel Networks

Introduction

The telecommunications industry has always prided itself on its reliability and availability, but the telecom network is currently undergoing a rapid state of change, as more services are being added to existing networks, new networks are being added to include those services, and new elements are coming into the network from nontraditional sources. And while the integrity of the network is still the number-one priority of the industry, competitive, first-to-market pressures are rising.

One of the results of these conditions has been the emergence of a wide variety of interpretations of the term "carrier grade." Without a firm consensus within the industry about what exactly constitutes carrier-grade products, services, and networks, the definition of this term will remain unclear and elusive. This paper discusses some of these interpretations, addressing the implications of leaving the term without a precise, standardized definition.

Carrier Grade—Why Care?

These new network elements (NE) work in performing critical functions and include new switching fabrics, new edge interfaces, and other powerful devices with sophisticated hardware and software. Many of the elements being introduced into networks are more related to a computer-type environment than what is normally considered a telecom-type environment.

Maintenance windows, as far as the network is concerned, are essentially disappearing, making the reliability of those elements even more important. The outage impacts of some of these new elements are quite significant, especially when a company is trying to introduce a leading-edge service to consumers and promoting regular use. In such an instance, up-time is paramount.

The industry lacks clear, specific, and consistent carrier-grade requirements, and products at the forefront of this transition often lack standardized guidelines. In light of these deficiencies, the first step is to define carrier grade; the next step is to explore how true carrier-grade service can be attained; and the third task is to determine the industry's level of responsibility for achieving it.

What Does "Carrier Grade" Mean?

As illustrated in *Figure 1*, carrier grade is founded upon four basic principles or "pillars": reliability, upgradeability, maintainability, and supportability. Without all four of these pillars, the overall integrity of the network is compromised. These capabilities, within any element of the network, have to be maintained.

Carrier-Grade Reliability

Carrier-grade NEs must be designed and manufactured to ensure robustness and longevity. Products and services must demonstrate the designed levels of performance measured against a uniform standard, such as TL9000. TL9000 is the evolution of the requirements and quality measurement system (RQMS), a measurement standard that has been used in the industry for some time. TL9000–based metrics provide data on outage downtime and frequency.

In terms of consistent availability or consistent objectives, the goal is for 99.999 (five nines)—a number that equates to about two minutes of downtime per year, a mean time between failures of 17 years, and a mean time to repair of 16 minutes. Both the network and the services need to be measured according to such standards. The first step in doing so is to break the network down into its component parts and measure the individual parts. The next step is to roll all the components up into the network and measure at that level. Finally, in some cases, a service-basis examination is necessary.

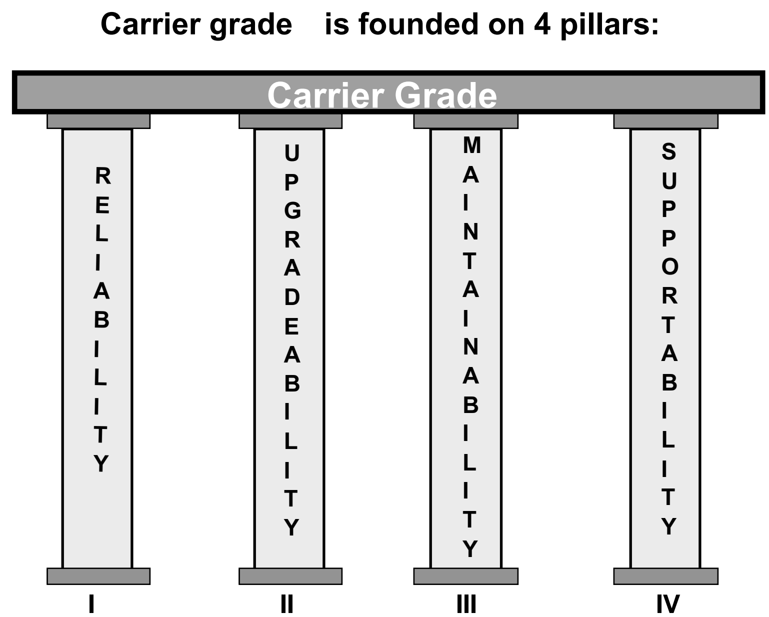
Achieving designed-in reliability requires operators to pay close attention from the very beginning to hardware- and software-component selection, manufacturing processes, environmental robustness (how the component operates in field conditions), and industry standards.

Carrier-Grade Upgradeability

Carrier-grade NEs must have the ability to flex with changing business needs and technology without impacting the end user. Software elements must allow seamless on-line growth, meaning they can accept feature additions as well as patch, generic, and upgrade applications. Such flexibility allows companies to develop hardware without out-of-service downtime.

FIGURE 1

What Does "Carrier Grade" Mean?



Hardware elements must allow for expansions, reassignments, and upgrades to the equipment. The hardware must also allow for network reconfiguration. For example, if a company needs to reroute traffic for service reasons, the system should allow movement to another element or another unit. The hardware must also have a uniform change process with adequate documentation.

Documentation is often written by scientists for other scientists. The problem is that most of the time the people in the field are not scientists. For that reason, the documentation needs to take more of a human-factors approach and to better address the ways the non-scientist thinks and does things. In the end, good documentation will help reduce procedural network outages.

Carrier-Grade Maintainability

Carrier-grade NEs must also have the ability to communicate easily with maintenance centers and to automatically perform a wide variety of maintenance activities. Self-diagnostics are important, giving the network the capability of routinely looking at itself and reporting if the operating system is functioning properly. Auto-imaging is another capability that needs to be built into all these elements because it systematically takes a view of the network. Auto-imaging can provide information on exactly what the network looked like before a reconfiguration of services.

Maintainability also includes on-line data changes and subscriber changes, system audits, auto-recovery, and auto-correction. The idea is that the system should be able to recover automatically when it detects an error through its self-diagnostic procedure. With auto-correction, the system should be able to reroute automatically if necessary or to change activity of its duplicated switch process or power supply.

Centralized access is also necessary for maintenance provisioning, monitoring, and usage. As the industry moves forward with this new mix of elements, people must be able to look at a total view of the network, understanding clearly what the elements provide as far as the end user is concerned.

Carrier-Grade Supportability

Carrier-grade vendors must have the mechanisms in place to support the installed base and meet industry standards for responsiveness. It is important to measure all the hardware elements and the responsiveness of the people on-line. One of the variables that TL9000 measures is how long it takes the carrier, service provider, or equipment provider to fix problems in the network.

Critical outages must be resolved within 24 hours, 100 percent of the time. Ninety percent of major problem reports that may affect service are handled within 30 days. Minor issues fall within the six-month window. These standardized metrics for TL9000 not only provide a framework for measuring outages but also provide a way to present the data that eliminates the ability to change scales or other variables to make a company look better than it actually is.

Furthermore, the people on-line must be technically skilled, available on a 24/7 basis, and available on-site. For a service organization, those issues are vitally important, as customers are rarely pleased when they hear that the technicians will look at their problem when they come to work the next morning or afternoon.

Carrier-Grade Network Element

For an NE, alarms are reported failures. For a typical carrier-grade NE for switching, the two minutes of downtime per year is equal to one incident per year. Availability is 99.9999. The element meets network-equipment building standards (NEBS) requirements and meets physical and human-factors design requirements.

This human element is important because although hardware and software are increasingly becoming more reliable, procedural errors are still occurring. People making mistakes is a growing concern in the industry, and such errors present the challenge of finding out what actually happened. Operators need to focus their attention on the way products are designed and the way they should present themselves via a human interface. The idea is to mirror how people look at processes. Product tests often show that people do not necessarily understand the element when they are asked to find a certain part in the frame or to find a certain element.

Additional requirements for a carrier-grade NE include the ability to self-identify its failures greater than 95 percent of the time so that people can take action prior to the product actually failing in service. Technical support must be provided on a 24/7 basis by skilled technicians. Redundancy is built into the design. Finally, the element must conform to zero outages even when reconfiguring the network, applying patches and maintenance releases and changing generics.

The zero-outage concept is relatively new. The industry formerly had planned outages. Nowadays, though, the system, ideally, should report a problem, and the on-line people should correct the problem, then reconfiguring to provide the service back to the individual as needed.

How Is Carrier Grade Obtained?

Failure within any one of the four pillars—reliability, upgradeability, maintainability, or supportability—should take away the ability to claim carrier-grade service. Elements that are not carrier grade do not permit reconfiguring, rerouting, or reloading without an outage. Once the network is in place, it is too late to consider these factors.

Carrier grade must be designed into the product itself. It cannot be added after the fact. *Figure 2* shows the overall product life cycle.

In the manufacturing phase, important considerations include the types of components and connectors selected and the types of processes used to actually build the components.

For the installation phase, grounding and earthquake resistance can be important. The key question is whether the element is resistant and stands up to the overall charges for that product.

During the upgrade phase, the product must permit processor changeout, hardware and software upgrades, and network-element visibility.

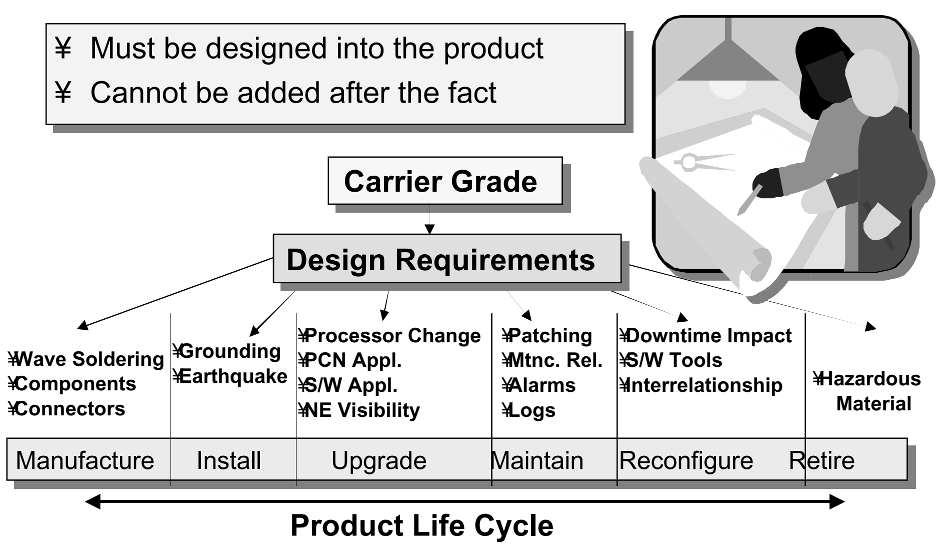
Maintenance considerations include the capability for the element to patch, auto-image, and auto-patch itself. Maintenance releases need to flow through the network. In terms of human factors, the more processes that can occur automatically, the less likely something will go wrong. Alarms and logs are necessary for maintaining the unit.

In the reconfiguration phase, the product must have zero downtime impact and software tools to help people walk through the configuration without any errors. If a system is designed properly, it is somewhat like a salt shaker. A salt shaker is a very simple mechanism: if used properly, salt comes out; if used improperly, nothing happens. The interrelationship of the reconfiguration is also important—knowing the effect that one action will have on all the other elements in that network.

Finally, in the retirement phase, hazardous material is a serious consideration. In the future, when the part is taken

FIGURE 2

How Is Carrier Grade Attained?



out of the network, disposal could potentially be compromised by the material that comprises the part.

What Is the Role of Industry?

The challenge to the industry is to establish formal carrier-grade requirements. Some standards are already well accepted, such as TL9000 and the evolution of RQMS, which is a global type of standard. Consequently, TL9000 will work anywhere in the world. Correlating traditional types of NEs to that standard is easier than working with some of the newer elements; so work remains to be done in the standards area.

These requirements need to be built on an element-family–type basis and viewed in terms of the service impact of the elements, the redundancy of the network, and other applicable pieces. As fabrics change, NEs on an individual basis probably become less important, but they are, and will remain, important as far as the network is concerned.

Once established, industry requirements need to be formally published so they become part of the decisions that drive the industry. Providers have to track the data to make sure that the elements actually meet the standards and to help drive continuous improvement in certain areas.

A few years ago, the standard for measuring outages was two minutes. Now, the bar is at 30 seconds and heading toward zero. It is vitally important to keep evolving the network and the elements themselves.

Adherence to requirements should drive business decisions on a day-to-day basis, always with an eye toward moving the standard forward or raising the bar as far as performance is concerned.

All these capabilities cost money, but a serious consideration of carrier grade involves understanding the real cost in the long term. After installation, a lower-cost product could end up costing much more than a higher-priced, carrier-grade product in service cost and customer complaints.

As shown in *Figure 3*, if products conform to the four pillars, they deserve the carrier-grade designation. Buyers of such products will be confident of being able to provide carrier-grade service to customers.

Conclusion

Carrier-grade service is increasing in importance. With data networks and services, there are now zero barriers preventing customers from changing from one service provider to another: customers can simply log on, cancel with one provider, and obtain service from another one. Service level, then, is going to become a paramount issue for providers, the linchpin for retaining customers.

Hewlett-Packard Consulting

Introduction

Companies are being challenged today by market conditions, business conditions, and enhancements in technology. To develop an operations support system (OSS) environment that is flexible, scaleable, and manageable, companies are reexamining their OSS strategies. There are several different types of OSS architectures: they can be common object request broker architectures (CORBA) or message-based architectures. This paper focuses on real-world implementation of OSS environments utilizing a message-based approach.

271 Testing

One of the most important test procedures in this area is based on Section 271 of the Telecommunications Act of 1996. Section 271 mandates rigorous and detailed validation tests on seven different processes: order management, inventory, trouble ticketing, network management, mediation, customer-relationship management (CRM), and billing.

The testing approach consists of three key areas: process definition, architecture, and implementation. Process definition, for which many tools are available, includes use cases and processes, activities, and sequence diagrams. Architecture encompasses integration events, rule-based logic, application logic, and object models. Implementation provides more information on the actual topography: client server, load balancing, monitoring, and system management.

The four regional Bell operating companies (RBOC) have shown particular interest in Section 271 because of their desire to enter the long-distance market. To initiate the process, the RBOC petitions the state commission and asks to have an independent test run to see how the company meets the 14-point checklist of Section 271. Reading the Telecommunications Act provides an entirely different perspective on what companies are supposed to do. In particular, the 14-point checklist mandates, among other requirements, an open and competitive environment; open and equal access to the network; back-office systems that are open, fair, and useable; and competitive pricing.

271 Testing Challenges

Section 271 testing involves an auditor role. Based on a statistical model, a test manager specifies the tests. Testing also involves a technology piece. Technology partners in such a test can create a pseudo–competitive local-exchange carrier (CLEC) with a fictitious name, a fictitious tax identification number, an operations center, and a marketing arm. The set of applications must meet the test criteria but may not need to be fully functional. Such arrangements can be made through the Federal Trade Commission (FTC), which supplies information and a special charter.

The fictitious company operates just as a real CLEC does, but with one key difference. A CLEC start-up must establish interconnection agreements and a gateway as quickly as possible to begin signing customers. In the pseudo–CLEC business, the testing company strictly follows the RBOC's published documentation. For example, if the steps are sequential, the pseudo–CLEC follows the steps exactly according to the sequence. If the step says that the RBOC will notify the CLEC, the test manager waits for the contact.

The pseudo–CLEC processes must include steps for sending information to and receiving information from the test manager. Another requirement is detailed logging of all interactions with the RBOC. Systems must be integrated across multiple companies.

271 Testing Implementation

The first implementation step is to start with the basic CLEC processes, such as order management and inventory, and to define additional steps for the exchange of information. Interconnection agreements have to deal not only with what products the pseudo–CLEC is going to sell but also with every product offered by the RBOC. Testing in this way provides detailed information about available services, profitability, and glitches in the process.

Twenty or 30 years ago, the standard timeframe for getting a service operational was between two and four weeks. Today, the timeframe is still the same. Because of complications in the back-end systems and across company process, new products can take even longer to rollout.

The real crux of the test is the logging system. The pseudo–CLEC must track how long each transaction takes. Part of this process involves spelling out duties, roles, and responsibilities explicitly. For example, the test process must define exactly what the call center is trying to do in order to identify problems with the technology. In many cases, the technology may not match the processes. Workarounds are common in the industry, but the questions to answer are these: How much time do the call-center workers spend in workarounds to execute a process? And how many errors are generated during this process? To rectify errors, the first step in the solution is to determine if personnel know about the process, if they are following the process, and if they are following it through to completion. If personnel are skipping steps, gaps in the process will inevitably result.

It is also necessary to establish procedures for a multicompany environment that involve real transaction screens and information exchange.

Telecom Processes

The integration of business processes has several different aspects: product, function, organization, and technology.

In terms of product, an integrated service manager (ISM) means many things to different people. For example, companies trying to write a business plan for a digital subscriber line (DSL)–ISM–integrated process generally do not look at it from a product base. This is a mistake, but it is driven by the nature of the business and by timing issues. Many architectures are available, but reality determines what the company must implement in terms of up-front costs and profitability.

In terms of function, a common practice is to establish an integrated call center to take care of Internet users and fold them into the same well-defined call processes.

In terms of organization, problems could arise from geography, power struggles, differences in tool sets, or any number of other sources.

In terms of technology, the principal issue is integrating broadband, voice, and Internet despite multiple mediation platforms and switches.

Order-Management Challenges

Process integration for order management presents several challenges. The first is order-type differences in which activities, such as customer-service requests and network-service requests, may be executed in different ways. By implementing a method for tracing through these specific scenarios, companies can determine if additional steps are necessary.

Validating the test when putting the process together is the key. After implementing the product-specific aspects, the timing of the information might be different depending on how the data values work in the scenario. Even though a process looks the same, it might not be the same.

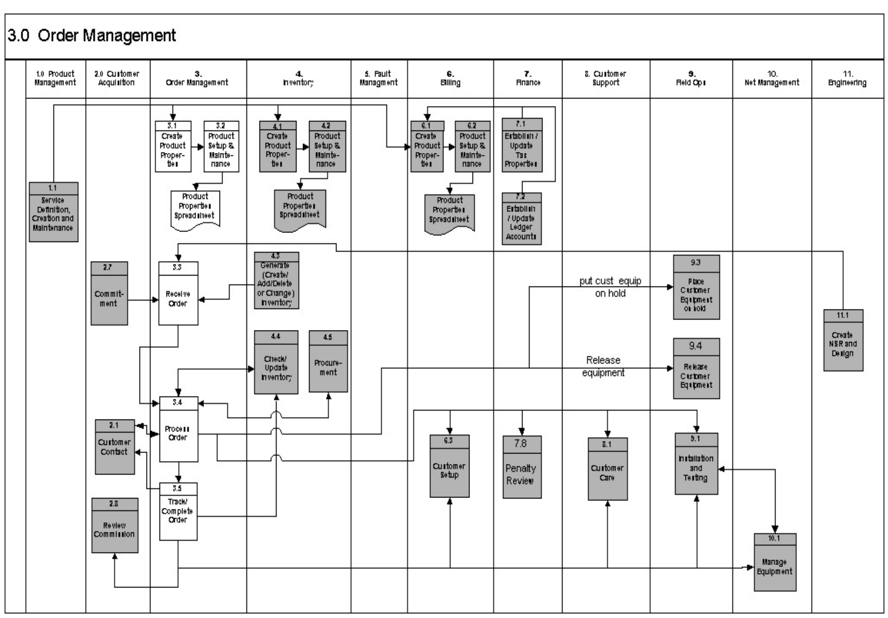
Process and Application Integration

Figure 1 shows the scenario tracing for Levels 1 and 2 of order management. It is important to look at how the applications apply to a process and determine whether or not to go business layer or application.

The issue is whether to "adopt or adapt." What is missing is the product-level information or the data aspects. The test-

FIGURE 1

Order Management



ing must include validation that will highlight differences between, for example, a customer-service request and a network-service request.

Figure 2 shows the scenario tracing for a network-service request, and *Figure 3* shows a similar diagram for adding an account. At this level of detail, companies can identify a number of problems: for instance, they can determine that the application does not meet the process, the data does not match the standard model, or the application programming interfaces (API) do not fit in the right place. Each application has its own implemented business process, so gap analysis must be performed between the business process and the application process.

Each application has its own data requirements and definitions. For data definitions, a popular solution is a common database. Implementation, however, may be precluded by costs. An alternative is data mapping between applications. Companies can develop an architecture or an implementa-

FIGURE 2

Receive Order (Network-Service Request)

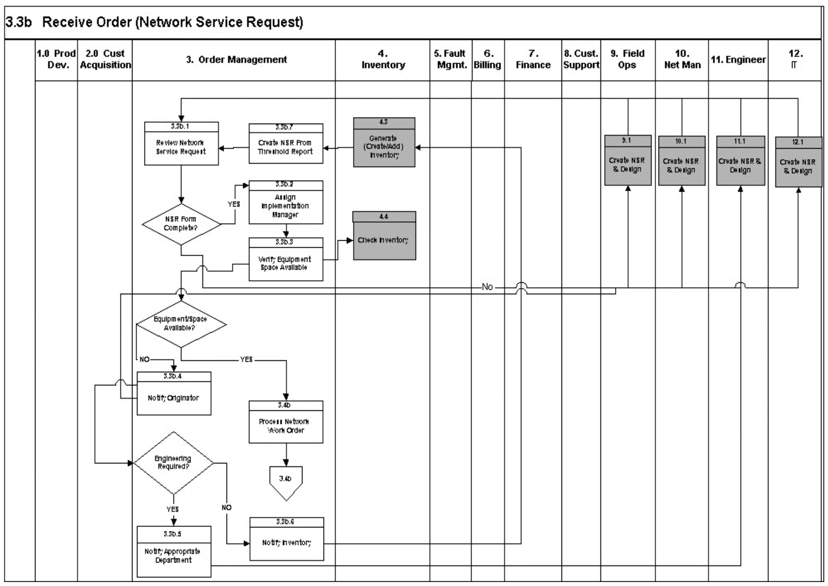


FIGURE 3

Add Account

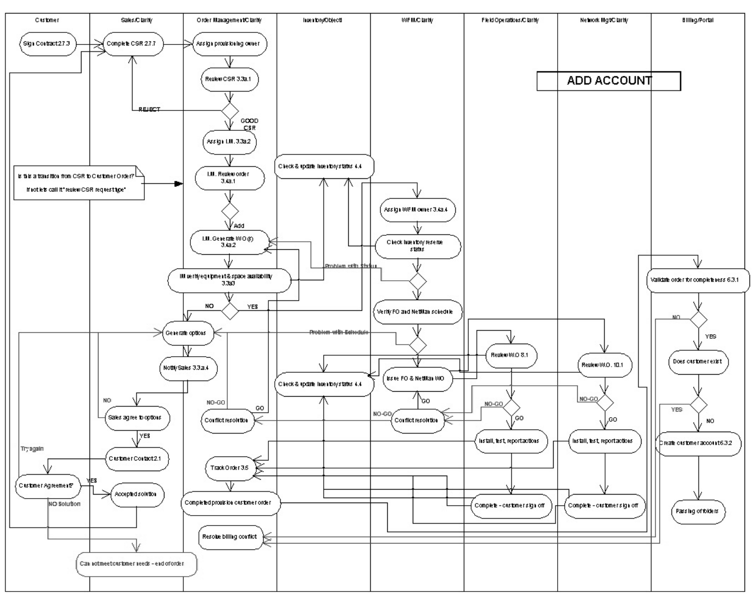

FIGURE 4

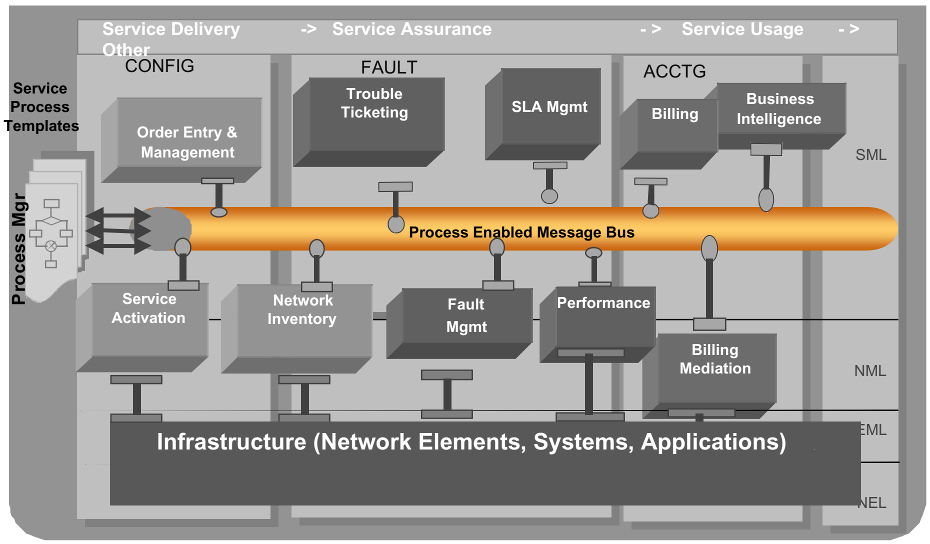
Integrated Service-Management Application Architecture



tion strategy that allows isolation to the data, first, and the capability of adding on, later. The product set is more important than the data model.

Integrated Service-Management Application Architecture

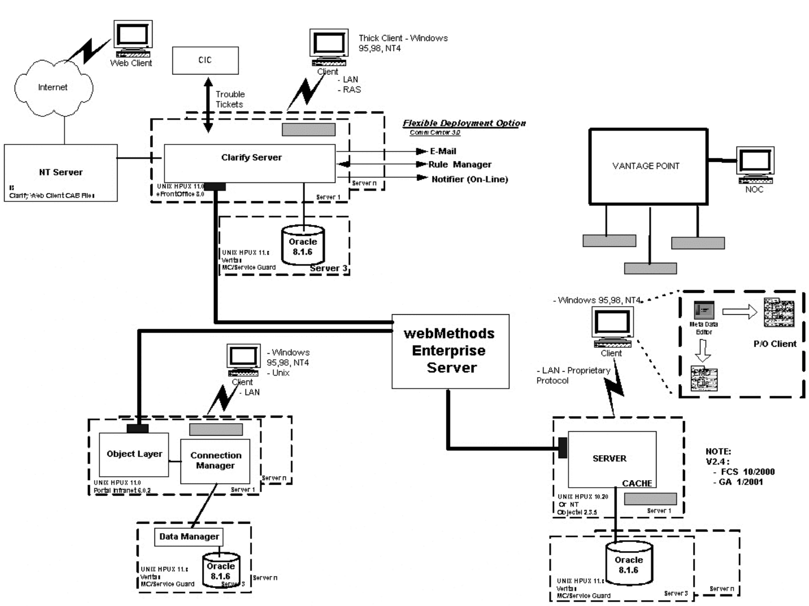
Standard architecture is common, but the issue is how to migrate to it. The solution is to start out slowly and choose a structure that will allow for growth (see *Figure 4*). Scalability is the most important factor to consider here, since new applications and processes will be a given. With the right tools in place, then, the company has a defensible baseline.

Environment Integration

Each application is normally implemented on its own configuration. The challenge is to architect an environment that supports an integrated messaging view of all applications. Each application also normally has its own file structure and database. The addition of a messaging layer means that an additional database must be synchronized and configured.

FIGURE 5

Environment Integration



With each application residing in its own environment, the challenge is to ensure that the messages will flow between different system environments, including logging, backups, and file structures. Messaging environments tend to have their own monitoring capabilities. The challenge is to include these tools on the network-management desktops.

From an environment standpoint, legacy systems ensure that companies will never shed their old baggage. There will always be some signaling system 7 (SS7) need, and there is also the issue of next-generation versions one, two, and so on. Once a customer is on a specific system, the company is tied to it for a minimum of five years. One way to structure the architecture, as shown in *Figure 5*, is to modularize it and conceptualize at it as a set of parts, instead of looking at it holistically as a large path called order management. The modular approach allows additions and changeouts to the architecture. In a migration strategy, the company can define a new bundle or packet, add it, and then test it. If it works in that specific area, it could be applied to another area, allowing the company to drop in a new application and phase out an older one.

What Are the Gains?

On the business side, this effort provides a clear definition of business processes and procedures that establishes a baseline and results in user acceptance and buy-in.

From the system standpoint, companies gain an understanding of the capabilities of purchased software, thereby helping to minimize custom code and gain the ability to combine bundled items in a flexible environment. The result is a migration strategy and a purchasing strategy with a measurable return on investment (ROI).

From an implementation and investment standpoint, companies gain the ability to manage change through a phase-in approach and to optimize resources.

Lessons Learned

Companies can benefit from five significant lessons resulting from Section 271 testing:

1. Customer involvement is important. Users are needed throughout the definition of the process.
2. A phase-in approach allows the project team to refine the approach and ensure customer acceptance.
3. The application and messaging teams need to be involved from the beginning.
4. A clearly defined approach ensures consistency, completeness, and understanding of the processes and system implementation.
5. The change-management approach must allow for each change to be evaluated and reviewed before implementation.

Complexity of New Network Architectures Creates SS7 Management Challenges

Kim Parker
Product Manager
Tekelec

Introduction

Network operators often lack sufficient information to effectively manage their signaling system 7 (SS7) networks. Their primary source of information comes from the network switch(es) and a variety of basic instruments. Unfortunately, the usual source of the missing information is subscribers complaining about network problems.

With the addition of emerging technologies, such as Internet protocol (IP) transport, the integration of multiple protocols in a single network, the rapidly changing and currently unstable nature of IP–based signaling, and the constant introduction of new telephony services for both wireline and wireless networksæwith the addition of all these, SS7 networks are becoming increasingly complex. In turn, these changes make managing SS7 networks much more complex. To minimize the impact of new architectures and services and to manage the growth of the network, operators need advanced network-monitoring and -maintenance systems that provide real-time information, a platform for troubleshooting, and an information "feed" for business applications.

Challenges of IP Signaling

In a converged network, operators are often "blind" to the transport of messages over IP. No equipment exists to manage high-level telecommunications signaling over IP networks. In a converged network, operators often are unable to detect faults in the services provided by IP–based transport protocols, such as the following:

- Transport adapter layer interface (TALI) and media device transport protocol (MDTP)
- IP device control protocols, such as media gateway control protocol (MGCP), session initiation protocol (SIP), and session description protocol (SDP)
- Interworking between SS7–based and IP–based signaling
- Gathering and consolidating traffic statistical data across both SS7– and IP–based networks

As a result, with no monitoring system for the IP links, or for times when two systems are employed (see *Figure 1*), an operator does not have a consolidated view of the calls crossing the network. For example, when troubleshooting a problem, a customer is not able to perform a call trace that captures the entire call. Instead, an SS7 monitoring system shows the portions of the call transported via SS7, and another system captures the messages transported over IP. Additionally, telecom service providers are challenged by the many different protocols at work in their networks. Invalid interworking between protocols and interworking failures between service providers are at the root of network problems.

Today, operators must troubleshoot network problems utilizing various protocol-specific tools. For example, when tracing a call that deals with interworking protocols, operators must employ a separate view specific to each protocol. In general, there is no way to consolidate the messages traversing the entire network. A mechanism is needed to allow operators to visually trace a call that traverses multiple protocols within a single view.

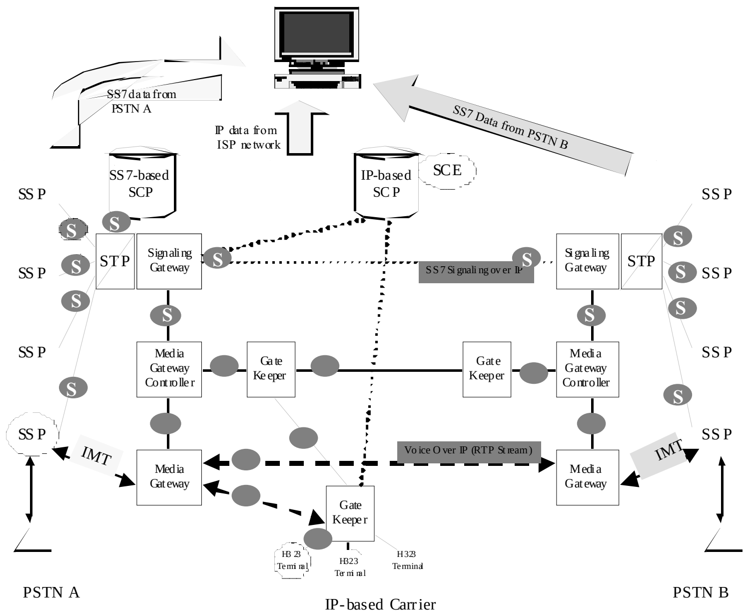
Finally, each new service results in modified protocols, the enhancement of software loads, and the deployment of new equipment into the network. Each introduction of software and hardware into the network opens the door for new problems. By being proactive and identifying problems before they occur, or upstream, operators can incorporate these new services by verifying and validating the pieces prior to full deployment. Therefore, operators do not have to rely on customers to be the "eyes" of the operator.

The Solution

The best way to ease the burdens faced by telcos is to provide a single monitoring system for the entirety of converged networks (see *Figure 2*). Such a solution enables wireline and wireless service providers to monitor, main-

FIGURE 1

IP–Based Carrier Network



tain, and ensure the reliability of innovative telecommunication products and services implemented across SS7–based public switched telephone networks (PSTN) and next-generation wireline and wireless networks.

Operators use the monitoring device to correct network-wide problems from a central location and monitor and trace calls end-to-end. It enables a number of applications, including those deployed for fraud detection, mass call detection, billing verification, and quality of service (QoS) measurements.

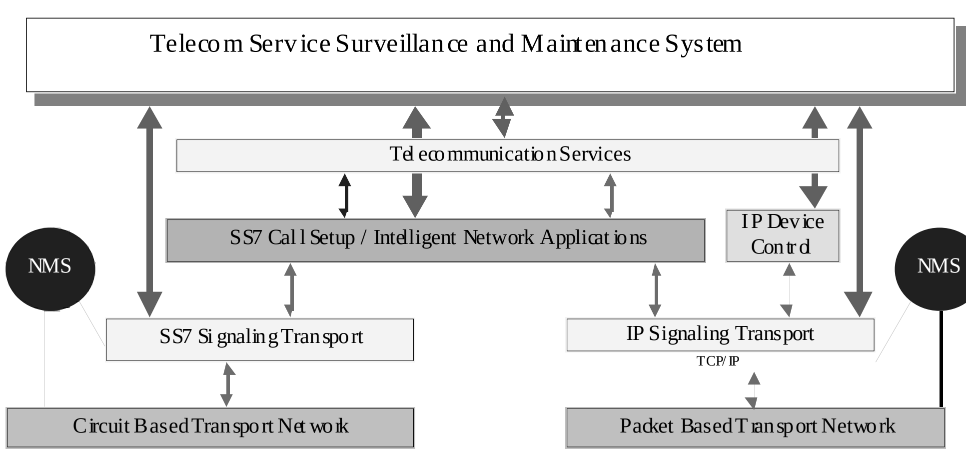
When looking for such a system, operators should consider a device that provides complete monitoring capabilities for converged networks. Such a device should have a central, unified system to gauge both high-speed and low-speed links to generate data.

Operator should also look for features that have the capability to do the following:

- Monitor SS7 signaling and other telecommunications-related protocols transported over SS7 and IP networks

FIGURE 2

Telecom Service Surveillance and Maintenance System



(A protocol-independent architecture allows providers to quickly adapt to new or modified IP–telephony signaling transport protocols.)
- Survey IP signaling transport protocols for faults and abnormalities
- Provide seamless protocol analysis across both SS7 and IP networks, assisting providers in maintaining and troubleshooting service-related problems.
- Perform proactive surveillance by troubleshooting problems and utilizing intrusive functionality across SS7 and IP networks
- Provide statistical traffic reporting for detailed traffic analysis across both SS7 and IP networks

In a perfect world, operators will be able to monitor, provide intrusive test generation, and complete protocol analysis, including filtering and call-trace capability. Additionally, a carrier would be able to gauge the performance of multiple protocols throughout its network, including TALI, MGCP, and SIP. Ideally, a single protocol analysis form allows the user to view messages and troubleshoot problems across the entire network, regardless of the interworking issues among various protocols. Real-time call-tracing capability allows the user to easily trace SS7 or personal communications services (PCS) call procedures. The user is able to trace calls involving multiple protocols, such as transactional capabilities application part (TCAP) interworking with integrated services digital network user part (ISUP), merely by providing the directory number of the call to be traced.

Looking Ahead

Future network operator developments include the incorporation of additional IP protocols, including stream control transmission protocol (SCTP), message transfer part (MTP)–2 user adaptation layer (M2UA), M3UA, MGCP, and SIP into networks. These protocols, like current IP and SS7 protocols, will require operators to dynamically shift their test and surveillance systems to meet these new challenges.

Increasingly, test and monitoring devices will rely on software platforms, which allow operators to purchase upgrades and add capabilities on an as-needed basis. In addition, current business applications, such as fraud detection and billing verification, are being expanded to incorporate data derived from emerging technologies and protocols. In today's quickly evolving networks, operators cannot afford to rely on subscribers to identify network problems. Via the deployment of a network-monitoring system that provides a consolidated view of a converged network, operators will be armed with the information they need to proactively manage their networks, services, and customer bases.

Non-Voice Network Management

Colin Pons

President

InJoy Communication BV

Abstract

The ever-increasing demand of new service offerings coupled with the ever-heightening cost-effectiveness programs result in an increased use of the installed intelligent network (IN). Cost-effectiveness often does not allow new service control points (SCPs) to be introduced. The result is that the operational risks are higher. These risks include not only failure, but also the size of the impact.

This paper discusses how congestion or overload conditions in the IN can be controlled. Several control methods are discussed, and a proof of the concept based on operational experience is presented. The objective of the presented concept is to assure stable performance of the network and a high quality of service (QoS).

Introduction

Like any other communications network, the IN is sized to carry the normal busy-hour traffic. A network such as this involves network elements (such as service switching points [SSPs], signal transfer points [STPs], and SCPs) and a communication interface (such as signaling system 7 [SS7]). At each of these four, abnormal conditions may occur that are not accounted for when designing the network. Or, it may occur for any reason that the number of queries is above the normal busy-hour traffic levels. For example, one can examine the SCP.

An SCP can handle only a finite number of queries (call attempts) from the network (SSPs). An IN should ideally be sized to allow the normal busy-hour traffic to be handled, taking into account at least a single network failure. If the number of queries exceeds the response capacity of an SCP, or a specific service on an SCP, the response either will be lost or will arrive too late to be handled by the SSP. This typically results in an error at the SSP network level and almost inevitably the calling-party redialing. This would cause a QoS degradation to be experienced by the customers.

Also, a SSP or a STP can handle only a limited number of queries. When the offered queries exceed this limit, it almost inevitably will cause calling-party redialing. These redial actions often worsen the congestion.

It is therefore necessary to implement sufficient measures to maintain a reliable service.

Intelligent Network Architecture

A typical IN may look like the one depictured in *Figure 1*.[1]

Each of the three nodes and the communication interface are shown in *Figure 1*. Typically, the SSP co-resides with the CCF on an exchange. This can be an exchange of any type. The STP can perform several roles. Among these are the traffic-load distribution, fall-over capabilities, and query routing (to the appropriate service).

The SS7 network provides for a standardized interface between these network functionalities. SS7 also provides the routing capabilities between nodes. Two types of routing are applicable within this network: routing on SSN, which uses the physical point code, or routing on GT, which uses the Global Title (a logical node identifier) for routing.

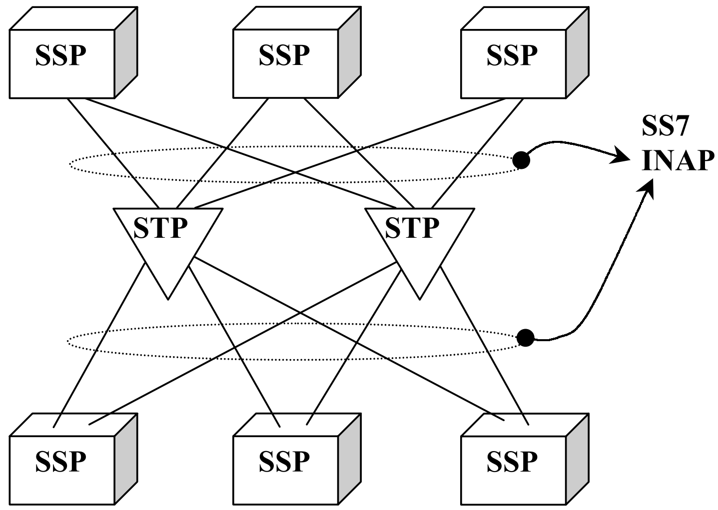
With respect to the SSF, losing responses from the SCP or responses from the SCP arriving too late is not an efficient way of handling an overload situation. An SSP will not release its resources until a timer used to protect against lost responses, known as T_{SSF}, has expired. The T_{SSF} timer is typically in the order of seconds, whereas the normal response time from the SCP is in the order of tens of milliseconds. Therefore, significant SSP resources can be wasted in the case of an SCP failing to respond. The outcome could be that the SSP will not have adequate resources to trigger an alternative SCP or, worse, may become overloaded and fail to handle other calls, whether IN or not. Similar concerns can be raised for the STP depending which functionality is used.

The SS7 intelligent network application part (INAP) stack utilizes the signaling connection control part (SCCP) layer for routing messages across this network. The SS7 links and SCCP routing tables are ideally suited for normal busy-hour traffic.

An SCP (or specific service) is considered overloaded when it cannot respond to a service query within a reasonable time (typically less than 100 ms). An SCP may become overloaded for a variety of reasons. For instance, if an SCP, or specific IN service, cannot process queries at a rate faster than they are being sent, then the SCP, or the specific service, is considered overloaded.

In this network model, a number of bottlenecks can be identified:

FIGURE 1



- Software resource shortage due to a sudden increase in queries possibly leading to one overloaded service affecting another and/or SSPs becoming overloaded
- An increase in central processing unit (CPU) load due to a concentration of events or a rapid build up of queries; SCP becoming unstable, possibly leading to failure
- A shortage in transmission capacity; the SS7 network becoming congested
- Routing errors, which are man-made errors

To solve the above, the following should be done:

- A reduction of the number of queries should be effectuated as close as possible to the source. This would help to eliminate unnecessary resource usage, allowing more successful calls to proceed.
- The effect of a disruption or a sudden increase in the number of queries for a service should be confined. The effect should be prevented from interfering with other elements of the network or other services.
- Any abnormal trend in query volume should be detected as soon as possible to allow early intervention.
- Better network resource usage efficiency.

Current Measures

IN Call-Gap Operation

IN call gapping is a mechanism to prevent SCPs (or specific IN services) from becoming overloaded. When IN call gapping is active, excessive queries, which would normally be sent from the SSP to the SCP, are throttled at the SSP by enforcing a minimum time interval between queries being passed to the SCP for processing, thus allowing the SCPs to process queries at its maximum supported rate. Calls gapped at the SSP[2] will receive a defined treatment known as the gapTreatment—e.g., an announcement, or more likely a tone, is played to the calling party. The SCP tells the SSP what to gap for in the gapCriteria (see ITU Recommendations Q.120x for more details).

IN call gapping is *not* the same as public switched telephone network (PSTN) call gapping and does not prevent SSPs from becoming overloaded. It is purely an SCP and SCP service protection mechanism.

IN call gapping can be utilized in two ways: manual call gapping and automatic call gapping.

Manual Call Gapping

This form of call gapping is instigated by operational personnel following understood procedures for a number of *anticipated* events. For example, the traffic-management group may anticipate an excessive call volume due to television quiz shows or special promotions taking place for particular service numbers. In this case, manual call gapping is set up ahead of the event to prevent SCP overload. Manual call gapping may also be established to protect SCPs during planned network outages or upgrades, when the overall available IN capacity may be reduced.

Automatic Call Gapping

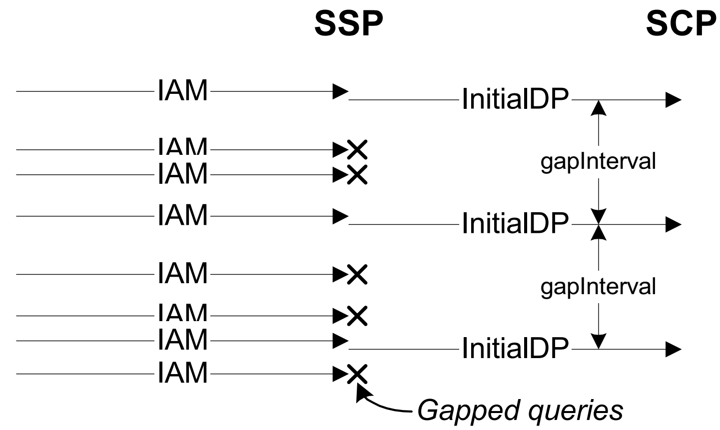
This form of call gapping is instigated automatically from the SCP network in abnormal or unpredicted situations. Once an automatic call gapping event has occurred, the cause of the overload should be investigated and manual call gapping procedures put in place if required. Calls gapped at the SSP will receive a defined treatment—the gapTreatment.

Notice in *Figure 2* that immediately after the overload condition subsides (i.e. the number of ISUP IAMs drops to a normal level) the call gapping is still active. Therefore if any calls arrive within the gapInterval they will still be gapped. After the duration time has expired the SSP removes the call gap and no further calls will be gapped.

SS7 Fail-Over Capabilities

It is assumed that the reader is sufficiently aware of the capabilities of SS7. SS7 allows a message transfer part (MTP)–level routing of messages over several routes and

FIGURE 2



link sets in a redundancy scheme. If one route or a link set fails or is congested, another route could be selected. At the SCCP level, a similar redundancy scheme is implemented. In the case of routing on GT, a secondary or back-up address can be used for redundancy.[3] At the MTP level or the SCCP level, there are no dynamic routing capabilities. The settings are operator defined and can only be changed by an operator or from outside the SS7 network. SS7 provides very reliable communication but is limited in network resource utilization.

Congestion Control

The IN consists of the SSP, STP, and SCP. Interestingly, the SSP and the STP are often special-purpose computers and telephony exchanges, whereas the SCP could also be implemented on a general-purpose computer. Actually, virtually all newly implemented INs use general-purpose computers for the SCP. Furthermore, it is important to notice that there are far more SSPs deployed than SCPs. In fact, at the SCP, an accumulation of queries from a number of SSPs takes place, and SCPs are more likely to first experience abnormal query volumes than any other element in the IN. Given these reasons, it is appropriate to take the SCP as a target node.

Detecting an Overload Situation

The SCP could be seen as a processing system that is built up out of a buffer for storage of queries that are awaiting processing, a mechanism for processing these queries (SLPI), and a CPU for running the service logic (SLPI) (see *Figure 3*). The number of messages (MSUs) waiting in the service logic program instance (SLPI) input and output queues can be used to determine if a service is overloaded or not. In practical terms, only the contents of the input queue need to be considered.

The queues or buffers reflect all buffers present in the system, such as the input/output (IO) buffer (SS7 link), the dispatcher buffer, the database queue, etc. The input queue reflects the number of queries waiting to be processed by a SLPI. The number of pending items in the queue will vary depending upon how quickly the SLPI can service the requests. If the rate of queries is greater than the rate of service by the SLPI, then the number of pending queries will increase. The SLPI will request the CPU for a time slice each time it wants to process a query.

Using queue size to determine overload conditions means that virtually all other external factors are automatically taken in to account. If the number of call attempts is normal but an abnormal event takes place on the SCP that reduces the amount of CPU available for a service, then the number of pending queries in the queue will grow.

Controlling an Overload Situation

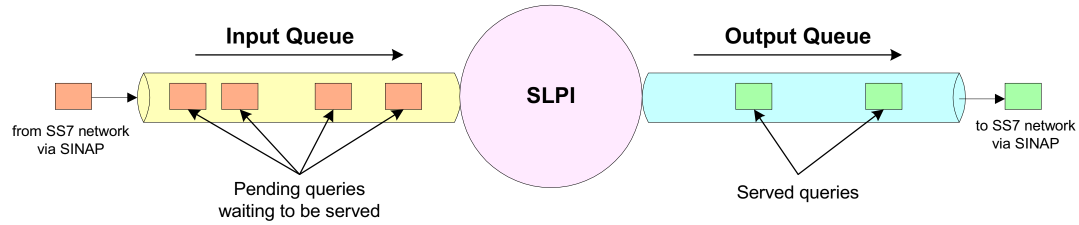
As mentioned earlier, traffic congestion and network congestion can occur in the following instances:

- A software resource shortage due to a sudden increase in queries
- An increase in CPU load due to a concentration of events or a rapidly built up of queries
- A shortage in transmission capacity, eventually reflected also by a software resource shortage

As discussed in the preceding section, a software resource shortage is reflected by the input and output queue occupancy. Either the SLPI cannot handle all incoming requests or the SCP cannot transmit all messages. The latter reflects a shortage in transmission capacity in the downlink to the SSP. There are several reasons that contribute to the ability of a SLPI to service the outstanding requests. The main factor, however, is the number of threads that can be supported and access to the CPU. This requires monitoring of the queues and control of the flow of queries.

CPU occupancy increase causes processing delays. This will harm SLPIs trying to gain access to the CPU. Eventually, CPU overload conditions result in an increase in uncompleted calls. To prevent an unhealthy concentration of queries, it is necessary to determine the maximum number of queries that can be accepted based on CPU load and where the SCP remains stable. This requires control of the number of queries toward a SCP.

FIGURE 3



From the conclusions for both reasons for congestion, it can be concluded that the flow of queries needs to be controlled. IN call gapping limits the number of queries and is suitable for preventing software resource shortages that cause congestion of the network. But IN call gapping limits the number of queries from an SSP toward an SCP. The problem with this is that other SCPs may well have the available software resources to satisfy the offered load from that SSP. IN call gapping is not suitable for limiting the *total* number of queries from multiple SSPs toward an individual SCP.

The IN call-gap operation needs to be backed up by a flow control mechanism.

Flow Control

The flow control manages the number of queries and their routing through the network. In contrast, the IN call-gap operation only limits the rate with which an SSP sends queries to an SCP. The flow control would allow for a better utilization of network resources and higher successful completion rates for calls.

Criteria for Control

Tests and network statistics have shown that the queue size starts to increase as the CPU load reaches 75 percent to 90 percent, depending on the circumstances such as high provisioning rate. A general-purpose computer is best operated not higher than 85 percent to allow necessary system processes to have access to the CPU. To allow a margin for handling an increase in queries (including redundancy) as well as provisioning processes and system management processes to take place, it is recommended that an SCP's CPU load is no more than 60 percent in normal busy-hour operation. Therefore, the queue size has a direct relationship with CPU occupancy.

In the IN, this means monitoring and use for flow control of the following:

- The offered queries per SSP
- The received queries per SCP (and if possible per service or SLPI)
- The CPU load
- The SS7 link occupancy
- If possible, the queue length of each SLPI at each SCP (system dependant)

Implementation

Currently, most networks already have network-management systems that collect the aforementioned data. If this is not already done, this information may be obtained from the network elements themselves. It is important to notice that the statistics should be readily available. A time lapse of 15 minutes would prove unsatisfactory in real life. Events that reshape traffic loads and possibly effect network QoS can take just a few minutes or even less. It is practical to have new statistics available once a minute. This would satisfy the need to have real-time data available and not to stress the network elements with obtaining statistics.

One other important issue to notice is that the flow control should be done outside any SSP, SCP, or STP node with the network. Each of them might fail, possibly impacting the flow control adversely. The flow control should be implemented at network-management layer as a separate system.

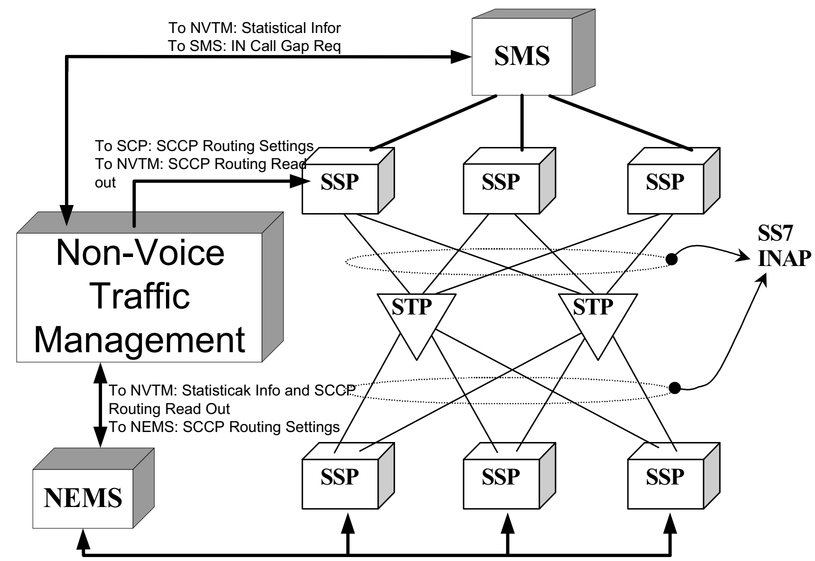
The flow-control management system could possibly interface with the network through the SCP or the STP, depending the exact network configuration. This interface would allow the initiation of IN call-gap operations. Another type of interface is necessary to manipulate SCCP routing tables at SSP, STP, and SCP.

Control Application

In a first implementation, the non-voice traffic-management system (see *Figure 4*) comprises two parts: one part for obtaining all statistical and SCCP routing information and sending SCCP routing settings and another for simulation. In the simulation, the effect of failing SS7 links, STPs, and SCPs can be examined. The simulation results can than be used for effective network control. The system is fed with information from the SCP (via the SMS) and from a link-monitoring system. The link-monitoring system allows the determination of the sending SSP's identity. The routing tables present in the different nodes are manually fed to the system. The results so far indicate that a good prediction of network behaviour can be made when the different elements fail. There is also a clear indication of what can be done to minimize the effect of multiple failures in the network, such as the initiation of an IN call-gap operation or changes to the SCCP routing tables. The first implementation is to serve as a proof of concept. The objective is to have the real-time part determine critical situations and to have it calculate the appropriate actions.

There is some issue with dynamically changing the SCCP routing tables. From an operator point of view, the operator is no longer aware of the actual settings each time. Furthermore, dynamically changing routing tables may have an adverse effect. We have avoided that by properly select-

FIGURE 4



ing the algorithm and by implementing thresholds and limiting the number routing table changes per time period.

Conclusions

This paper has defined the most prevailing causes of congestion and QoS deterioration in an IN. The uses of IN call gapping and the flow-control concept, and their implementation have been described. Flow control allows for a better network utilization and better network control in cases of failures. In the future, it will be necessary to develop an automated non-voice traffic-management system. The algorithms are available, but they need to be implemented and fine-tuned to provide the desired results.

The ever-increasing demand of new service offerings and the cost-effectiveness programs in place at virtually all telecom operators require that current investments be better utilized. This is only possible if the appropriate measures are taken to prevent a failure from having a detrimental impact on the experienced service offering. We believe that a non-voice traffic-management system plays a key part in ensuring QoS despite increased demands on the IN.

Notes

1. For reasons of simplicity, elements such as special resource functions (SRFs) are omitted. However, this discussion also applies to them, since the same issues are involved. The conclusions can also be applied, therefore, to IN nodes such as the SRF.
2. Not all SSPs interpret the IN call-gap operation, and the *most specific match* rules, in the same manner. Therefore, it is important to understand the call-gapping behavior of the specific SSP before gapCriteria can be applied.
3. If the sending node is aware that the next node is the end node (SEP), the recommendation is to use routing on SSN. In this case, the end node's point code is used to address it. There is no SCCP back-up route applicable in this scenario (although one could be provided through the MTP level). If the sending node is unaware of the status of the next node, or if it is aware that the next node is not the end point, the recommendation is to use routing on GT.

OSS Flexibility and Interoperability

Richard G. Ramos
B/OSS Solution Architect
EDS

Overview

Few telecommunications and Internet service providers (ISPs) are immune to the unrelenting pressure to improve their earnings performance, leverage their existing network infrastructure, improve customer satisfaction, and bring new services to market more quickly. They endure these pressures—all while striving to reduce their capital and operating costs in a chaotic, unpredictable market.

To meet these challenges, next-generation service providers are realizing great value by deploying a new breed of operations support systems (OSSs) based on service-enabling platforms (SEPs).

SEPs are Web-based middle-tier software and hardware technologies that rapidly deploy and change new service models. They instantly deliver dynamic, personalized bundles of enhanced-quality voice, video, data, and content services over any browser-based appliance. SEPs can provide unprecedented levels of scalability, flexibility, and repeatability by applying e-business and Internet technology to solve some long-standing problems that plague next-generation service delivery.

This white paper examines the application of Internet infrastructure technology to OSS deployment and addresses two of the most expensive and painful problems with next-generation OSS implementation: multivendor interoperability and flexibility.

How the Internet Has Transformed OSS

Before the Internet, OSSs managed circuit-switched voice services and their networks in a tightly regulated, anti-competitive environment. The resulting systems became increasingly monolithic environments in functional silos of the incumbent carriers.

In the pre-Internet days, each department—whether customer service, sales, billing, provisioning, or order entry—defined its OSSs according to its organization and within the scope of specific services. In effect, wireless, high-speed data, voice, business, and consumer services all resided within different organizations. Each service was often its own profit-and-loss center with its own information technology (IT) infrastructure and budget. OSSs evolved as point solutions based on fixed, controllable, predictable business models.

The Internet and e-business revolution, however, has shattered any hope of predictable business models. The new digital economy demands telecom e-business services that require collaboration between trading partners (such as application service providers [ASPs] and content providers) to deliver the next-generation services that their customers need.

Service providers competing in the digital economy must endure chaos, uncertainty, intense competition, and rapidly evolving, diverse technology options. Two of the most expensive and painful problems facing service providers' OSSs are multivendor interoperability issues and system flexibility. In fact, these problems are gateway factors in the successful deployment of next-generation services.

The Importance of Interoperability

Achieving interoperability, or system integration of multiple OSS components, is a problem rooted in the evolutionary nature of OSS technology. The functional silos have often made it necessary to integrate 10 or more systems for the basis-fulfillment, assurance, and billing functions. The following are some of the problems inherent in achieving interoperability:

- ***Integration:*** Costs are typically $1million x (N x [N-1]), where N = the number of systems that must be integrated[1]. This expense can result in first-time OSS project implementation costs as much as three to five times the system's software license cost and annual operating costs as high as the software license costs.
- ***Implementation:*** Time frames may stretch into years. Implementing a provisioning system in a legacy environment today means that the service provider must migrate product catalogues and customer databases to a new environment—and in some cases several environments. This data migration often adds many months to an integration project.
- ***Order-to-Fulfillment Completion Rates:*** Order completion rates are fundamental to the efficiency of a service provider's operations. Today's service providers are doing well if three out of 10 orders make it successfully to completion. Effectively coordinating an order across multiple systems—such as order entry, order management, billing, provisioning, activation, inventory, and sales-force automation—depends on how well these functions are integrated. Any compro-

mise affects the time and cost of successfully fulfilling an order.
- ***Data Synchronization and Maintenance:*** The more systems that must be integrated, the greater the likelihood that multiple databases must be maintained. If the systems require redundancy, OSS operating costs increase significantly. Add these maintenance costs with software revisions of multiple systems and upgrades, and the total cost of OSS ownership increases to 75 percent of the initial capital expense (CAPEX).
- ***Service Fault Root-Cause Determination:*** Correlating a service or network fault to an affected customer—and then calculating and applying appropriate credits to that account (based on a service-level agreement [SLA])—is a primary objective of service-assurance flow-through. Sixty percent of all time spent dealing with any given network fault is spent pinpointing its root cause. That means 60 percent of the network's fault-related downtime can be attributed to root-cause analysis not happening fast enough. Faster, more automated root-cause analysis can reduce network downtime by half—a significant competitive advantage in a market that puts a premium on SLA guarantees.[2]
- ***Comprehensive Customer View:*** A comprehensive customer view requires real-time access and synthesis of all pertinent customer information, regardless of where it resides. The degree to which all service-provider entities have a consistent, thorough, and current view of the customer and the resources required to serve that customer determines the level of customer service and satisfaction that providers can deliver. By taking a 360-degree view of customers, service providers can market to them on a one-to-one basis, strengthening the relationships, improving revenues per customer, responding to their problems satisfactorily and, ultimately, ensuring their long-term loyalty.

Many of these interoperability problems have their genesis in the attitude OSS vendors take toward interoperability, which is often regarded as someone else's problem: "We provide an application programming interface (API) the customer integrates to, and it is their problem to make sure it works."

Today, most service providers still choose to procure tactical point solution OSSs according to function and price, and at the expense of the entire integrated solution. Little wonder that few OSS implementations demonstrate the value expected of them at the outset. Clearly, the point solution versus an entire integrated approach has not served the industry well.

Fortunately, OSS knowledge is growing. Service providers now have the tools to understand and measure the impact of interoperability problems and to transform them into opportunities such as flexibility.

The Importance of Operational Flexibility

Flexibility benefits the bottom line by increasing customer loyalty and reducing operating costs, total cost of ownership (TCO), and time to profitability for new services. Flexibility is vital to a just-in-time service provider, particularly one in which the OSS enables rather than impedes the business. In the chaotic, unpredictable environment of a collaborative digital economy, the next "killer app" is unknown, but service providers who adjust rapidly when they see the killer model starting to emerge will be the ones who rapidly gain market-share.

Flexibility problems not only increase operating costs related to system changes but also bottleneck time to market for new services. These factors increase lost-opportunity costs and frustrate IT managers in their efforts to more effectively serve the customer.

To improve earnings performance, next-generation service providers must increasingly and continuously differentiate themselves by doing the following:

- Offering premium, dynamic, personalized bundles of voice, video, applications, and content services
- Transacting over the Web (configured, procured, paid, activated, supported, and assured)
- Deploying over any type of infrastructure (circuit- or packet-switch, optical, wireless, cable, satellite, or copper)
- Functioning across a complex value chain
- Ensuring five-nine (99.999 percent) reliability and quality just as traditional voice services do

Services that differentiate one company from another include secure, guaranteed quality of service (QoS) virtual private networks (VPNs) for enterprises, on-line gaming, instant messaging (IM), and streaming video/audio for consumers.

Because the benefits are often difficult to measure and quantify, they tend *not* to be used as the primary purchase criteria for an OSS solution. New economic models, however, have begun to reflect these benefits in faster time to profitability, accelerated earnings, higher revenues per customer, and reduced customer churn. It is vital that service providers consider the importance of flexibility in their OSS evaluations.

Consolidation Makes Interoperability and Flexibility More Critical

Interoperability and flexibility will become even more vital in the coming wave of consolidation among telecommunications and ISPs. Carriers looking to offer new services or enter new markets are opting to merge, acquire, or partner rather than grow organically. Such options may speed market entry, but they wreak havoc on business support systems (BSSs) and OSSs, and on the ability to adapt and change in a chaotic world. Network integration is difficult enough with an array of devices such as 4ESS, 5ESS, optical, edge/core routers, gateways, softswitch and media servers. Further integration at the service and business-systems layer, including multiple billing systems, order management, provisioning, activation and assurance—and all for different services and physical networks—magnifies the complexity. One global service provider that followed this integration strategy now faces more than 50 different billing systems alone!

Internet Technology Applied to OSS

The Internet and e-business revolution has spawned a new generation of enterprise operations technology. Innovations such as enterprise application integration (EAI) middleware, application-server technology, Java, extensible markup language (XML), and a host of other tools offer a new alternative to OSS implementation and help next-generation service providers meet the demands of their business and consumer customers.

Web server, J2EE, Java, XML, enterprise workflow, and rules-based environments as the building blocks of e-business are ideal platforms for OSSs in the collaborative digital economy. BEA, IBM, HP, iPlanet, Oracle, Sybase, and Fujitsu have each introduced their own version of these platforms, and industry experts already regard these platforms as revolutionizing enterprise computing. When these proprietary platforms are applied to OSS implementation, however, their effect is *transformational* and *disruptive*.

A new breed of OSS platforms applies these e-business components to solving the next-generation OSS challenges of zero-touch, end-to-end, flow-through provisioning; single-point-of-entry; Web-based self-care; guaranteed QoS; value-based pricing; and dynamic, personalized bundles of voice, video, applications, and content services. These new OSS platforms meet the demands of today's services and, more important, are flexible enough to address services yet undefined. We call these service-enabling platforms.

SEPs apply the TeleManagement Forum's e-business Telecom Operations Map (eTOM model) to address the business issues facing next-generation service providers. These platforms couple the network and service (the operation) with the business layer (the customer) by correlating customer-affecting issues with network events.

SEPs are designed with service order-to-fulfillment at their core. Generic business processes, rules, and workflow templates for specific types of providers are available out of the box to dramatically speed implementation. Workflow or rules can be added or modified according to specific business requirements, which speeds implementation and reduces recurring and non-recurring costs.

More important, SEPs shorten the service order-to-fulfillment lifecycle by enabling the interoperability of all customer-service resources to a specific customer's order request. In the telecommunications industry, fulfillment response time and the market demand for products correlate directly. The faster you can activate customers, the higher the service volume per customer.

Another subtle but important benefit of SEPs is their ability to provide accurate enterprise health checks through a business-intelligence or enterprise-analytical application. The rich information these platforms provide allows managers to examine all levels of the enterprise and understand root causes of service and performance problems, such as customer dissatisfaction and negative earnings. This deep, timely information speeds remedial and proactive measures to improve enterprise performance and customer satisfaction.

The Components of Service-Enabling Platforms

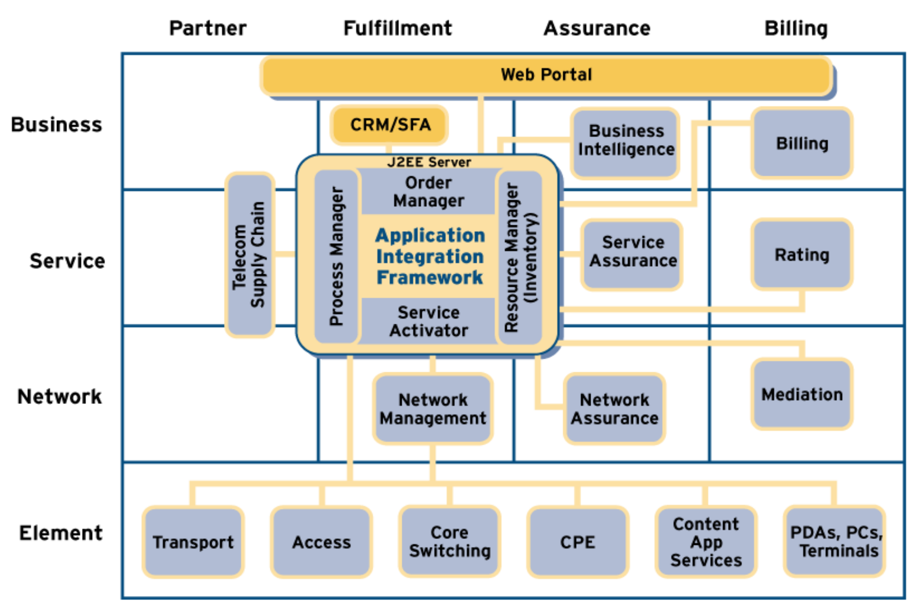
SEPs take an enterprise-wide approach to solving the OSS flexibility and interoperability problems plaguing the industry. A SEP involves the following e-business platform components and their relationships (see *Figure 1*).

Enterprise-Wide Process Automation

Enterprise-wide process automation allows interoperability between front- and back-office applications at multiple decision levels. It also instills the ability to instantly modify

FIGURE 1

Enterprise-Wide Automated Processes



workflow and business rules at the enterprise level, which is vital for rapid response to market and business changes. Enterprise-wide process automation requires that all applications and data be controlled directly by the business rules and workflow engine (process manager). Applying and enforcing rules and workflow to enterprise business processes can reliably invoke other activities—such as automatically sending confirmation e-mails to customers, notifying account managers to contact customers, and so on—that can ensure consistent, superior service quality, fewer operational errors, and enterprise-wide control across a broad organization and supply chain.

Application Integration Framework

The application integration framework accepts data from legacy or other OSS applications in native format. By accepting data in native format using plug-in adapters developed in XML, Java, or Corba, massive data migration is not necessary before the SEP can deliver service. The plug-ins are used only to expose the resource object to workflow and contain no embedded logic. The result: significant reduction in the time required for integration with proprietary application programming interfaces (APIs). Removing data migration from a legacy OSS interoperability project reduces implementation time frames by months.

J2EE Application Servers

J2EE application servers handle many of the functions that were traditionally coded in the OSS application's proprietary framework. They also handle the functions that were managed using traditional message brokers. Load balancing, persistence, state machine, directory and security services, messaging, transactions, and database access are out-of-the-box J2EE services. J2EE application servers support XML, Java, extensible server page (XSP), extensible stylesheet language transformation (XSLT), and Enterprise Java Bean (EJB). These J2EE servers, in combination with the supported applications, simplify OSS development and integration. While traditional OSS vendors have developed such functions internally, leaving the customer with the integration challenge, J2EE application servers form the core technology upon which the next-generation OSS can be built.

Document Object Model

The document object model (DOM) is an EJB supported in the J2EE application server. The DOM dynamically transforms data into a format that can be used to synchronize disparate data sources in a complex OSS environment. Data synchronization is vital for enterprises with multiple OSSs that handle overlapping functions such as billing. The DOM makes dynamic data views possible by transforming data from disparate OSSs and using XSLT and hypertext markup language (HTML) to present a common look and feel to users.

Web-Based versus Web-Enabled

Next-generation OSSs developed with J2EE application servers and Web servers provide an out-of-the-box interface for accessing data from a variety of appliances. The devices merely need connectivity and browser capability. All users receive the same graphical user interface (GUI), regardless of the device.

Core OSS Components (Order Management, Service Inventory, and Service Activation)

Traditional OSS implementations integrate disparate service-fulfillment components such as order management,

FIGURE 2

Service-Enabling Platform Implementation Methodology Comparison

Conventional OSS Implementation Model	*Service-Enabling Platform Implementation Model*
System design 80% completed up front	System design 20% completed up front
Heavy up-front business process engineering	• Out-of-the-box embedded business processes • Iterative process engineering and refinement
Heavy front-end requirements analysis process	Rapid prototyping via multiple configuration levels: o Business processes o Inventory object modeling o Presentation layer o API plug-ins
Best-effort (no guarantee) integration to multiple APIs of adjunct systems	Well-understood integration framework that ensures end-to-end business performance is not compromised through integration
Expensive change-management process for specification changes	Changes expected in the implementation process

service provisioning, inventory management, and service activation. The decoupling of these core components is a significant cause of OSS integration problems. SEPs allow for a tighter coupling of these functions using enterprise-level business rules and workflow. In comparison to traditional approaches, SEPs turn issues of multiple product catalogue aggregation, data migration, and application interoperability into minor inconveniences.

Implementing Service-Enabling Platforms

As is true with all enterprise IT, achieving successful results by adopting SEPs is as much a function of their implementation as of technology itself. In this new economy, OSSs can no longer be designed or implemented using traditional best practices, which assume a stable service model. Service models can change overnight, and even long-term models are difficult to predict[3]. OSSs have to keep up with the business, and keeping up requires methodologies that facilitate rather than impede implementation and that minimize one-off customization. To reap the full benefits of easy interoperability and rapid flexibility, SEPs require new implementation models. *Figure 2* compares these new methods with conventional ones.

A Look at the EDS B/OSS Solution

EDS' BSS/OSS (B/OSS) Application Interoperability Framework (AIF) is a Web-based OSS that utilizes a SEP. EDS, in conjunction with several solution partners, has developed a fully interoperable Web-based OSS for integrated communications providers (ICPs). The B/OSS is a highly scalable and robust OSS solution that EDS provides as a hosted service, charging clients on a pay-as-you-grow model. The core B/OSS modules are Order Management, Service Inventory, and Service Activation. These modules integrate with the J2EE application server through the AIF. Application interoperability is choreographed by the Process Manager (business rules and workflow engine). EDS worked with solution partner—Digital Fairway—to create Process Manager templates that decrease time and expense for implementation.

Conclusion

Next-generation service providers rely on OSS vendor support to meet the changing business climate demanded by our collaborative digital economy. As deregulation and competition continue to erode transport prices, providers must rely on value-added services, collaborative trading partners, QoS, speed to market for new services, and a quality customer experience as market differentiators.

SEPs at the core of providers' OSSs will result in significantly improved earnings performance by reducing integration costs, speeding new service time to market, improving customer satisfaction and loyalty, and increasing revenue per customer.

Introduction

Rapid proliferation of networking technologies, ubiquitous computing nodes, dispersed storage services, and advances in markup languages are contributing to the transformation of conventional enterprises into digital enterprises. These digital enterprises should support high availability, integrity, and confidentiality of their digital assets. As this transformation continues, protecting the digital assets of an enterprise from compromising external/internal attacks and ensuring continued operation in the presence of partial degradation of the system assume paramount importance. While a networked system is inherently more capable of continued operation and graceful degradation in the presence of faults than a centralized system, it is also more vulnerable to malicious attacks, since there are many more points of entry. Furthermore, the inherent distributed nature of large-scale public networks such as the Internet prohibits any central enforcement of any single security policy. However, any attack on the digital assets of an enterprise results in a disruption of services within as well as outside the enterprise, resulting in a significant loss in productivity and revenue. A designer of a digital enterprise system is faced with balancing these countervailing forces.

What Is a Survivable System?

We begin by observing that a networked digital enterprise system exists in a hostile environment where every transaction is presumed to be "suspect," whether originated internally or externally. A system may be considered to be survivable if it can continue to function as defined in the presence of malicious attacks, failures, and accidents by incorporating redundancy, recoverability, and intelligent management of transactions. In other words, a survivable system guarantees that the digital assets are highly available and highly secure, maintains integrity, and ensures system confidentiality in the face of malicious attacks. In the remainder of this paper, we briefly describe a number of design and deployment imperatives for survivable networked systems:

1. Redundancy
2. Recoverability
3. Quarantined Transaction Execution
4. Transactions and User Profiling
5. Virtual Node Isolation
6. Audit Nodes
7. Dual-Track Execution
8. Predictive Models
9. Signature Matching
10. Ephemeral Entry Nodes

A brief description of each of these design imperatives follows.

Redundancy

This is one of the foundations of reliable systems. Traditional engineering systems incorporate more than one component or subsystem for each function to deal with failures. They are active only in tandem—not simultaneously. However, networked digital systems must have redundant subsystems that are simultaneously active. These subsystems must be not only physically apart, but also designed in such a way that all of them are not susceptible to the same type of attacks. Examples of redundant technologies in an enterprise include the following:

- *Redundant Array of Independent Disks (RAID) Arrays:* These can support mirrored data and also have the ability to reconstruct data that is lost due to failed disks (RAID level 5).
- *Web Farms and Clustered Computing:* In most large organizations, there are Web server farms for serving high-volume Web transactions. Usually the server farm consists of many servers performing the same function managed through a load balancer. Cluster computers such as Beowulf Clusters consist of clusters of commodity processors connected by commodity networks to perform a complex task. These clusters can also be used as an enabling technology for survivable systems.
- *Clustered File Systems:* These provide applications with a unified view of a single system even though the actual data and the metadata are distributed across multiple nodes in a cluster. An example of a clustered file system is the Petal file system from Compaq Research.

Recoverability

In a digital information system, each transaction alters an arbitrary number of data objects. By the time a "rogue transaction" is discovered, it may have already altered a number of data objects that may be distributed across the enterprise. To ensure system integrity, the design must incorporate techniques for undoing all the "suspect" transactions and also establish a checkpoint from which the system can move forward with the assurance of system integrity. Some technologies that may be used include the following:

- *Journaled File Systems:* The basic idea of a journaled file system is to maintain a log of all "write" commands to a file system in a journal that is separate from the file system. Upon a system failure, the system can be checked for the status and restarted from an earlier safe point. Such log structures are routinely used in databases for recovery of transactions.
- *Snap Shots:* Here the metadata of a file system is frozen and accessed as it existed in some earlier point in time. A product such as the Network Appliance WAFL™ file system uses this approach for data filing and recovery.

Databases routinely provide checkpoints from which they can recover when a transaction aborts. Databases also use "shadow" transactions and "two-phase commit" protocols to support recoverability.

Quarantined Transaction Execution

Since our basic premise is that "all transactions are suspect," the design of a survivable system should incorporate techniques for the execution of transactions in "quarantine," i.e., in isolation from other parts of the system. The effects/results of these transactions may be migrated to the rest of the system only after validating that the set of transactions have not compromised or corrupted the system. This may be thought of as a system that moves in steps, while the transactions are executing continuously. The quarantined transactions may be executed by a separate "processor-memory-network" combination to obtain complete transaction isolation.

Transaction and User Profiling

Every enterprise could be described by the type, number, and distribution of a set of transactions that may form "patterns." As transactions are executed, there could be "watchdog" processes to monitor the activity. These monitors could interact with a knowledge-based system that analyzes the transaction patterns to detect any unusual activity. This could be interpreted as telltale signatures of undesirable or hostile transactions. In a like manner, we can also assign "patterns" to user types. When significant deviations from ad hoc patterns are detected, a compromise could be inferred. Lessons learned from security organizations could form the basis for these knowledge-based systems.

Virtual Node Isolation

A networked system by definition has a number of discrete nodes that are distributed across the network. Survivability of such a system can be enhanced by making it more difficult for an intruder to detect the related nodes of the system. Inter-node communication could be mediated by "black boxes" that encapsulate the origin/destination node mapping and are designed to resist probing. An attempted probe on a "black box" could automatically signal/infer the presence of hostile activity. To make the discovery of mappings more difficult, they could be made dynamically driven by secret algorithms.

Technologies such as virtual local-area networks (VLANs) in Ethernet or Zones in Fibre Channel technologies may be used as the basis for achieving virtual node isolation.

Audit Nodes

A survivable system should incorporate specially designed nodes whose sole purpose is to audit the changes that are taking place at performance nodes. When an audit node discovers compromised data, it will alert every performance node to shift into an enhanced security mode. These audit nodes should be designed in such a way that they cannot themselves be discovered and compromised. These audit nodes can also dynamically change roles to thwart the discovery of audit patterns.

Dual-Track Execution

In multimedia systems, the encoded data is often transmitted in parallel streams: one with high quality and another with a lower quality. When parts of high-quality data are lost, they can be substituted with corresponding lower-quality data so that the signal continuity is maintained, albeit, with a somewhat reduced quality. In a similar manner, under some circumstances, we can incorporate dual execution of transactions that are independent of each other but can be mutually substituted in order to repair damage caused by hostile acts.

Predictive Models

A simulation model of a distributed information system at multiple levels of abstraction may be created and executed in parallel with the real system being tracked. At any point in time, key performance attributes of the simulation model could be compared with their counterparts in the real system to ascertain unusual deviations or compromised states. These models could serve as external triggers to audit nodes to initiate consistency checks. Some of the intrusion detection systems use a similar technique to alert statistically significant behavior.

Signature Matching

Many attacks on information systems follow "predictable" patterns. By analyzing the transaction patterns, the system may be able to infer that a known type of attack is underway. Once such a state is established, predefined protective measures or damage-limiting measures could be invoked. Also, concomitantly, a knowledge base of known types of attacks and their signatures could evolve and serve as a knowledge source for the designers of survivable systems.

Ephemeral Entry Nodes

A distributed network–based system often has a designated entry node that may also be mirrored to ensure scalability. Malicious attacks on the system also enter through the same nodes. Changing entry nodes randomly or according to some secret algorithms could frustrate the efforts of the attackers who will try to enter through degraded or disabled nodes.

Conclusion

In this paper, we have outlined a number of design imperatives for the designers of survivable networked systems to consider. It should be noted that not all of these imperatives are applicable to every type of system. Some may be even in conflict with others and therefore may not exist simultaneously in the same system. Undoubtedly, these design strategies will significantly increase the complexity of the system and may degrade the performance of the deployed system. As with all systems, a careful trade-off between enhanced survivability and performance degradation should be considered. Emerging technologies such as storage-area networks (SANs) are addressing many of the issues outlined in this paper to make the future networked systems more survivable.

Template-Based Network Management, Ordering, and Service Provisioning

John Reilly
Principle Member of the Technical Staff
MetaSolv Software

Introduction

The rapid evolution of network technologies enables service providers to deploy networks that offer a variety of new services. Many service providers differentiate their services by constructing what resemble customized networks. This places an adaptability requirement on applications that support network management, ordering, and service-fulfillment business processes. Service providers must be able to bring these new services on-line quickly. This speed helps to ensure the provider's competitive advantage and allows the provider to quickly realize additional revenue associated with the new services.

This article describes the type of next-generation applications that satisfy this requirement. The applications should employ some type of *user-defined* templates that allow logical networks to be defined and designed. The templates should also contain rules that facilitate the ordering and provisioning of services enabled by next-generation networks. Functionality must also exist to allow users to define attributes unique to the networks and services offered.

What Is a Template?

A template is a collection of building blocks and rules that govern the design and provisioning of service-provider logical networks and the design and provisioning of customer networks and services (connections) that utilize the resources offered by provider's networks.

Four types of building blocks make up a template:

1. Types of networks
2. Types of elements
3. Types of connections
4. Custom attributes for each type

Types of networks specify the kinds of networks that make up a service provider's infrastructure and the kinds of networks offered to customers. Network types are the foundation building block for a template in that they are created first. Examples of service provider's networks include digital loop carrier (DLC), Ethernet, asynchronous transfer mode (ATM), digital subscriber line (DSL), multiprotocol label switching (MPLS), and so forth, as defined by a service provider's network planners. Examples of customer networks include virtual local-area network (VLAN), transparent local-area network (TLAN), virtual private network (VPN) intranet and extranet, and so forth, as defined by a service provider's network planners and product managers.

Element types define the groupings of equipment types that enable connections to be made within the provider's network or a customer's network. Element types represent the connection points in a network design template and are created next. For example, ATM switches, DSL access multiplexers (DSLAMs), frame relay (FR) switches, subscriber management systems (SMSs), routers, and switch routers are all examples of the types of elements that make up a network. Many types of networks can share the same type of element. For example, a switch router can be used as an element type in an Ethernet access network template, a VLAN, and an Internet protocol (IP) VPN. Element types can also represent other types of networks. For example, an ATM access type of network can be part of a DSL type of network.

Types of connections represent the manner in which elements can be linked. Connection types can be service-provider– or customer-related. Connection types represent the glue that holds a network together. For example, service-provider types of connections include bandwidth circuits, inverse multiplexing groups, facility circuits, Ethernet links, and so forth. Customer types of connections include bandwidth links, switched virtual connections (SVCs), permanent virtual connections (PVCs), Internet connections, TLAN connections, and so forth.

The network, elements, and connections that make up a network are described by very few hard facts, other than facts such as network name and network-element ID. Custom attributes represent additional facts that can be gathered and kept about a network, element, or connection. This is a necessity in today's rapidly changing technological environment. The attributes are defined and related to the template building blocks. When networks, elements, and connections are defined, these attributes are assigned values. For example, a TLAN ID is an attribute that represents the identity of a TLAN type of network. When customer X's southwest TLAN is designed, the TLAN ID is assigned a value of SW1.

Defining Template Rules

Template rules define how logical networks can be constructed, how orders can be placed for customer networks and connections, how customer connections are provisioned, and definitions of custom attributes and associations between custom attributes.

Logical Network Design Rules

Logical network design rules govern the construction of the networks. As seen in *Figures 1* and *2*, some of the rules can be graphically depicted. These rules include the types of elements that can be used to construct the network, along with the types of elements that can be connected. Definition of the rules does not end there. Rules also include, but are not limited to, how many of a specific element type can be used in a network, what type of equipment can be associated to each element type, what roles (such as customer edge, provider edge, and so forth) an element can play in a network and what type of connections are used to link elements.

Ordering Rules

Ordering rules facilitate ordering both customer networks and customer connections. The rules include linking items in a provider's product catalog to types of networks, types of elements, and types of connections in the network design templates. The rules also include such things as necessary element types that must be ordered to construct a customer network, location requirements for elements and connections, and time-of-day and recurrence sensitivity for connections. As an example of the latter rule, a multicast connection may be ordered for the next five Fridays between 2:00 pm and 3:00 pm.

Provisioning Rules

Provisioning rules govern the way customer connections are designed and activated. Some of the provisioning rules defined in a logical network design template are depicted in *Figure 3*. The rules in the figure are for a customer LAN to customer LAN virtual connection. The circled element types represent the types of elements used to design the connection. The numbered lines represent a possible path that the connection can take through the network of this type.

Some of the other rules not depicted in the figure, but included in the template, are connection assignment/allocation rules, equipment assignments, and whether the connection is a candidate for auto (sometimes called frictionless or touch-less) provisioning. An example of a connection allocation rule is the one stating that an Internet connection type must be assigned to the next available virtual path identifier associated to the bandwidth type of connection to which the Internet connection can be allocated.

Custom Attribute Rules

Custom attributes provide a unique way in which to extend the definition of network, element, and connection types. The rules define the custom attributes and relationships among custom attributes. Definition rules include the valid values for an attribute, applicable languages, whether the attribute is mandatory or optional, its data type and length, associated processes where it appears on a user interface, and its display properties. Relationship rules include the

FIGURE 1

A Logical Network Design Template Graphically Depicts What a Network Template Could Look Like

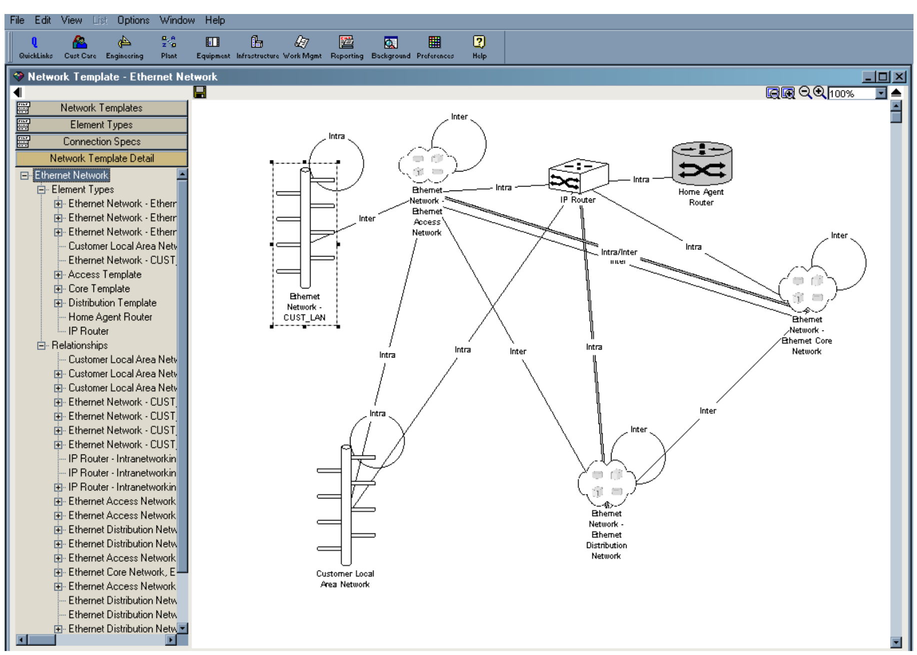

FIGURE 2

Logical Network Design Template Rules

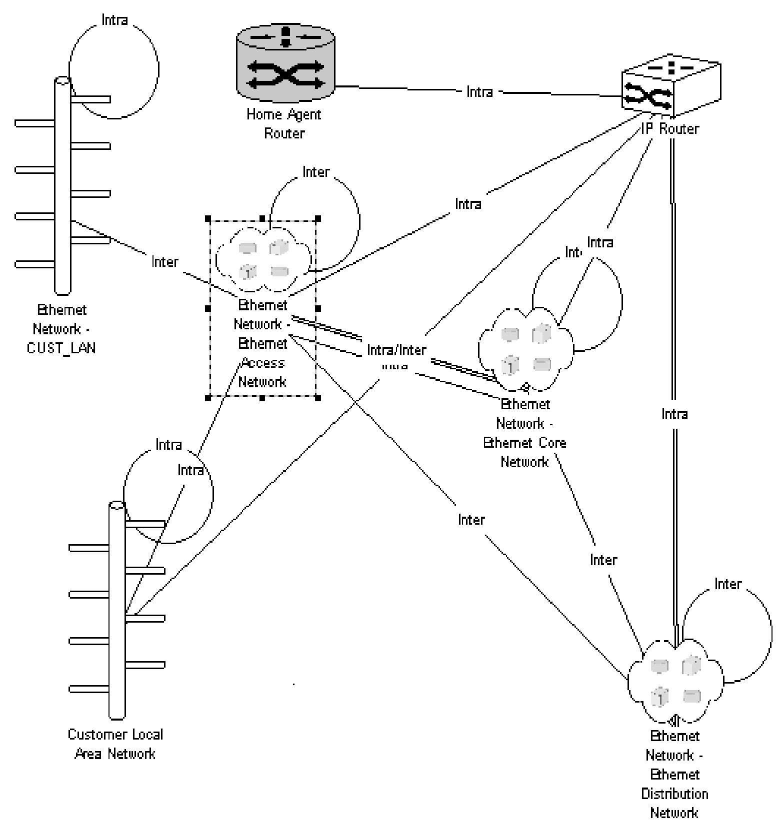

FIGURE 3

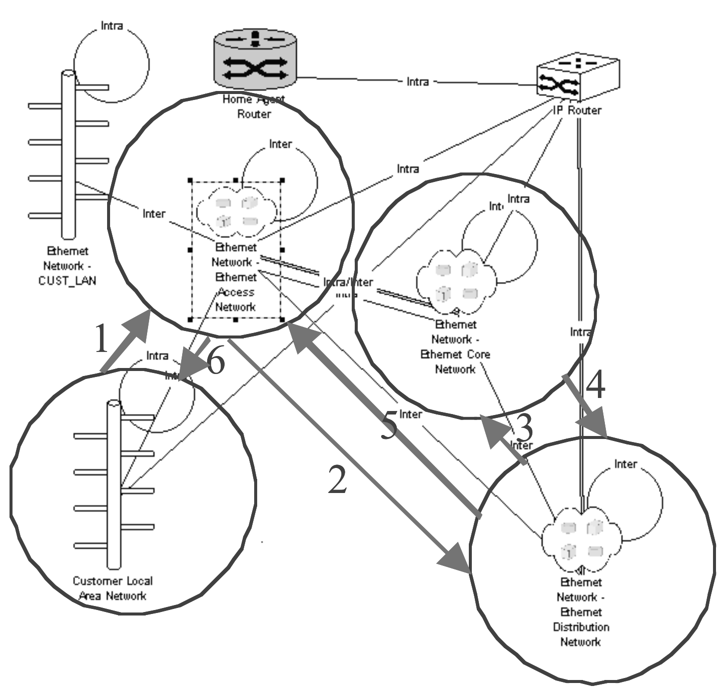
Template Provisioning Rules



ability to default one attribute from another, validation that must be performed between attributes, derivation of an attribute from other attributes, and so forth. There should also be a provision for an attribute's value to be determined by some externally defined algorithm.

An example of the definition of a custom attribute is that its name is VLAN ID, that it is a number that can be a maximum of nine digits with no decimals, and that it is mandatory for a VLAN type of network.

One example of relationships between custom attributes is that the downstream bit rate defaults from the upstream bit rate. Another is that the committed information rate (CIR) is compared against bit rate for capacity tracking purposes.

Using a Template

Once defined, templates support a number of processes, including the following:

- Designing an internal network
- Accepting an order for a customer network
- Designing an ordered network
- Provisioning an ordered connection

Designing an Internal Network
Figure 4 shows a graphical representation of an internal (service-provider) logical network. This network's design is based on a logical network design template. Networks, their elements, and their connections are instantiations (occurrences) of network design template building blocks. For example, the northeast ATM access and southwest ATM access network are instances of an ATM access network template's building blocks.

The creation of the logical network was accomplished by completing the following steps:

- Selecting the template that will be used to instantiate the network
- Selecting the types of elements and instantiating them as elements
- Linking elements connected in the network
- Specifying the types of connections that link two elements
- Designing the connections that link the elements (optional if already designed)
- Associating connections with the link between two elements

Accepting an Order for a Customer Network
Relating items in a service provider's product catalog enables a process called assisted ordering. An assisted ordering scenario is contained in *Figures 5* and *6*. Once the type of network is known via its association to an ordered item, all of the ordering rules in the product catalog and logical network design template can be brought to bear.

In the first step shown in *Figure 5*, rules specify that site-type elements make up a VPN intranet. Assisted ordering, knowing this, can ask, "how many sites?" Locations are required for this type of element, as specified in the template. Therefore, locations are requested. Equipment is also associated to the element types in the catalog, so assisted ordering can ask about equipment to order for each site.

FIGURE 4

Internal Logical Network

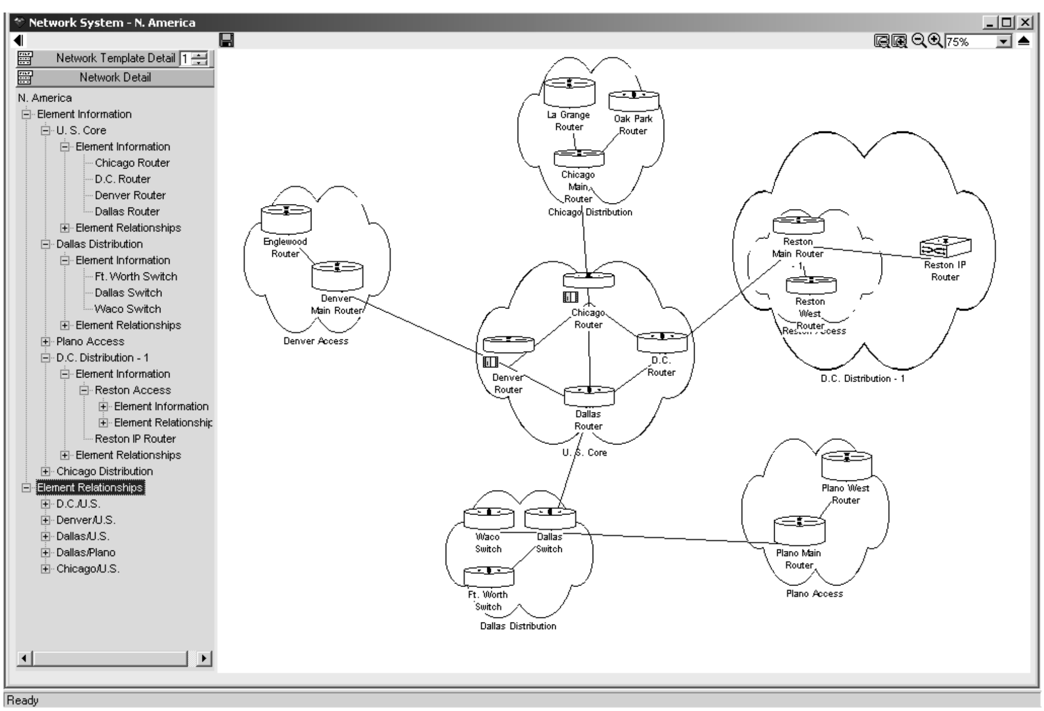


FIGURE 5

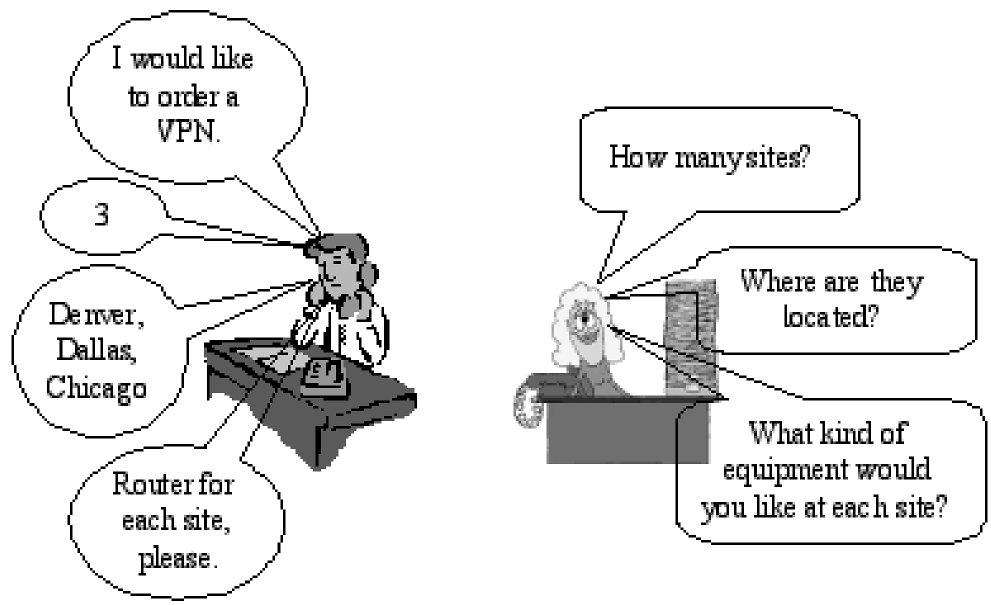
First Step of Assisted Ordering



Similarly, ordering of connections can be assisted, based on the association of connection types to product catalog items that are part of the VPN intranet type of network. Using connection-provisioning rules, assisted ordering requests information about not only the types of connections desired, but also information about the terminating points of the connections. Use of these rules is demonstrated in *Figure 6*.

Designing a Customer Network

After accepting an order for a customer network, the customer network is designed as shown in *Figures 7* and *8*.

The rendering process uses information from the order and template rules to make a first pass at designing the network, as shown in *Figure 7*. Elements are placed on the drawing along with the serving portion of the service provider's network that will support the customer network, if the serving portion of the network can be determined.

The next steps of the customer network design process include the following:

- Linking elements connected in the network
- Designing the connections that link the elements (optional if already designed)
- Associating connections with the link between two elements (should be done automatically based on rules in the template)

FIGURE 6

Second Step of Assisted Ordering

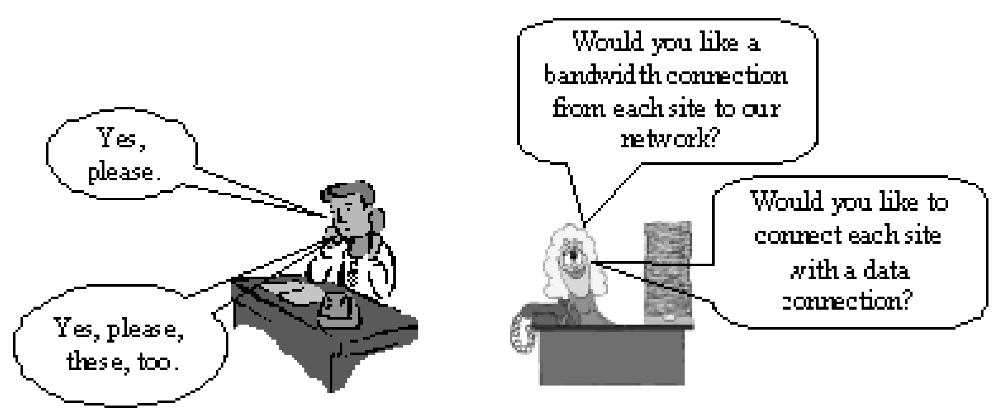


FIGURE 7

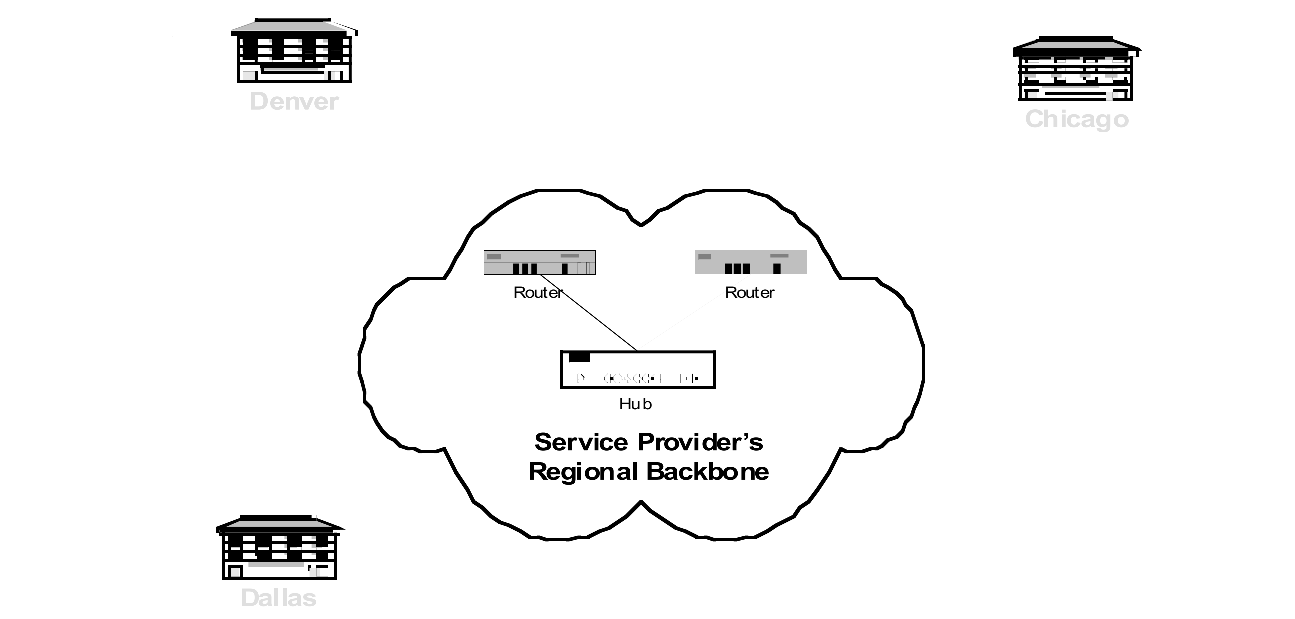
Initial Rendering of Logical Customer Network



Provisioning an Ordered Connection

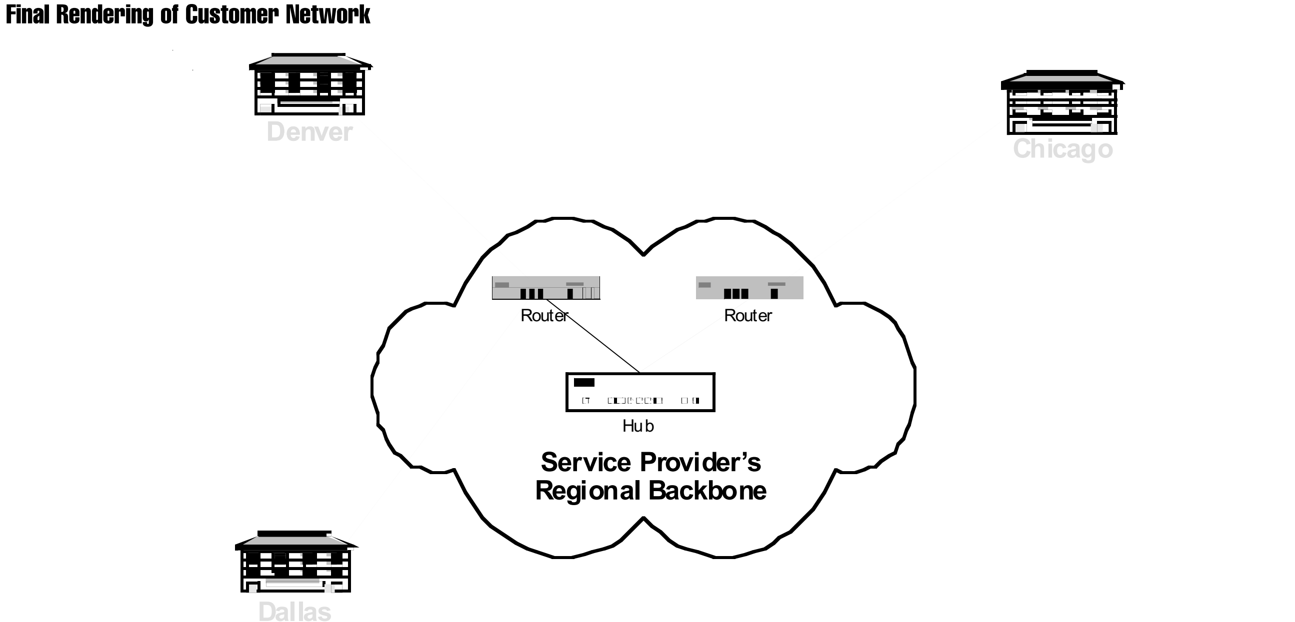
The design and activation of customer-ordered connections that are part of a customer network or standalone customer connections also benefit from rules contained in network design templates.

Figure 9 depicts a path through a service provider's network taken by a customer-ordered standalone connection between the two igloos. Finding a path is facilitated by rules in the template as described in the section on *Provisioning Rules*.

Design and activation processes are manually performed, totally automated, or partially automated based on rules in the templates and user choices made during the manual design process. For example, there are rules that govern the connection assignments and equipment assignments for each segment in the igloo-to-igloo connection shown in *Figure 9*.

FIGURE 8

Final Rendering of Customer Network



The steps involved include the following:

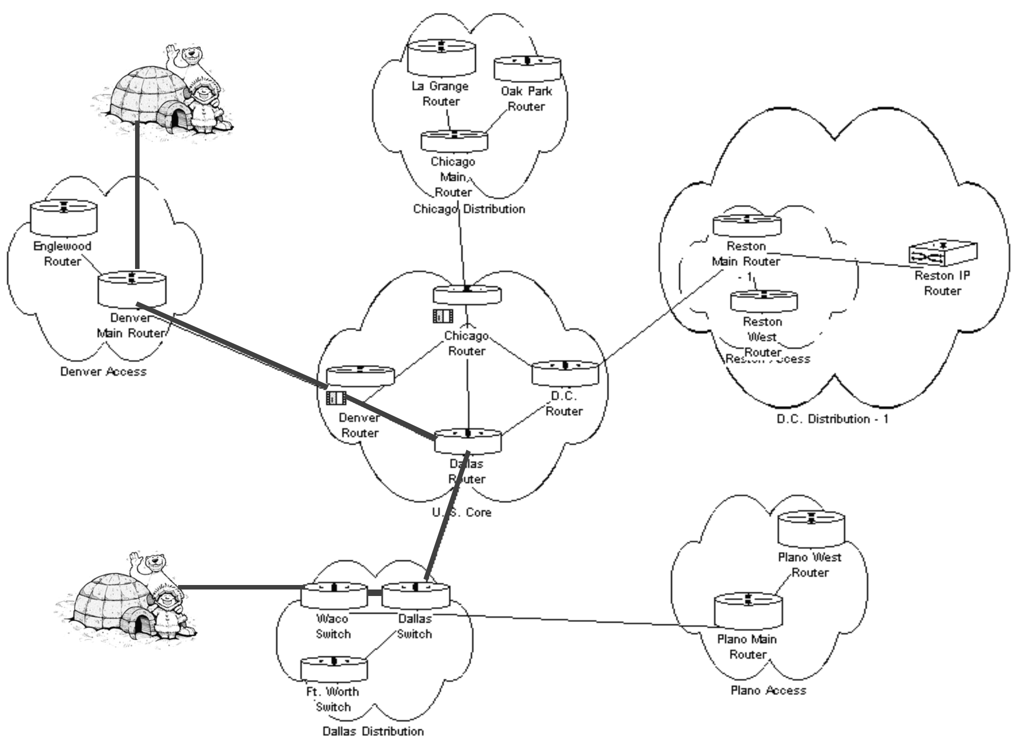
- Finding a serving network over which the connection will be provisioned
- Finding a path through the serving network
- Making assignments/allocations to other connections
- Making equipment assignments
- Activating the connection

Summary

Template-based network management is the wave of the future. Employ applications that are template-based to keep your competitive advantage.

FIGURE 9

Provisioning an Ordered Connection



Automate Your Revenue-Assurance Organization

Gary Ross
Vice President, Product Management and Marketing
Connexn Technologies

In an age of automation, revenue assurance has strangely been left behind. It is ironic that while automation is a primary weapon in the war against revenue leakage, comprehensive automation of revenue recovery itself appears to have been passed over. It is true that some targeted areas of revenue-assurance automation have been addressed—for instance, call-through testing and usage-data monitoring in mediation operations support systems (OSSs)—but for the most part communications service providers' (CSPs') revenue-assurance organizations have few automated tools with which to work. With revenue leaking at the rate of 11 percent of annual gross revenues, this is a critical shortcoming that may very well affect a CSP's ability to survive in our current unforgiving economy. Or looking at it another way, state-of-the-art revenue-assurance tools may be the competitive edge that allows a CSP to pull ahead of its competitors.

In this article, I will describe the current dilemma for revenue-assurance organizations and suggest a way for them to overcome it. This is a critical issue that should be of interest to executive management working to improve margins by increasing top-line revenues and decreasing operating costs. I will make it clear why automation is critical to the process of revenue assurance itself.

Evolution of Revenue Assurance

First, let's take a moment to review the typical evolution of a CSP revenue-assurance organization to better understand how "lack of automation" happened and what needs to be done about it. Unfortunately, attention to revenue assurance usually begins with a catastrophic event, such as a switch that stops recording usage data, often resulting in multi-millions of dollars in lost revenue. Such a loss gets the attention of the executive team, which is quick to feel the pain and prone to action. Resources are dedicated to clean up the mess and ensure that it doesn't happen again. An executive governance or oversight committee may be formed, and under their direction a revenue-assurance organization is created, frequently in the finance organization.

This newly formed and empowered revenue-assurance team sets out to identify risk and develop initiatives to protect against leakage. At this point, they begin to build staff and alliances, either centralized or distributed, throughout operations organizations. Overwhelmed with the enormity of their task, for revenue-assurance is an end-to-end concern, they soon seek out ways to be effective, and this is where their troubles begin. Their options are limited. Even though empowered by the executive team, the only way to keep up appears to be by adding staff. Their work is labor intensive and frequently involves time-consuming manual audits. Consultants are more than happy to roll up their sleeves and pitch in, but their contribution is mostly manual and at high cost. Internal information technology (IT) organizations are sometimes willing to take on point solution automation projects, yet frequently are a dollar short and a day late. This is where revenue assurance gets bogged down. The initiatives stack up, and the organization gets stressed.

Clearly, manual revenue assurance and point solution automation projects simply are not an option in light of the ever-increasing complexity of CSP revenue streams and the sheer volume of work to be done.

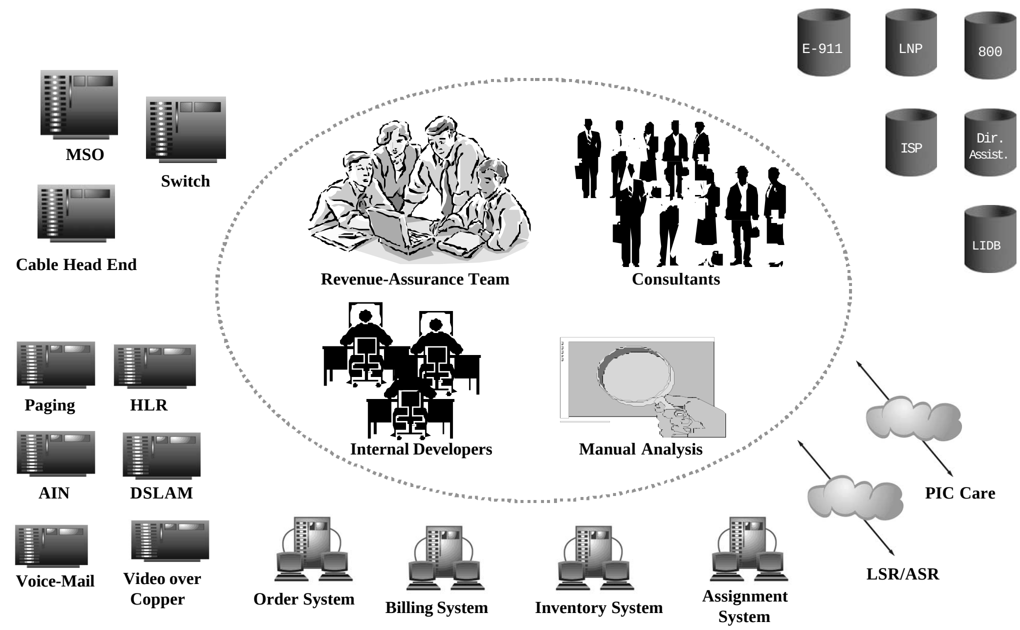
Revenue Leakage

At this point, it will be helpful to examine revenue leakage itself, which will give insight into why automated tools are a must. There are really two kinds of leakage occurring—one that I refer to as *systemic* and another that I refer to as *pervasive*.

Systemic leakage impacts many customers of which a single occurrence can result in huge sums of loss. An example would be a network-element translation error that turns off usage recording for many customers. This is also the kind of leakage that is most visible, referred to as low-hanging fruit by some. To date, most point solution attempts at automation have been focused on systemic leakage, such as "call-through testing." In addition, revenue-assurance metrics and controls are also focused on systemic leakage. In other words, there are some clear-cut ways to go after systemic leakage, and one might argue that mature revenue-assurance organizations are doing a pretty good job of it.

FIGURE 1

Service Providers Today



Pervasive leakage, on the other hand, is associated with a single customer or network component assigned to a single customer. An example is the customer who has been provisioned for voice-mail but is not being billed for it. Pervasive leakage takes the form of unbilled/underbilled services and features or assets that have been lost track of (stranded assets) and therefore are no longer earning revenue. Pervasive leakage is really tough to go after, since it usually requires accessing and analyzing huge amounts of data. It also usually requires the comparison of data from two or more sources. Not only is the data likely to be difficult to access, but it is also rarely, if ever, in a comparable format. Anyone who has done services and features audits, manually or otherwise, has found astonishing rates of underbilling of lines across their customer base. Connex^{n} Technologies has found that 3 percent to 20 percent of all lines/subscribers are being underbilled, with an average of 12 percent. Most CSPs suspect some level of pervasive leakage, but they usually have no hard data on how much. Connex^{n} Technologies has also found that most CSPs are not even looking for pervasive leakage, mostly because of the time and resources required to detect and correct the errors. Yet, ironically, this is where the highest payoff of revenue-assurance work is, and today it simply is not being done. Enter the need of automation.

Today

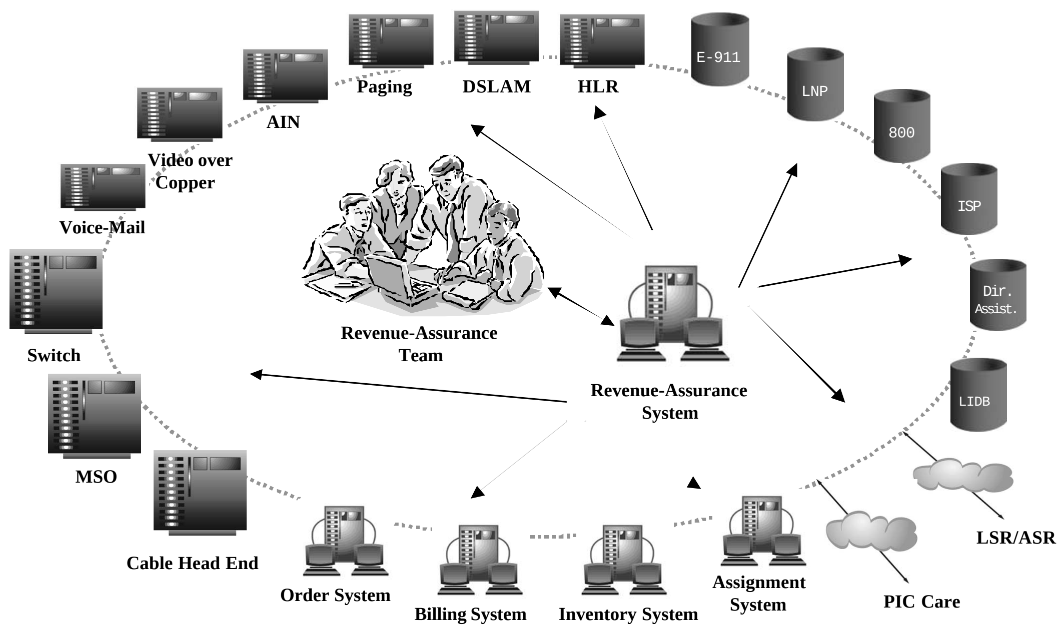
Today, most mature revenue-assurance organizations are slowly working through long lists of initiatives at the slow rate allowed by resources and funding levels. Metrics and controls have been put into place. The low-hanging fruit has been harvested. The tough work of addressing pervasive leakage has now begun and the going is extremely slow. Their instincts tell them that unseen revenue must be leaking, yet they have no hard data to substantiate their feelings. Worse yet, they have no capacity to go after it. Key to their long-term success is access to data locked away in business processes and OSSs. Looking for pervasive leakage requires access to volumes of data and the ability to efficiently and effectively audit for leakage. *Figure 1* depicts the typical revenue-assurance organization and the lack of automation that they face today. The data of value for revenue-assurance work is distributed widely across most corporate systems and processes. Access to the data usually requires a custom interface. Once the data is accessed, it then needs to be transformed before it can be compared to another data source.

Tomorrow

What revenue-assurance organizations need is a flexible, automated way to access and analyze data from distributed sources. In addition, they need an automated approach to the correction of their findings. In short, they need a revenue-assurance support system. *Figure 2* depicts a revenue-assurance organization with a revenue-assurance support system. In general terms, such a system will need three levels of functionality, all three of equal importance. First, it must be able to connect to a wide variety of systems and network elements. The connections must be reasonably easy to establish and maintain. Second, it must have the flexibility to interact with those systems in a way that allows it to both extract desired data and to communicate changes in the data back to those systems. This will facilitate ad hoc audits and allow for automated error correction. Finally, a revenue-assurance support system must have robust reporting capabilities that allow quantification of audit results both in terms of revenue and root cause.

FIGURE 2

What Service Providers Need



The obvious question at this point is does such a system exist? I would say yes, in its early stages. Automated detection of pervasive leakage and automated correction of the findings has been going on for some time. The ability to connect and communicate with a wide range of systems and databases is also available. However, the idea of a user interface that supports ad hoc auditing and performs advanced reporting is somewhat new and will be evolving over time as CSPs clarify needs and requirements.

Conclusion

Automation is necessary for revenue-assurance organizations to bust through current resource constraints. During a period of economic downturn, when capturing all revenues earned is more important than ever, manual auditing and analysis is simply not an option. CSPs need to realize that this is why their revenue-assurance organizations are stalling out and take action. Now is the time to take revenue assurance to the next level.

Roots of Reliability

John W. Sawyer
Director, Mission-Critical Facility Services
Johnson Controls, Inc.

On-line business is driving explosive growth in computer networks. These high-value systems are destined to fail without proper attention to the basics of climate control and power quality.

"(A) popular online auctioneer...is still working on a major system problem that has disrupted service since last night. (The) latest outage is its second major service disruption this week alone, and continues a string of service outages that have plagued the company since the beginning of this year.…Though the company didn't offer details, earlier bulletins blamed a hardware issue relating to (the company's) database servers."

—*Computerworld*, June 11, 1999

No matter where, when, or how long, network outages make news. They are the nightmare of on-line merchants, Internet service providers (ISPs), telephone and wireless communications companies, banks, and on-line brokerages.

An outage means immediate loss of sales and revenue. It also can mean loss of customers, a steep decline in market capitalization, and lasting damage to the company's reputation.

The cause of a given outage can be as obvious as a lightning strike or as arcane as flawed application software code. But often, the root cause can be traced a flaw in basic infrastructure: the electric power and climate controls that support critical computer equipment.

What shuts down an on-line merchant at the height of holiday shopping may be a remarkably low-tech problem:

- A power failure traced to an uninterruptible power supply with insufficient redundancy or imbalanced load
- A server room that ran too warm because an improper rack configuration blocked the flow of conditioned air
- An inadequately trained employee who tripped the wrong circuit breaker during a routine maintenance inspection

Recent events on Wall Street show the financial perils of new-economy companies growing too fast, too soon. Such companies can place themselves at similar risk by building critical infrastructure with an eye on speed to market but without systems in place to ensure uninterrupted service to customers for the long term. Just as lasting success on the stock market depends on sound business fundamentals, reliable critical equipment depends on sound engineering and operating standards at each step of development:

- Site selection
- Design
- Construction
- Commissioning
- Steady-state operation

"I think you need to bring an elephant gun to kill a mouse. Hardware is cheap, the pace of the game is frenetic, and being the first mover in an industry like this is very important....You really need to figure out what the business plan is, do a what-if scenario that is beyond your wildest dreams, and build an architecture that lets you scale beyond your wildest estimation."

—Maynard Webb, Chief Information Officer, eBay Inc.
Computerworld, September 8, 1999

Critical Facilities: Brave New World

Critical facilities in business are far from new. Banks, telephone companies, credit-card merchants, and brokerages have owned vast computer networks for years. What has changed with the new economy is the speed of deploying technology.

Since the Internet emerged as a communication channel and a place to shop for goods and services, demand for critical facilities has exploded. It is estimated that within the next 36 months, annual sales through e-commerce will reach $60 billion in the consumer sector and five times that for business-to-business (B2B) (see *Table 1*). Consumer transactions will increase 22 percent, and B2B transactions will increase 78 percent.

This growth profoundly affects the telecommunications, Internet service, and fiber-optics industries. New and existing companies, jockeying for market position and points of presence (POP), rush to build new critical facilities, with speed and budget as their key criteria.

Those are far different from the factors that drive critical facilities development in more established industries. Ten years ago, the typical critical facility was a data center that housed mainframe computers and a range of peripheral devices. Today, those companies still prefer to concentrate their network and data technology in one or a few locations.

TABLE 1

Projected Growth in Electronic Commerce: 2001 through 2003	
Sector	**Increase**
Financial	400%
Personal Computers	340%
Travel	1,031%
Entertainment	806%
Apparel	460%
Books/Music	605%
Tickets/Events	2,432%
B2B	2,250%

To insulate against risk, they grow according to a plan, and they apply strict engineering, operation, and maintenance standards. Support personnel are experienced and technically capable. In-house staff, architects, and consulting engineers form a network of expertise, constantly vigilant for trouble. They are familiar with clients' business processes and the associated business plans and projections.

That stability and discipline are often missing in the competitive world of the new economy. Fledgling technology companies financed by initial public offerings (IPOs) staff up quickly, hiring people from multiple organizations. Critical facilities staffs are hybrids of people with facilities, information technology (IT), and management backgrounds.

The speed-to-market imperative greatly accelerates the build cycle. At the same time, cost pressures dictate the maximum productive use of floor space. Equipment configurations may violate temperature and humidity requirements and may fail to consider future maintenance needs. Facility design and operating practices may lack standardization across locations.

Most serious, growth may outstrip the capability of standby electrical power, power quality protection, and air-conditioning systems. While the occasional power or climate-control problem may not seriously harm a traditional business, it can devastate an Internet-based firm, especially one that has lured customers with guarantees of nearly 100 percent reliability.

The risks reach well beyond Internet companies themselves. Today, many corporations outsource specific computer software applications and related support by using Internet-based application service providers (ASPs). However, transferring technology means transferring risks of network failures and downtime, along with related consequences.

"More than 1,000 companies this week experienced slow performance and other problems on their Web sites because of troubles that (their) Internet hosting firm had with a router at its data center...."
—*Computerworld*, June 28, 2000

"If you find out your system can't handle the job, it's not something you can buy your way out of on the spot. You have to plan ahead."
—Stephen Scullen, Fidelity Brokerage Services Inc.
Computerworld, April 10, 2000

The Anatomy of Risk

Critical facilities must closely regulate temperature and humidity and their rate of change. Operating outside manufacturers' specifications can decrease mean time between failures (MTBF) in servers and other computer data storage and communications devices. Low humidity increases the risk of damaging electrostatic discharge.

In recent years, manufacturers have made computer equipment somewhat more temperature and moisture tolerant, but 68°F to 72°F and 40 to 60 percent relative humidity are still considered ideal conditions in critical facilities.

Critical equipment rooms are typically cooled through subfloor plenums that deliver conditioned air under pressure through a system of floor vents. In a well-designed system, cooling capacity is sized to the equipment's heat-rejection requirements, and air pressure and flow patterns are carefully managed to deliver the necessary cooling to each area of the room. For example, floor openings are strategically located to discharge air in front of servers so that the units' cooling fans can draw it in.

The overall room design recognizes manufacturers' requirements for "white space"—open areas around racks that enable front, back, or side access for replacement and service.

Problems occur when companies strive to maximize revenue potential per square foot of space outside the context of a sound facilities plan. When servers and other devices are added without considering the effects on air conditioning and power requirements, the critical environment can slip out of control.

Often, personnel building critical equipment rooms ignore "white space" requirements, installing equipment in any open area of floor. Besides increasing heat load, the added equipment has a side effect, requiring more electrical cable cutouts in the floor. These allow the uncontrolled escape of conditioned air, reducing subfloor pressure and impeding the delivery of air to points where it is most needed. Further, improper alignment of equipment racks can impede return airflow, causing air stratification or "hot spots."

As cooling effectiveness declines, a common reaction is to install more air-handling units in the room. At best, this is self-defeating, because those units consume the same valuable floor space from which the company seeks to maximize revenue. At the worst, in extreme cases, equipment-cooling requirements exceed the capacities of chilled water piping, system air volume, condenser loops, or cooling towers. This easily happens because system efficiencies, age, and maintenance histories are seldom taken into account.

In any case, the net result is loss of the ability to cool equipment properly over an extended period. Equipment runs above manufacturer-recommended temperatures, or, just as serious, its temperature fluctuates beyond manufacturers' rate-of-change specifications. While this may not immediately affect reliability, it inevitably accelerates wear and in the long run increases the risk of failures. High outdoor (ambient) temperatures aggravate these conditions.

Ill-planned commissioning or installation processes also can affect electric power reliability. For example, improperly organized circuits may create phase imbalances large enough to cause an uninterruptible power supply (UPS) to trip off-line. At bare minimum, a level of power-protection redundancy is lost, and the risk of a system outage is magnified.

"In response to severe web service outages, (a web hosting firm) plans to offer affected customers one month of free service, worth about $150."

—*Computerworld*, July 10, 2000

"Giving credit for downtime is not what these people want. They want reliable service."

—Rosemary Cochran, Vertical Systems Group
Dedham, Massachusetts

"The lesson there, I guess, is that I would gladly pay a hundred times what I got refunded not to have the outage."

—Charles Rice, Coatingsmart.com Inc.
Ann Arbor, Michigan

Cases in Point

A properly designed system, an ongoing management program, and properly trained personnel are keys to effective critical environment control. Two recent examples illustrate how the risk of failure increases when either component is lacking.

Case 1: Flawed Design
A major computer software and on-line service company was experiencing climate-control problems in a 15,000-square-foot critical facility. As the company installed critical equipment in the raised-floor room, temperatures were slipping outside specifications in multiple areas. In response, the company commissioned an analysis of the climate-control system, including air handlers, the condenser loop, and subfloor airflow. The analysis found the following:

- The 15-year-old condenser loop was providing insufficient heat transfer because of severe tube scaling caused by inadequate water treatment.
- Air-conditioning equipment was running at full capacity with efficiencies of less than 60 percent and with multiple equipment problems—yet no alarms were being produced.
- Improper alignment of server racks impeded the return path of air to the in-room air-handling units, causing hot spots and stratified air conditions.
- Obstructions in the subfloor lowered the available subfloor air pressure to near zero in certain areas, preventing delivery of conditioned air.

In summary, the facility was at significant risk of a failure that might have caused a system outage affecting large numbers of customers and possibly leading to widespread adverse publicity.

The company corrected the problem by upgrading cooling equipment, moving the air-handling units so that return air flowed perpendicular to the units, removing subfloor obstructions, introducing a process to manage floor cutouts, and installing chemical treatment programs. The modifications made temperatures in the room far more uniform.

Case 2: Training Deficiencies
Studies of critical facility service interruptions document that eight of 10 are caused not by the initial event (such as a lightning strike or dig-in fault), but rather by how systems or personnel respond.

An Internet-based services organization faced a potential crisis in its call center after one of two UPSs in a redundant system tripped off-line. Immediately after the event, operating personnel called for service. The service technician assessing the problem went to the circuit breaker to disconnect the UPS that had failed.

Without consulting the as-built drawings, the technician threw the breaker labeled for the failed UPS. In reality, the labeling was incorrect because it was not changed after a recent retrofit. As a result, the technician's action cut the utility power feed to the operable UPS.

That UPS went into alarm, reporting to the building automation system that its battery was discharging and that a shutdown of the protected systems was imminent. No one noticed the alarm. When battery power ran out, a major outage occurred, affecting all terminals in the call center.

The incident could have been avoided if labeling of electrical circuits had been correct, if the technician had not assumed the labeling was accurate, if facility personnel had been properly trained and drilled in handling such events, and if strict policies had been enforced on system monitoring during abnormal operating conditions.

"System outages and capacity problems rank as the chief concerns among executives at online brokerage firms, according to a new survey by Deloitte & Touche LLP. The New York–based accounting and consulting firm polled 60 online trading executives between November and January. It found that 60% of executives at full-service brokerages and 38% of managers at discount firms listed 'system outages and mistakes/handling growing transaction volume' among their fears."

—*Computerworld*, April 10, 2000

"We're reaching the stage where (customers of web hosting companies) are going to want to have telco-grade reliability. There's no excuse, really."

—Courtney Munroe, International Data Corporation
Quoted in *Computerworld*

Toward Long-Term Reliability

Reliable critical facilities depend on supporting infrastructure built with discipline and foresight. In the long run, a slower, planned approach speeds progress by eliminating errors and resulting rework. In the bargain, the risk of outages during system evolution declines dramatically. An effective critical-facilities plan accounts for four key components: people, process, systems, and technology.

Building for reliability is a five-step process that allows no shortcuts. Each step requires coordination among multiple functions. Those who design, engineer, and construct the facilities must consider the needs of those who will eventually commission, operate, service, and maintain them.

Site Selection: Construction cost per square foot is a key business consideration; low-cost real estate is thus attractive. But cost savings must not overshadow the long-term operating requirements of critical facilities. Needs like security, power quality, fire protection, and structural integrity may easily outweigh low cost.

Companies planning critical facilities should also consider local earthquake potential, lightning strike frequency, crime levels, and, most important, electric service reliability. Key considerations include the frequency of power outages (scheduled or unscheduled) and of switching on the grid. Sites near foundries or other operations with large electrical loads require careful planning for power-quality protection.

While older buildings can be appealing because of their low prices, their disadvantages can be considerable. Potential issues include roofing integrity, excessive numbers of windows (potential break-in points), floor load-bearing capacity, and absence of floor drains (essential for fire sprinklers). Some older buildings may be technically unsuitable; others may have renovation costs that erase their initial price advantage.

Design: Facilities must be designed around specific standards that cover equipment and material specifications, code compliance (fire, electrical, plumbing, ventilation, and others), and installation practices. These standards should be consistent from location to location and must relate to original availability requirements and staffing considerations. Critical considerations include the following:

- *Utility Power:* Historical grid reliability figures going back three years or more should be secured.
- *Cooling Capacity:* Cooling equipment—chillers, piping, duct capacity, headers, condenser loops, cooling towers—must be sized for the heat-rejection needs of the fully built facility, with allowance for system losses. Computer equipment manufacturers' cooling recommendations must be observed.
- *Airflow:* Equipment must be arranged to prevent airflow obstructions, which can create warm and cool spots and thus allow some equipment to overheat. Server racks should be aligned parallel to the direction of return airflow. Cable cutouts and other floor openings must be minimized to prevent misdirection of air and loss of air pressure. Subfloor airflow restrictions can be reduced with cable-management systems that direct electrical cables into troughs. Such problems can be nearly eliminated with overhead electrical cabling.
- *Maintainability and Safety:* Systems must be configured so that maintenance can be performed without sacrificing redundancy. For example, cooling system condensers should be connected in parallel (not in series) so that a repair to a single unit does not require shutdown of all or most units. Multiple power buses require adequate clearance so that one can be serviced without de-energizing the others.
- *Standardization:* Use of the same materials, devices, and technologies across all sites helps reduce costs in the design, construction, and operating phases.

Construction: Facility buildout must follow accepted installation best practices and must adhere to all design standards and metrics. When possible, systems and equipment should be tested to verify that they meet design specifications. For example, UPS systems should be factory witness tested under load. Tests should also be conducted for continuity in grounding systems, on links between generators and transfer switches, and on power-cable insulation.

Commissioning: Before start-up, design specifications and construction standards require verification by an outside source hired by and accountable to the facility owner. The entire power system must be confidence tested. Equipment warranties must be initiated. Commissioning also includes the generation of critical documents: as-built drawings, standard operating procedures, general maintenance plans, and training procedures. These, along with equipment specifications, warranties, and call numbers for service, should be placed in a reference library. Factory representatives who supplied the equipment should take part in staff operations and maintenance training. Baseline performance data and confidence-testing data should be captured. All critical procedures should be tested and verified and a training program established.

Steady State: Sound operation, maintenance, and contingency plans should guide day-to-day activity. Plans should include an escalation policy specifying whom to call (on-site staff, outside repair service, vendor representative, corporate technical support) for different levels of alerts or alarms. Critical spare parts should be identified, sourced, and stored on site as required. (In this regard, standardization on products adds economies of scale.)

Whenever a change in critical equipment is proposed, appropriate personnel should carefully evaluate the effects on the critical environmental. If the change is made, as-built drawings, maintenance procedures, training programs, and other facets of the operations plan must be updated. This process should include updates all associated document, equipment-labeling, and equipment-testing procedures.

A change management policy should guide any necessary adjustments to operating procedures. To protect "tribal knowledge" held by long-time staff, personnel should be cross-trained and succession plans should be in place for key staff members.

The Reliability Imperative

Without exception, technology companies are best served by designing, building, and maintaining critical facilities according to a comprehensive, integrated plan.

Companies seeking advice on critical systems design should look to an advisor with extensive experience in building critical environmental control. Such a company will be qualified to devise a cost-effective supporting infrastructure; to help assemble a coordinated team of company personnel to plan, build, and operate the system; and to provide financing options for critical assets.

In the long run, this approach allows the development of sound, reliable systems that meet customers' service expectations.

QoS Your Way

Sara Sedighi
Product Manager
Metro-Optix

Considering that most service providers currently have solid infrastructures providing the highest level of quality of service (QoS) with synchronous optical network (SONET) transport, how do they maintain this superior quality level and yet add new revenue sources as we migrate toward data-centric networks? With the explosion of the Internet and the high demand for enhanced data services, service providers are struggling with the challenge of this migration without stranding their current customer base and sacrificing the corner stone of their business. Most analysts project that data traffic will be the dominating network traffic in the near future, and service providers need to strengthen their position in the new data market in order to maintain their profitability without sacrificing reliability, survivability, and quality.

Transitioning from the legacy time division multiplexing (TDM) services to the next-generation data-oriented optical networks makes a compelling business case simply because data traffic is mission critical in today's network. But should the delivery of quality and reliable services be sacrificed along the way? Due to customers' demand for multiple service types, service providers are faced with the challenge of managing multiple network elements to support all of the different services and networks. Provisioning and maintaining all of these different network elements makes it prohibitively expensive for the service providers, potentially limiting their business opportunities due to cost constraints.

What is really needed is a single network element that provides support for multiple-tiered, multiple services and multiple networks without sacrificing quality and reliability. This ideal network element should also support QoS for each service layer. Fortunately, next-generation metro access vendors are deploying bandwidth managers capable of handling all these solutions—providing one-stop QoS shopping!

Bandwidth Managers

The quest for a complete QoS solution has introduced a new breed of next-generation bandwidth managers. Developers of these new bandwidth managers understand the importance of offering a variety of services with commitment to deliver QoS for each service layer. These new bandwidth managers are designed with built-in QoS support and the ability to support multiple protocols without requiring hardware forklift upgrades as customers' traffic patterns shift from traditional voice to converged voice and data. Support for different transmission methods (whether cells or packets) provides total flexibility and freedom in designing a reliable and efficient network.

And how do bandwidth managers achieve this level of flexibility and efficiency with optimal reliability and quality? They combine different protocols in one compact, high-capacity network element. They handle TDM, asynchronous transfer mode (ATM), and Internet protocol (IP) traffic with the highest quality to satisfy the needs of today's demanding and versatile networks—true protocol agility! These new bandwidth managers can easily scale from all–TDM to all–ATM to all–IP, or any incremental combinations of all three protocols (see *Figure 1*). This capability will help the network services provider to seamlessly migrate today's TDM network to the next-generation data-oriented optical network, while still providing traditional TDM transport. The flexibility of a bandwidth manager enables the service providers to provision any type of service based on their customer demand and their growth. Changing from TDM services to ATM and IP does not necessarily translate into inferior QoS. Here is how they address the QoS issue, their way!

TDM QoS

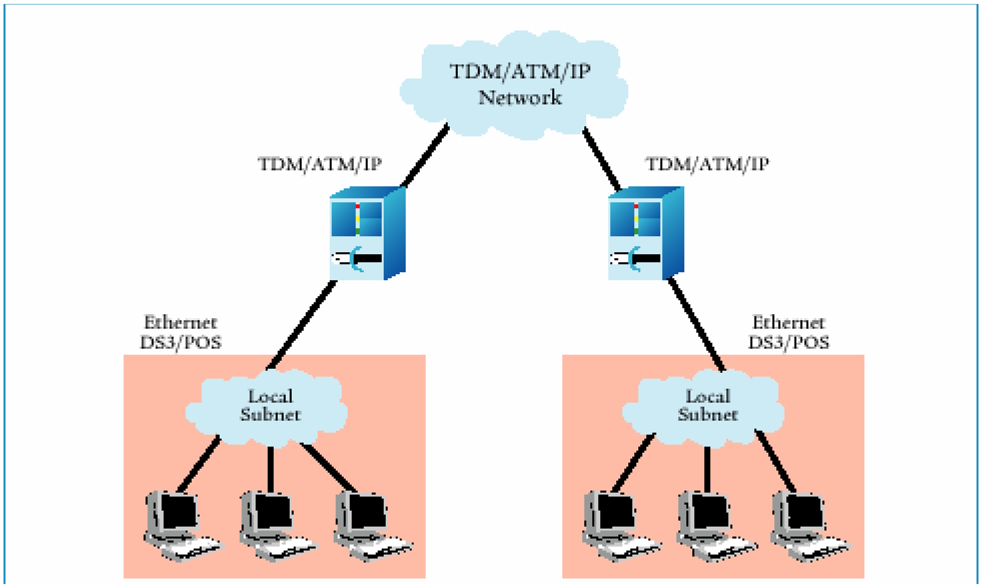
The SONET (TDM) portion of the bandwidth managers support the quality transport of Layer-1 traffic. The nature of a circuit-switched TDM network is to support dedicated connections and real-time data transfer, and that's what SONET networks offer—100 percent availability and reliability. The circuit-switched lines are still the best and most reliable for carrying voice traffic, therefore delivering the highest level of QoS. A bandwidth manager with SONET synchronous transport signal (STS) and virtual tributary (VT) multiplexing and grooming offers guaranteed bandwidth and a high level of service in the network.

ATM QoS

The ideal bandwidth manager provides QoS with no restriction on the service type, which enables the service providers to defer services and cost until the need arises. When service providers are ready to deploy ATM services in their network, the ATM portion of a bandwidth manager supports QoS at the ATM layer independently or simultaneously with other layers.

FIGURE 1

Bandwidth Manager



ATM is inherently connection-oriented and started as a single-queue traffic management, but it could not meet the multi-tiered, multiservices needs of today's networks. To provide multiple services with negotiable service-level agreements (SLAs) and maximize the performance of data networks, ATM QoS technology started to take shape and multiple classes of service were introduced. ATM QoS is implemented by defining five classes of service: constant bit rate (CBR), variable bit rate–real time (VBR–rt), variable bit rate–non–real-time (VBR–nrt), unspecified bit rate (UBR), and available bit rate (ABR). The service class defines parameters and acceptable cell loss and delay variation through the network. As each virtual connection (VC) in an ATM network is created, a specific service class is assigned to it. To provide complete QoS coverage, these bandwidth managers support all five traffic classes: CBR, VBR–rt, VBR–nrt, UBR, and ABR. Depending on which services are activated, their scheduling mechanism selects which VC queue to service at each cell dispatch time and whether to buffer ingress/egress data. This enables them to meet the QoS requirements of different VCs while simultaneously promoting high utilization of both bandwidth and buffers in the switch.

The services are divided into three levels of priority:

1. The highest priority is accorded to CBR and VBR–rt traffic. These services demand committed bandwidth and low latency. Bandwidth managers reserve enough bandwidth in each ATM node for CBR and VBR connections.
2. The second priority level is for guaranteed traffic services (GTS), which include the VBR–rt and VBR–nrt classes. These services are characterized by the average cell rate and are used for carrying packetized voice, video, and data. Within GTS, the different services are shaped according to what service customers agreed to pay for.
3. The lowest priority level is called excess bandwidth service (EBS) or best effort. This service is available in weighted shares for ABR and UBR as determined by programmable weights.

Service providers are able to offer QoS differentiated services based on the different service classes and varying bandwidth guarantees in the traffic contract. Service classes and traffic contracts are enforced using input policers and output schedulers that enable bandwidth managers to measure input traffic rates, identify the violating traffic, and manage the traffic with multiple queues and sophisticated algorithms to guarantee service classes.

The evolution of ATM QoS from best-effort services to guaranteed services has remarkably changed the QoS standards such that ATM networks offer QoS levels comparable to dedicated TDM networks, therefore providing maximum reliability and availability. This makes it possible for service providers to offer ATM QoS services independent of the underlying transport technology. Best-in-class bandwidth managers provide full support for all of these multi-tiered, multi-classes of service.

IP QoS

As service providers are preparing to meet the increased customers' demand for bandwidth with typical applications such as virtual private network (VPN), voice over IP (VoIP), and Web hosting, the need for a new set of value-added IP services is increasing. These new services demand SLAs for multiple QoS classes. Bandwidth managers are capable of offering QoS at the IP layer for all transmission methods, whether transmitting over leased lines, frame relay, ATM, or even packet-over–SONET links. They offer guaranteed QoS levels by SLAs to enable service providers to gain a competitive edge in their service offering.

IP networks started out as a best-effort service with no traffic contract, which means no guarantee for delivery of data packets. With data traffic becoming mission-critical and the integration of voice and video traffic over the IP–based networks, QoS has become a major issue on the Internet and in enterprise networks. Fortunately, IP technology is readily extended to accommodate the QoS issues for insuring predictable multiservice support, and the ideal bandwidth manager's architecture extends to meet this challenge by supporting IP QoS services. These services are comprised of two critical components: the differentiated services (DiffServ) model and multiprotocol label switching (MPLS).

DiffServ provides a model for establishing multiple service levels in an IP network. It defines an architecture to provide service differentiation at edge nodes with service-provisioning and traffic-conditioning policies decoupled from forwarding behaviors. The per-hop behavior (PHB) describes the forwarding behavior, which is applied to a particular group of packets.

PHBs are implemented via the following:

- Queue management
- Scheduling
- Congestion management and avoidance

DiffServ edge nodes classify, mark, and condition packets, while DiffServ interior nodes forward packets based on priorities. DiffServ is supported in both IPv4 and IPv6 headers. DiffServ service classes are divided into the following three PHBs. They range from best effort (no guarantees) to an IP equivalent of ATM CBR (very strict guarantee). DiffServ classes are Best Effort, Assured Forward, and Expedite Forward services. Best Effort gets whatever bandwidth is left over after the other classes are processed. Assured Forward delivers a guaranteed sustained rate with bursts up to a defined maximum. The Expedite Forward delivers guaranteed bandwidth, with the least delay and packet loss. DiffServ is being widely used in most enterprise and edge data networks for delivery assurance.

MPLS is the new approach to expedite the packet forwarding while engineering the traffic, and it is a true end-to-end QoS enabler. MPLS is implemented by labeling IP packets at the ingress label-switched routers (LSRs) (see *Figure 2*). Labels are assigned as each router builds its routing table and distributed to the peer routers by means of a label distribution protocol (LDP). At the edge router, the outgoing MPLS label is determined based on source address, destination address, and priority level. The label-switched path (LSP), to traverse from upstream to downstream LSRs, is established using one of the signaling protocols (such as resource reservation protocol [RSVP] and constraint-based routed–label distribution protocol [CR–LDP]). The upstream LSR then forwards the packet to the downstream LSR. This router in turn examines the MPLS label and decides what the next hop should be. This process is repeated throughout the network until the packet reaches its destination. This approach has proven to be much more efficient, since it does not examine the IP packet headers that can cause data delay at intermediate routers. Instead, it only examines the MPLS labels that are much shorter, hence speeding up the data transfer rate remarkably.

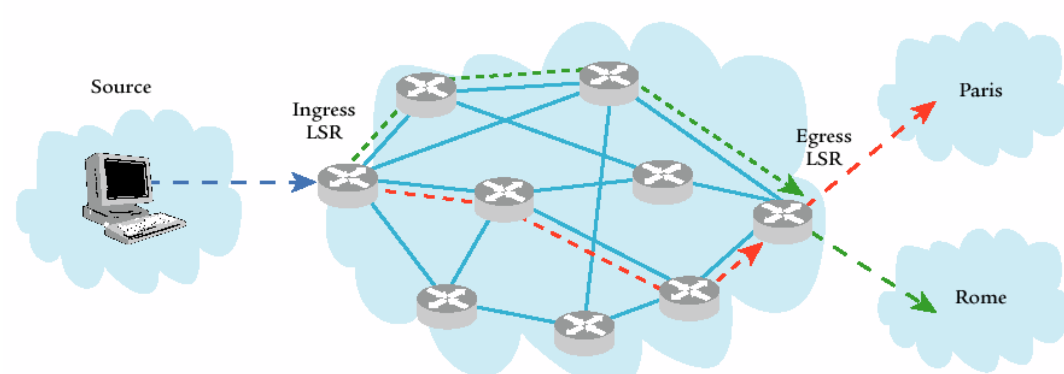
With MPLS's ability to support different data types (including IP, frame relay, and ATM) and its ability to overlay over pure IP, ATM, and frame-relay networks, it clearly offers most promising foundation for QoS solutions for today's network. MPLS will enable the service providers to gain a competitive edge by simplifying and accelerating service provisioning, routing, and cross-connectivity. This service turn-up acceleration translates into revenues for carriers.

- Ingress LSR determines forwarding equivalence class (FEC) and assigns a label
  - Forwards Paris traffic on an LSP
  - Forwards Rome traffic on an LSP
- Traffic is label swapped at each transit LSR
- Egress LSR
  - Removes MPLS header
  - Forwards packet based on destination address

The main challenge for wide deployment of MPLS has been the lack of stable specifications. MPLS specifications are still

FIGURE 2

MPLS Forwarding Model



being constantly revised, and a situation has been created that does not guarantee wide interoperability among multiple vendors' products. The Internet Engineering Task Force (IETF) expects to finalize MPLS specifications by late 2001, and after that networking vendors will start shipping products with standard MPLS implementations, and then wide deployment of MPLS will occur in the network. Until then, bandwidth managers meet the IP QoS requirement by utilizing the currently defined standards such as DiffServ on platforms that will easily migrate to accommodate MPLS when the time is right.

The evolution of IP QoS from best-effort to MPLS–based services reminds us of the ATM QoS evolution and the quest for guaranteed QoS delivery on every layer of the network independent of the underlying transport technology. Bandwidth managers are strategically situating themselves in today's data market by recognizing the needs of the multi-tiered, multiservices nature of today's networks and catering to these needs.

QoS Delivery

Deploying QoS–based services is challenged by the ability to monitor and bill for such services. QoS is measured according to the SLAs between a service provider and its customers. The SLA is what requires the service provider to prove their technical competence, dedication to business, and business integrity. Today, SLAs for leased-line services are based on guaranteed bandwidth and uptime, which can be trivially supported using a dedicated TDM circuit. However, the economics of the next-generation optical network require that access and transport facilities be shared among multiple users. The ability to offer these types of services backed by SLAs requires the extensive QoS capabilities provided by ATM networks and envisioned for future MPLS–based IP networks. Due to its unique architecture that integrates TDM, ATM, and IP technologies and multiprotocol support into a single common platform, the ideal bandwidth manager provides the service guarantees necessary to support SLAs via ATM QoS today with migration to MPLS in the near future.

An essential part of a bandwidth manager is to make QoS metrics possible through smart element-management systems (EMSs). The management systems are dedicated to the true management of services and interfaces throughout the network to enable service providers to deliver accelerated, seamless end-to end solutions to their customers.

Today's technological advances allow for QoS at all layers, and multilayer bandwidth managers are designed to handle multiple traffic types while still applying QoS techniques at every layer. It seems like service providers dreams have finally come true! Now service providers, with their existing SONET infrastructures, are able to maintain the superior quality levels that they offered with SONET and to add data services to their networks while continuing to be profitable. A protocol-agile bandwidth manager fits perfectly into both the present network and the next-generation network, supporting multiple service classes and maintaining the highest QoS. The time is here to take advantage of QoS your way!

Distributed Fault-Tolerant/ High-Availability Systems

Harry Singh

Product Manager

Trillium Digital Systems, Inc.

Executive Summary

Today's telecommunication platforms must provide "five-nines" availability, meaning practically no loss of service due to hardware or software errors, nor any downtime for software upgrades or hardware maintenance. This expectation places an unprecedented burden on service providers: to ensure that all of the network elements needed to support a service are functioning whenever a user requests that particular service.

Five nines means 99.999 percent availability. Achieving 100 percent perfection, while desirable, may be impossible, and a fault-tolerant system is designed to function correctly given two predictable contingencies: one, the small (0.001 percent chance) but practically inevitable presence of a fault in the system, and two, the likely requirement for periodic maintenance or system improvements. We will return to this point.

Supporting five-nines service availability depends on the near-flawless interaction of software (application, operating systems (OS), and management middleware), hardware and network design, as well as environmental and operational factors. Hardware fault tolerance typically relies on redundant processors, memory, buses, power supplies, and databases. Software fault tolerance uses a combination of software redundancy and simple hardware redundancy to provide the necessary availability in the case of failure. Network fault tolerance uses redundant data link cross-connects (T1s, digital signal [DS]–3s, optical carrier [OC]–3s, etc.).

This paper gives an overview of fault-tolerant/high-availability (FT/HA) components. *Figure 1* shows where all the FT/HA components of a system can reside. Both the hardware and software solutions and the challenges addressed by these solutions are discussed. This paper also outlines Trillium's FT/HA and the patent-pending distributed fault-tolerant/high-availability (DFT/HA) architectures and implementations, and how they are designed to overcome these limitations.

FT/HA Concepts

High Availability

To understand availability, we first need to understand reliability. The reliability of an element is the conditional probability that the element will operate during a specified period of time. A system may be considered highly *reliable* (that is, it may fail very infrequently), but, if it is out of service for a significant period of time as a result of a failure, it will not be considered highly *available*. One measure of an element's reliability is its failure rate, or mean time to failure (MTTF), which is the interval in which the system or element can provide service without failure. Another measure of reliability is the mean time to repair (MTTR), which represents the time it takes to resume service after a failure has been experienced. Systems may go out of service for any number of reasons, such as the occurrence of a fault, repair activities, software loading, hardware upgrading, or periodic maintenance. In any such case, MTTF and MTTR immediately become vitally important.

The availability of an element is the probability that the element is in service and available to a user at any instant in time. It can be expressed using these measures of reliability.

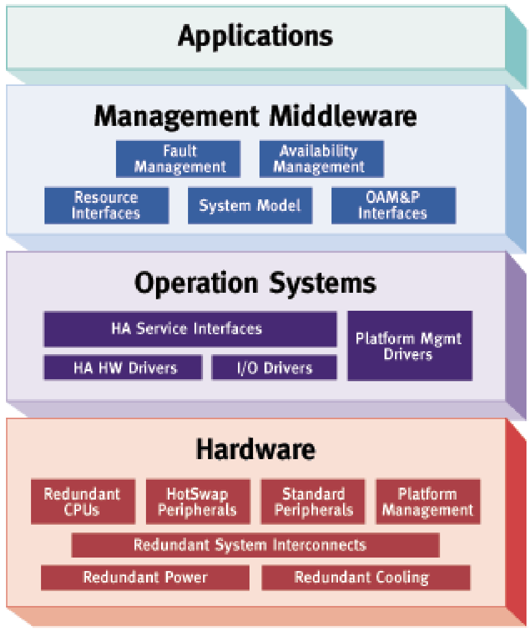
$$Availability = MTTF/(MTTF+MTTR)$$

As the equation shows, the availability of systems can be increased by designing components that are highly reliable (high MTTF) and/or by shortening the time required to repair the system and return it to service (low MTTR). Since it is impossible to create systems that never fail, the key to high availability is to make recovery time as brief as possible.

Network elements typically operate with a target of five-nines availability. Such a level of availability in a telephone switch, for example, means that the switch is expected to be out of service only for about five minutes *per year*. These few minutes are all the time needed to repair faults, load software, upgrade hardware, and perform periodic maintenance and any other necessary activities.

FIGURE 1

FT/HA Components within a System



Fault Tolerance

A fault-tolerant system is available in the presence of faults. The design, development, and testing of highly available systems is challenging and expensive. It generally proves more economical to assure high availability by detecting faults and avoiding service disruptions through redundancy in the system, that is, designing fault tolerance into the system so that it functions correctly and is continuously available in the presence of faults. Fault tolerance will increase the availability of a system, which is measured by the probability that the system will operate and be accessible when required for use, even during periods of preventative maintenance or repair.

The simplest failure-response strategy is to let a non-redundant system fail and then repair it off-line. This is the lowest-availability strategy, and it is unacceptable for mission-critical computer and communications applications in which high availability is a necessity. Such applications require systems that include fault-tolerant capabilities that make them highly available.

Fault tolerance can be achieved through a combination of system hardware and software. One way to achieve system fault tolerance is to use redundant hardware components within the system (e.g., multiple processors, buses, or power supplies in a single system) that operate simultaneously and in parallel, comparing results of the operations performed. This is referred to as a hardware fault-tolerant or redundant system. Using software to handle the fault management of two or more subsystems, regardless of whether each subsystem has redundant hardware components, can enhance system fault tolerance. When one subsystem fails due to the presence of a fault, the other subsystem takes over, so that the overall system can continue to operate without disruption in service.

Periodically causing a switchover between the software modules and restarting the passive software module can achieve software redundancy.

As we mentioned in defining "five nines," failure is just one of the contingencies that must be overcome to achieve 99.999 percent availability. The other and more likely event is anticipated maintenance to the hardware or software. Fault tolerance is necessary to enable the system manager to plan and execute "rolling" upgrades, that is, controlled, programmed improvements that avoid system shutdown. In a fault-tolerant system, five-nines availability can be ensured because the system manager can execute a rolling upgrade at an optimal moment—an anticipated fix with no downtime instead of a remedial one with a minimized interruption.

Market and Technology Drivers

Following are some of the market drivers for FT/HA systems.

Converged and Decomposed Network

Telephone companies and their equipment manufacturers have set standards for five-nines availability that other network elements in a converged and decomposed network must meet. Internet infrastructure and services will need to strive for near-perfection to provide services seamlessly across both the Internet and the public switched telephone network (PSTN).

These decomposed network elements (signaling gateways, media gateways, media gateway controllers, etc.) are built using commercial off-the-shelf (COTS) hardware and software solutions. Because of open standards and architecture, these solutions are obtainable from multiple vendors, and not, as before, from a single vendor that supplied everything—applications, hardware and software—in one box. These COTS solutions must meet the stringent availability expectations set by the PSTN.

Internet

The growing popularity of the Internet as a channel for business transactions and as an alternative to the traditional voice network is driving manufacturers to provide equally reliable and near-continuously available systems. Internet customers expect to be always on and always connected (AOAC), and they demand quality and reliability levels such as those established by the telecom industry during the past 10 to 15 years in the PSTN. Convergence is driving these same requirements into data networks and mainstream infrastructure equipment.

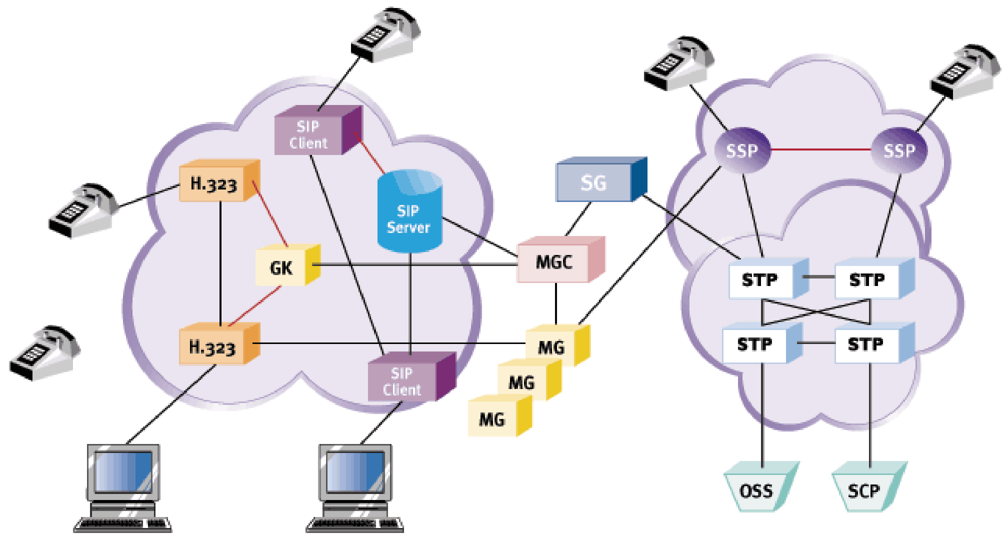
In addition to mission-critical data-processing servers and carrier switches, Web servers, signaling gateways, media gateways, media gateway controllers, wireless base-station controllers (BSCs)/mobile switching centers (MSCs), and computer telephony (CT) servers are expected to have higher levels of availability. *Figure 2* shows many of these elements in a decomposed network.

FT/HA Hardware Solutions

Designers and developers can take several design approaches to ensure high availability for individual network elements. The simplest type of network element is non-redundant and must be repaired off-line if it fails. This

FIGURE 2

A Decomposed Next-Generation Network



type of element will have relatively low design complexity and low cost. (Depending on its reliability, it may also have low availability.) In contrast, HA elements require both the ability to support on-line repair (usually through the "hot swap" of components while the element is in service) and additional redundancy. Hardware fault tolerance typically relies on redundant processors, memory, buses, bus cross-connects, power supplies, cooling systems, and disk storage. *Figure 3* shows two extremes of these solutions.

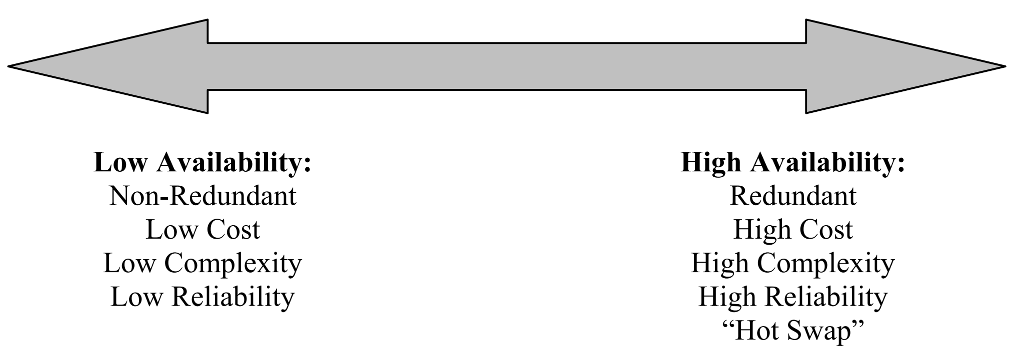
Elements with additional redundancy typically use "retry" and "masking" for recovery. Retry-based elements attempt to ensure that there is a second attempt at the operation if an initial operation fails. If the second attempt succeeds, the fault was probably transient. If the second attempt fails, the fault is probably permanent. Masking-based elements attempt to ensure that only the results from the correct operating portion of the element are used if a component fails. In either case, if a component has failed, the system attempts to detect, diagnose, isolate, recover, repair, and compensate for the fault.

System designers can enhance the fault tolerance of a system by combining simple hardware redundancy with fault-management software: replicating hardware subsystems to provide the necessary backup hardware in the case of failure and executing a copy of the same software on each node provide simple hardware redundancy. These hardware subsystems, or "nodes," can either be entire computers complete with processor, memory, buses, power supplies, cooling systems, and disk storage (in practice this is called "clustering") or any of these components individually. The fault-management software manages the switchover from the failed node to another operational node, maintaining the node-state information of the failed node so that it can be used by the system after the switchover. This eliminates the need for complex circuits, typical of more complicated hardware fault-tolerant approaches, and can significantly decrease the design complexity and cost of the system.

In telecommunications and networking applications, system designers typically achieve fault tolerance by using

FIGURE 3

Spectrum of FT/HA Hardware Solutions



either dual-node or multi-node architecture. In a dual-node architecture, two nodes are running simultaneously. In some systems, both nodes are active. In other systems, one node is assigned to be active and the other node is a standby. A more scalable multi-node architecture allows for the number of active and standby nodes to be configured and for the active nodes to share the system load. The dual-node architecture is more popular because of its lower cost.

A dual-node system typically achieves fault tolerance in one of two ways:

- Both nodes are active, sharing the load of the system by executing different tasks. If one active node fails, the other active node takes over the tasks of the failed node.
- Both nodes are capable of executing the same tasks, but one node is active and the other is standby. If the active node fails, the standby node becomes active and takes over the assigned tasks.

In either case, the switchover from one node to another is either controlled (operator-initiated) or forced (system-initiated). Generally, an operator-initiated switchover is performed for maintenance purposes, whereas a system-initiated switchover is carried out when a node fails. Application software is usually unaware of underlying HA hardware. These hardware nodes communicate with each other via current technologies such as cPCI buses or some upcoming technologies such as InfiniBand, RapidIO, or switched Ethernet.

Platform-management software provides the monitoring and controlling capabilities required for the detection, diagnosis, isolation, recovery, and repair of nodes.

Three common redundancy schemes found in hardware-based solutions are as follows:

- *2N:* One node in standby for every node in operation. For example, two independent cPCI chassis providing redundancy at the central processing unit (CPU) and input/output (I/O) level.
- *N+1:* One standby node for N operational nodes. For example, two cPCI chassis with crossover providing redundancy at the CPU and I/O level.
- *N+M:* A pool of N nodes working in normal operation with a pool of M nodes in standby. This is more typical of distributed systems, where nodes are active and also the standby of each other.

FT/HA Software Solutions

As discussed before, hardware fault tolerance usually relies on redundant processors, memory, buses, power supplies, and disk storage. Software fault tolerance, on the other hand, uses a combination of software redundancy and simple hardware redundancy to provide the necessary availability in the case of failure. Unlike hardware fault tolerance, software fault tolerance is absolutely necessary to provide system-wide redundancy. A major technology differentiation of HA systems is the inclusion of configuration and fault-management software functions, enabling the detection, diagnosis, isolation, recovery, and repair of faults anywhere that could result in the failure of the HA system. This section discusses how the OS, management middleware (MM), and application software can provide FT/HA functionality.

Operating System

HA systems put certain requirements on the OS. Some of the important requirements are as follows:

- *Memory Address Space Protection for Kernel and Applications:* Support for virtual address space. With this type of memory protection, the active process cannot corrupt the memory space of other kernel processes and applications in the system.
- *Robust Kernel:* The OS should be able to isolate and prevent the propagation of, or mask the impact of, potential hardware and software faults.
- *Ability to Deal with a Dynamic Hardware Configuration:* An HA–aware OS must be able to support the dynamic reconfiguration of applications and drivers as faulty hardware is replaced with healthy hardware. This "hot swap" support should include fast restarting of applications and dynamic installation, and an update of device drivers.
- *Support for Fail over Mechanisms:* The OS should be able to respond rapidly to faults and fault-recovery procedures. The OS should be able to support fault recovery as dictated by policy management.
- *Interface to MM:* For the management of the OS itself and the ability to report faults externally.
- *Support for On-Line Upgrades*

Management Middleware

Management middleware provides a set of configuration and fault-management capabilities. MM typically contains direct interfaces to the OS, to hardware devices, and to the applications, and it adds additional capabilities, such as messaging or state replication services, to an OS.

The following are some other important capabilities of MM:

- *Fault Management:* Detects, diagnoses, isolates, recovers, and assigns the role and repairs the faults anywhere in the HA system. MM may also support prediction of faults by looking at changes taking place in the system.
- *Availability Management:* Collects data, does role assignment, and performs rapid recovery in conjunction with fault management.
- *Resource Interfaces:* Provides interfaces to the OS and application.
- *Systems Model:* Manages configuration and dependencies among system-wide components. This also maintains a state-aware model of the total system.
- *Operations, Administration, Maintenance, and Provisioning (OAM&P) Interfaces:* Provides local and remote interfaces to view and manage the system or its components for control and intervention.
- *Messaging Services:* Supports checkpointing and inter-application messaging.
- *Support for On-Line Upgrades*

Application

The application software may or may not be aware of the underlying HA system infrastructure. Application software will typically interact with the OS and MM no differently than in non–HA systems. In case the application needs to be made aware of the underlying HA system infrastructure, there must be an interface between the application software and the MM. This interface may provide access to services unique to the HA system, such as checkpointing application state or heartbeating.

Current Challenges

Legacy fault-tolerant systems were built using special fault-tolerant hardware platforms that were, in many cases, designed specifically for the application/service that they were to host. In addition, fault-tolerant applications were constructed from scratch and were expensive to design, produce, and maintain. Along with specific hardware and applications, the system-management software was also designed for the specific system that it was supposed to manage. In such cases, the FT/HA software might be available in binary form only, rather than source form. This would limit the available platform choices. For the system designer to be able to select a different board, processor and OS for a specific application, the availability of portable software—written in a popular programming language—is paramount. Otherwise, system designers and engineers will be forced to make a platform choice that may not be suited to their needs: They will be precluded from choosing alternative platforms that would work better for their application or provide cost or other competitive advantages. Moreover, they will not be able to modify the software to provide their own proprietary value to the end product.

Some other important limitations of current software solutions include the following:

- They execute the same software simultaneously on both active and standby nodes. Using this solution, the entire system could fail, since the same fault could occur in the software on both nodes at the same time.
- Some systems are unable to protect individual software instances separately if both the instances are on the same node (either active or standby). This amounts to an "all or nothing" solution. A more flexible approach is to distribute the protected instances on separate nodes as appropriate for their application. The benefit of this approach is easier fault detection.
- Some systems are unable to detect and resolve sequential faults. It is possible for an error to occur during the recovery period of another fault. The second error must also be considered and resolved in a graceful manner (e.g., first queued, and then processed after the first error has been resolved).
- Some systems are incapable of rolling upgrades and therefore are to be taken off-line to perform planned maintenance.

Trillium's FT/HA Solutions

Trillium's source-code software solution provides a flexible framework that is platform-independent and cost-effective. Trillium provides FT/HA communications layers and stacks that can be classified as applications that provide service to a system user. This FT/HA solution maintains active calls during software and hardware failures. Provided in source code, the Trillium solution gives systems designers and engineers total freedom when choosing their hardware platform and OS (kernel or user space). Developed primarily for telecommunications products, the Trillium solution is also applicable to other types of products requiring high availability.

Trillium's solution does not employ the standby node to execute the protected application at the same time as the active node, thereby protecting the system from "mirror-image" errors that could occur on both nodes. Instead, the active node updates the standby node's internal states, so that when the standby node becomes "active," it will start executing the software based on the most recent update. This approach does not allow the propagation of a software fault from the active node to the standby, since the standby is not executing the same segment of the code at the same time as the active node. Therefore, the system can potentially bypass a software problem that may occur in the active node.

Trillium's solution includes an FT/HA core product, plus a series of technology-specific products, each called a FT/HA protocol-specific function (PSF). Trillium's FT/HA core software product can be used on systems consisting of either hardware–fault-tolerant nodes or non–hardware–fault-tolerant nodes.

The FT/HA core enables system designers and engineers to replicate a node and turn those nodes into a FT/HA system. Trillium's solution can be used for open service platforms, which in turn can be used as a basis to create other products. For example, it can be used for a service control point (SCP), which accesses databases for telephone number translations. The Trillium-enabled SCP is able to use the dual-node architecture using either a telecommunications board manufactured by any of the major hardware providers or a board developed in-house, and it is able to use any multi-tasking OS. For other systems, such as an intelligent peripheral (IP), the multi-node approach using the Trillium solution can provide the high level of availability that is required by such systems.

For specific telecommunications applications, Trillium develops the FT/HA PSF for particular technologies (e.g., signaling system 7 [SS7], asynchronous transfer mode [ATM], integrated services digital network [ISDN], H.323), providing a complete solution for FT/HA systems. The user need only place an application, such as a mobile application part (MAP), on top of this stack and configure the protocol stack for its particular requirement specifications.

Trillium's FT/HA solution provides the following functionality:

- Maintenance of all active calls during software or hardware failures by updating the states of the standby node without execution of its state machine.
- Alarming the stack manager software when a fault occurs within the protected layer and carrying out a forced switchover. The stack manager is a system-dependent function and must be implemented by the system designer. Once the stack manager has received a failure indication, it can initiate corrective action by invoking Trillium's system manager to carry out a forced switchover.
- Protection of a single application (layer) or multiple applications (stack) with each layer residing in separate nodes or multiple nodes. When a node fails, Trillium's

FT/HA software will reroute the messages destined for the failed node to another operational node.

- Trillium's FT/HA software will work in a system in which the stack manager carries out a controlled switchover for operator-initiated routine maintenance. The stack manager "requests" the switchover, and the software subsequently carries out the "request."
- Trillium's FT/HA software will work in a system designed to detect and resolve sequential errors. The stack manager must queue the errors and notify the software.
- Trillium's FT/HA software supports rolling upgrades, thus ensuring five nines of availability even during planned maintenance.

Most equipment manufacturers use a dual-processor architecture with active and standby subsystems. Trillium's FT/HA solution enables the standby subsystem to maintain state information through state updates from the active subsystem. These updates prevent the loss of state information, enabling an orderly switchover procedure from the failed subsystem to the standby subsystem. *Figure 4* illustrates this functionality.

Trillium's DFT/HA Solutions

Trillium's portable FT/HA solution has been extended to include distributing the processing load across multiple processors. These solutions, called DFT/HA, provide the high performance and scalability demanded by network infrastructure manufacturers.

The patent-pending DFT/HA software, coupled with Trillium's broad suite of communications software solutions, will enable manufacturers to build products meeting today's stringent carrier-grade telecommunications requirements. The Trillium's DFT/HA products are designed for the active/standby dual-node architecture and scaleable multi-node architecture, which allows for the number of active and standby nodes to be configured and for the active nodes to share the system load. In this way, different processors can be active and standby of each other, providing an N+M configuration. *Figure 5* shows this functionality. This N+M configuration goes beyond the pure distributed solution, with no standby nodes in the system. In the non-redundant solution, if the active node goes down, the services provided by that node are no longer available.

Trillium's solution includes the DFT/HA core product and a series of technology-specific products, each called a FT/HA PSF and load-distribution function (LDF). The LDF distributes the traffic of a protocol layer onto multiple hardware nodes to increase the traffic-handling capacity of the protocol layer. Currently, Trillium's DFT/HA solutions include the popular transactional capabilities application part (TCAP) (TCAP, SCCP, and MTP3) and ISDN user part (ISUP) (ISUP, SCCP, and MTP3) stacks.

These solutions add the following functionality to the existing FT/HA solutions:

- *Flexible Architecture:* DFT/HA allows manufacturers to design distributed FT applications, pure distributed applications, and pure FT applications. A DFT/HA solution supports 2N, N+1, and N+M (same as N+1, when M is 1) redundancy schemes.
- *Load Distribution and Scalability:* DFT/HA supports multiple active processors simultaneously with multiple

FIGURE 4

Trillium's FT/HA Solutions

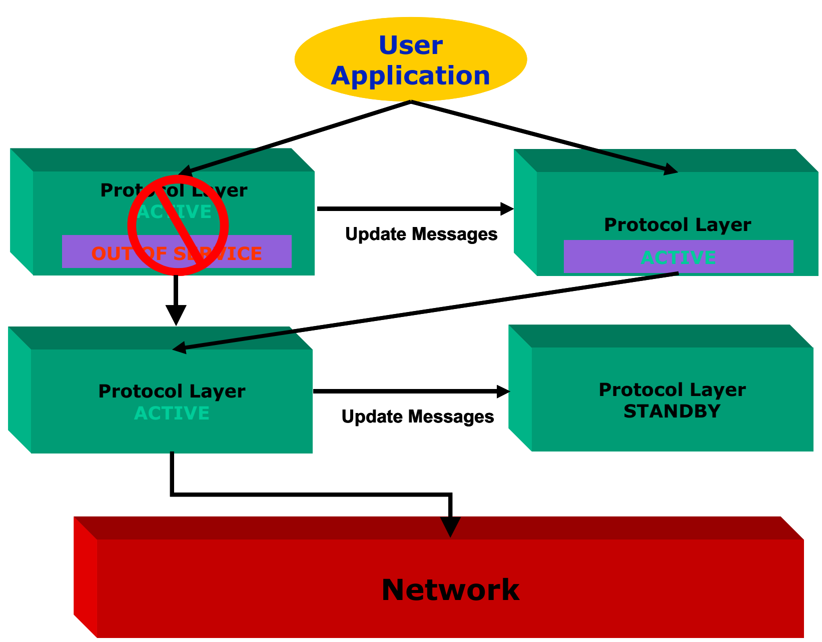


FIGURE 5

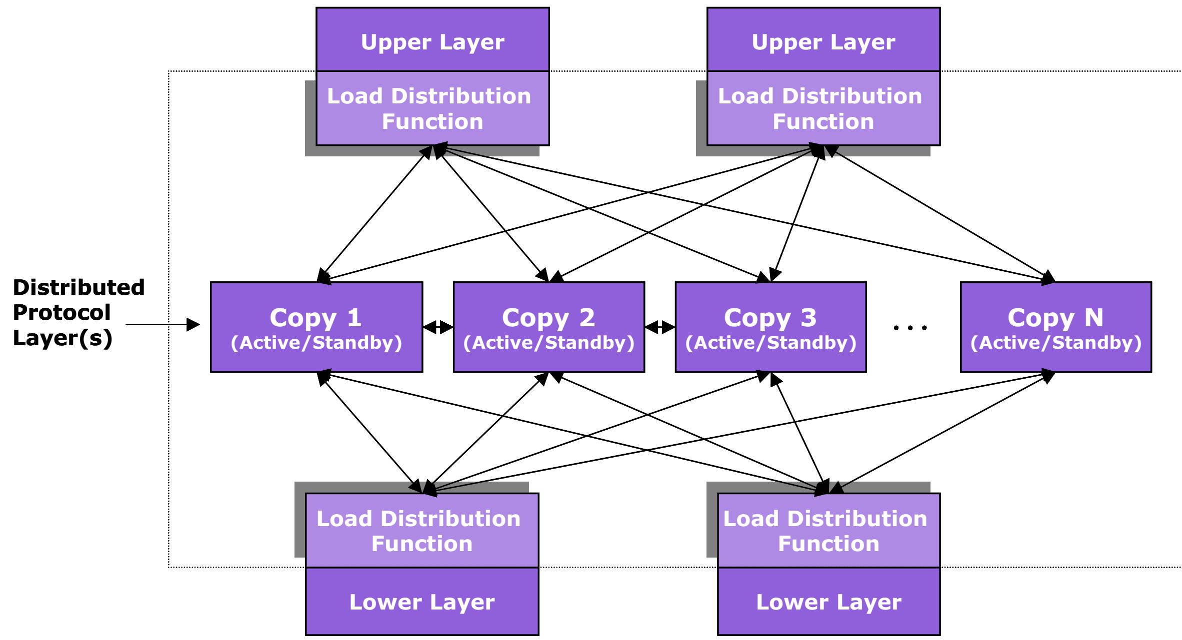
Trillium's DFT/HA Solution



standby processors, thus avoiding the need to reconfigure the system's architecture when it needs to be expanded to handle the extra traffic.

- *Smooth Migration Path:* DFT/HA allows the co-existence of both distributed and non-distributed software layers within a protocol stack.

Summary

HA products and services will play an increasingly important role in the network of the future. The availability of services is a complicated function of the equipment design and also of the network design. Different design choices will result in different levels of complexity, cost, performance, potential information loss, and (of course) availability. The reliability and availability of the public telephone network has set the standard against which future services from an integrated Internet and PSTN infrastructure will be measured.

For mission-critical applications such as telephony, FT/HA systems are vital. To achieve FT/HA, Trillium has undertaken a substantial development effort in recent years to enable it to offer a FT/HA solution that is flexible and platform-independent. Because it is offered in portable source form, Trillium's FT/HA software solution does not force users to limit their choice of hardware platform and OS (unlike binary solutions). Trillium's solution gives system designers and engineers the freedom to select the optimal platform for their specific application and to focus on ways in which they can add proprietary value to their products with an optimized investment of time. In addition to supporting Trillium's existing fault-tolerant capabilities, the new patent-pending DFT/HA architecture enables high performance and scalability in a system by distributing a protocol layer across multiple processors while maintaining fault-tolerance support.

OSS Microcosm: Time to Think Afresh

Ashish Srivastava
Practice Head, OSS

Dinesh Rathi
Consultant, Process Management
Wipro Technologies

Introduction

We have all seen the network building frenzy that caught on like a bug last year. Operations support system (OSS) implementation followed the trend. The best and only the best was the *mantra*. What ensued is now a well-known fact. A rare few exist to share the experience of those mindless implementations with little strategy. It is rightly so that today the service providers are ever more cautious to safeguard their investment and make sure that every penny of OSS worth is brought in at the right time at the right price.

It will be, however, too simplistic to assume that everything that is happening on the service-provider front is right from the OSS standpoint. Rapid changes in the business plans of organizations keep making the OSS solutions obsolete, even before they are implemented. The organizations are creating and recreating themselves almost on a monthly basis in an attempt to discover the magical formula for success. The ideal product mix is still a mirage. These are definitely no ordinary times. What is required is a fresh approach to the OSS implementation.

Pitfalls of Classical OSS Strategy

The classical OSS strategy is based on many assumptions, which need revalidation in the current context. Some of them are being covered here.

Myth 1: Organizational Model Needs a Focus
How the service providers started being "network-centric" has long been discussed. They then became "service-centric," graduating to "customer-centric" model. Such hair-splitting discussions have lost their value in the current scenario. There cannot be one center of this complex world of OSS at any point of time. Try to focus on the customer, and you can safely bet that your internal organization will never catch up with the customer demands. Focus inwardly and be sure that the customers have walked away before you can say "VPN." Start debating about your product mix, and the yawning customers would have moved on while your sales department waited on the sidelines like an army without arsenal.

How does the OSS strike the right balance?

Myth 2: OSS Is a Strategically Well Planned Affair
The Big Bang approach has long since been rejected. The recommendation was to iteratively evolve the OSS in a well-planned manner. So where is the catch. Well, the fact is that there is too much flux in the operational plans of the service providers. There is no long-term basis to act as a foundation for the long-term OSS strategy. The OSS solution has to contend with five cardinal truths of today's business:

- Products will change.
- Market will change.
- Processes will change.
- Organizations will be ever evolving.
- Solutions will be ever evolving.

Where in the world can we find a super-flexible OSS that allows adapting to the needs of the service provider at will? Even the loosely coupled OSS integrated through middleware architecture can go haywire in the first few cycles of change.

Looks like we have hit the wall when it comes to OSS implementation.

Myth 3: OSS Comprises of Independent Functional Layers
The TMN Forum's functional hierarchy of layers of OSS management is etched in every mind related to the field of OSS. It is an undisputed fact that this structure by itself brought a lot of clarity to understand the OSS implementation. However, this model leaves a lot of holes in terms of adequately relating the OSS to the rest of organization and the customer.

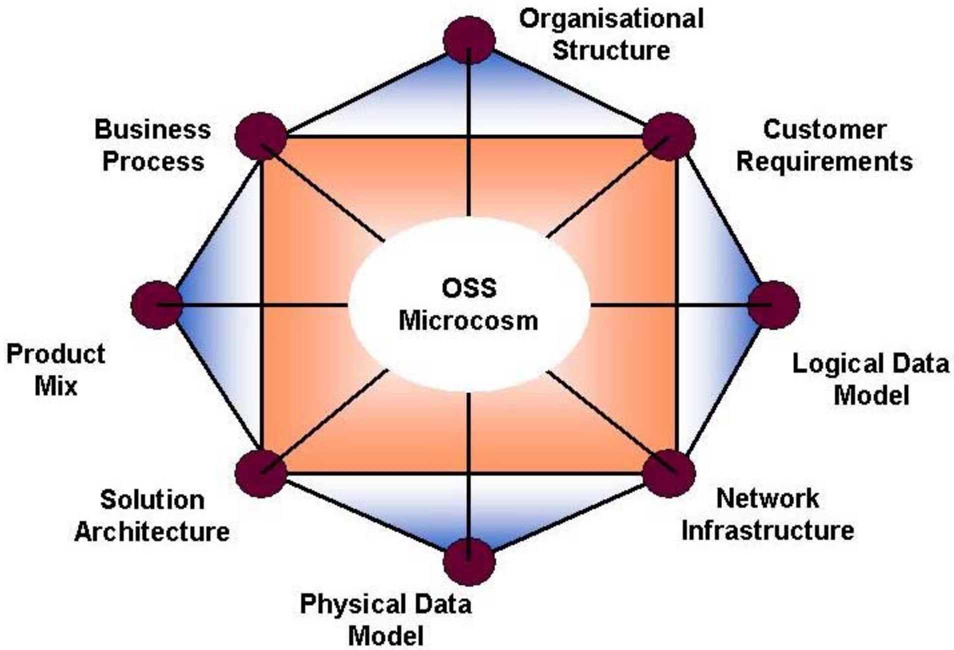
OSS is no longer a set of functional layers that can be managed independently. The interrelationship of OSSs and business support systems (BSSs) runs deep within the organizational processes. Unless a bond between the business and the solution is established, the chances of success are dim.

OSS Microcosm

It is time to look at OSS in a different way. These are times that require reliability, flexibility, and economy of scales all together. To achieve this, we have to break the old-world view of an OSS being just a bundle of individual or integrated solutions. The OSS has to be viewed as an integrated mesh of varied factors. Change one of them, and you have a ripple effect on the others. It is important to move all of them together in any evolutionary model of development. We will call this interrelationship an OSS microcosm.

Figure 1 shows the visual representation of an OSS microcosm.

FIGURE 1



Microcosm Management

The very complexity of the model may dissuade the systems integrators (SIs) as well as service providers with the enormity of the task of managing and implementation. The problem, however, is not such a discouraging one. All it requires is a combination of methodology and discipline. The following three simple tenets, if followed to the core, make the whole issue a manageable one (see *Figure 2*):

- Manage business processes.
- Manage traceability.
- Manage change.

Let us look at each one of them, one at a time.

Business-Process Management

The business processes are often treated in isolation. They are often treated as independent to the core OSS solution. Business wisdom dictates that the business dictates the process and that the process dictates the solution.

However, we often fall into the trap of technology and follow the aforementioned principle in reverse by allowing the solution to dictate the process. This should be watched for carefully. In the short run, the application-dictated process leads to fast implementation but proves to be inadequate for the growing business needs.

The key to efficient process management lies in the way the processes are modeled and represented. A hierarchical approach of process representation is the most common one and serves the purpose well. A typical hierarchy includes the following:

- *Level-1 Processes*: Indicating the functional organization.
- *Level-2 Processes*: These are the processes at the organizational level.
- *Level-3 Processes*: Represent the break-up of the level-2 processes to the next level of detail. These include the sub-activities, the input and the output details, and the business/validation rules.
- *Level-4 Processes*: These are the operational procedures used by the end users.

Using a tool for process modeling is a good idea. Tools allow for greater accuracy, version control, and advanced features such as simulation to check out the efficiency of the process.

Some important points to note in process modeling are as follows:

- All of the processes do not get automated on day one. It helps to segregate the manual and automated processes (preferably at level 3). This helps in keeping track of the changes to operational procedures as the solution evolves and encompasses more and more of the process.
- The process handoffs should be carefully noted so that the integration can be carefully tracked.
- The level-3 processes should be at a level of detail at which they can be mapped to the solution requirement.

Traceability Management

We have discussed before the interdependencies between various entities of the microcosm. Without a formal way to track the traceability between these entities, it will be but a matter of time before chaos takes over. There will be no way to judge the impact on any one of them due to the others.

FIGURE 2

However, traceability management is no joke. From the OSS perspective, I recommend that traceability to be managed within the quadrant in *Figure 3*.

It is very important to note that the business processes translate into a solution through two different paths:

- Through the functional requirement
- Through the data model

It is also necessary to ensure that the traceability within these entities is maintained for all of the products. It is true that a large part of the solution or processes may not change with products, but then there will be some product-specific parts that need to be tracked as well. What works well for one product may not always work well for another.

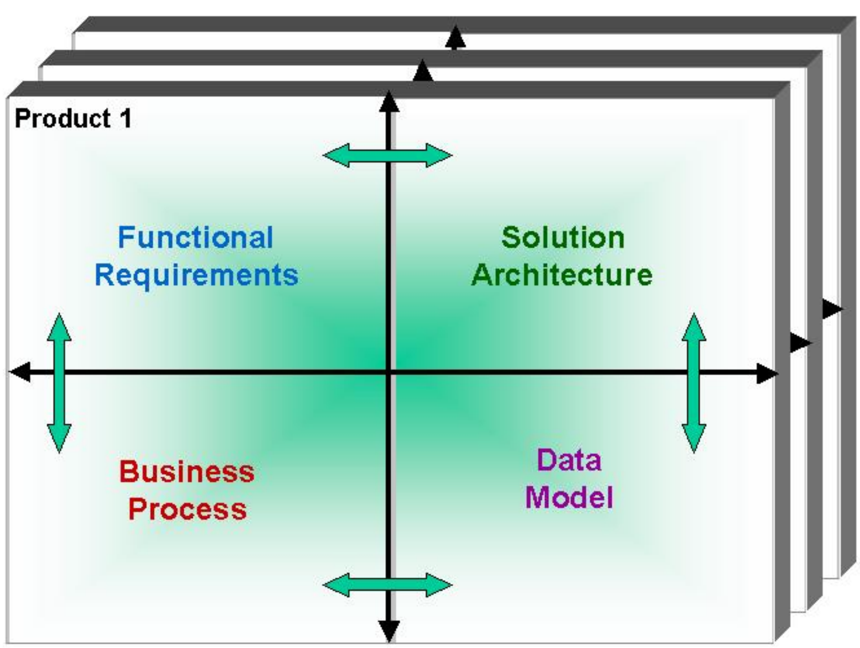
Business processes at their detailed level are nothing but functions and data. Functions are important for the end users. They understand the language of functionality that they would need to run their part of the business. This functionality is what they would expect to see in the solution.

A solution architect's point of view is, however, different. It is imperative to have a robust architecture that is scaleable and devoid of data redundancy and data integrity issues. This is achieved by mapping processes to a data model, which should then translate into the solution architecture.

Unfortunately, there is no single tool that can claim to manage all of this traceability together. Lack of a single tool often discourages integrators to map traceability efficiently. The result is a loss of the holistic picture and a divergence of the processes and the solution. However, the tool issue is often exaggerated. There are off-the shelf tools that help to map the processes to the data model. Then there are tools that derive the data model from the solution. There are a host of requirement-management tools that help to keep traceability a requirement of the solution. A good combination of these will achieve the purpose. If managing multiple tools is an issue, the good old Excel spreadsheet is better than having no traceability at all.

FIGURE 3

OSS Microcosm: The Traceability Quadrant



Change Management

The last important tenet for managing the OSS microcosm is having a controlled change management. We touched upon the inevitability of change at the beginning of this paper. The issue is to manage that change so that if one entity changes, the impact on all of the other entities is taken care of. This ensures that the interrelationship retains its integrity.

From the OSS perspective, change can occur from many sources. Some common change triggers are as follows:

- Organizational structure change
- Business-process change
- Functional requirement change
- Solution changes

If the previously discussed issues of process management and traceability have been well addressed, the change management is a cakewalk. The crucial steps in change management are as follows:

- Initial assessment of the change
- Notification of the change to all stakeholders
- Impact analysis of all the affected entities
- Change implementation strategy

It should be noted that it is not always possible to propagate changes to all of the affected entities instantaneously. There will be a period of time when the discrepancy in the interrelationship has to be managed. This requires a clever strategy.

Figure 4 shows an example of how an interim discrepancy can be managed through a temporary stage of work around. At the earliest next opportunity, all the entities are brought in synch and new traceability is established.

Summary

In the current times, it is important to see the OSS as being an integral part of a meshed relationship in a service provider's business. Most important are the relationships of the OSS solution to the business process, functional requirement, data model, and product offering. We have termed this interrelationship as an OSS microcosm.

To be able to manage the microcosm, it is important to manage the business processes, traceability, and change control. With the aforementioned approach in place, OSS is likely to be in sync with the business objectives and will be able to sustain its integrity in a rapidly changing environment.

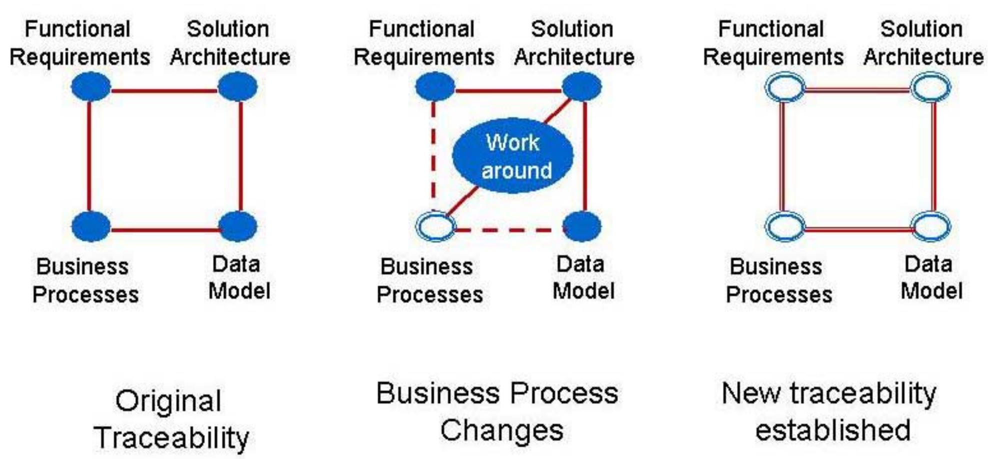
OSS Microcosm: The Change Life-Cycle



Real-Time Billing in SIP

Baruch Sterman

Chief Scientist

deltathree

1. Abstract

Session initiation protocol (SIP) [1] is fast becoming the protocol of choice for Internet protocol (IP)–based communications—specifically telephony (voice over IP, or VoIP), video, and instant messaging. SIP's strengths lie in its e-mail–like addressing scheme, its plain-text headers (similar to hypertext transfer protocol [HTTP]), its scalable architecture, and most of all in its ability to carry generic data (following the multipurpose Internet mail extensions [MIME] standard of e-mail fame). Though interconnecting a SIP call leg with the legacy phone system (public switched telephone network, or PSTN) is well defined and communication flows seamlessly, the billing model regnant in the telephony world does not mesh quite so naturally with SIP. For example, the ubiquitous pre-paid calling-card services require querying the account status before a call is authorized and a real-time adjustment of the balance as soon as a call terminates. SIP does not address either of these functionalities. This paper will examine the requirements of such systems and suggest possible implementations within an SIP architecture.

2. Review of SIP

2.1. Introduction to SIP

SIP is a signaling and session-management protocol that is meant to establish a communication session between two IP–based endpoints. SIP provides the capabilities to do the following [2]:

- *Find the Target Endpoint:* Endpoints are addressed in a format similar to e-mail, i.e., user@InternetAddress, where the Internet address may be either an IP address or a fully qualified domain name, such as "deltathree.com."
- *Negotiate a Common Method of Communication:* Different users may have different capabilities. In a SIP message, each user lists its own set of codecs that it supports and the precedence of each. This information is carried as session description protocol (SDP) in the body of a SIP message.
- *Manage the Session:* SIP messages are defined to set up and tear down a communication session and can pass information between the two endpoints outside the media channel.

2.2. SIP Network Elements

The basic elements that form the building blocks of a SIP network are the following:

- *User Agent:* These are the endpoints that initiate and terminate calls. Examples of user agents are IP phones, software clients, and IP voice gateways that interconnect with the PSTN (the legacy telephone network).
- *Proxy Server:* Proxies forward SIP messages on to other SIP network elements according to rules that are defined within the proxy.
- *Registrar:* The registrar is used to dynamically track the location of user agents and forward messages to their provisional address. Typically, a user agent will "register" with a registrar and provide the information regarding its current address (i.e., IP address). The registrar will then forward calls destined for the registered user on to the specified location.
- *Redirect Server:* This server is similar to a proxy, but instead of forwarding messages, it responds to SIP requests with the location of a user agent or server. The entity that sent the request will issue another request directly to the location specified by the redirect server.

Often, proxy software contains proxy, registrar, and redirect functionality. A proxy may also keep a set of rules that determine how to route calls when the attempt to establish a connection with a user at its default location fails. An example of such "location service" rules would be to reroute a call to another SIP address when the primary address is busy or unavailable.

2.3. SIP Messages

The common SIP messages are the following:

- INVITE: Initiated by a user agent inviting a second user agent to participate in a session.
- ACK: Acknowledgement that is returned confirming that the user agent has received a final response (as opposed to a provisional response, such as "trying" or "ringing").
- BYE: Indicates that one endpoint user agent is terminating the session.
- REGISTER: Contains the location information necessary to reach a user agent.
- CANCEL: Indicates that a pending request should be cancelled.

2.4. SIP Responses

SIP responses are similar to HTTP. Responses are numbered, with the first digit indicating the type of response. *Table 1* shows the different response types.

TABLE 1

SIP Response Messages

Response Group	Description
1XX	*Informational:* Indicates status of call prior to completion.
2XX	*Success:* Request has succeeded.
3XX	*Redirection:* Server has returned possible locations.
4XX	*Client Error:* The request has failed due to an error by the client.
5XX	*Server Failure:* The request has failed due to an error by the server.
6XX	*Global Failure:* The request has failed.

2.5. Why SIP

SIP offers the following benefits:

- *Simplicity:* SIP messages are encoded in plain text and are easy to understand and troubleshoot. A SIP stack is much lighter than other VoIP stacks.
- *Distributed Functionality:* The proxy/forward approach utilized in SIP encourages distributing intelligence throughout the network. A call may flow from proxy to proxy, each working on the call with its own logic and functionality. Changes can be made to one component while leaving the others untouched.
- *Extensibility:* SIP is very flexible in that the message body can contain attachments similar to e-mail. User agents are free to use SIP for any type of communication, as long as both endpoints can process the attached information.

2.6. SIP: Past, Present, and Future

SIP was initially proposed as a method of inviting users to join in large-scale multicast conferences. It was soon realized that SIP could be used to establish point-to-point IP phone calls as well. By 1999, SIP was a proposed standard for establishing communications sessions. Over the next few years, device manufacturers, software vendors, and service providers got together at "bake-offs" to test the interoperability of their SIP components. In November 2000, the third-generation partnership project (3GPP) wireless initiative adopted SIP as its protocol. Further validation of SIP came in the spring of 2001, when Microsoft announced that its Messenger platform and voice services (released in the fall of 2001) would be SIP–based. Device manufacturers and application developers are continuing to roll out SIP–based products and services.

3. SIP Call Flows

3.1. A Simple SIP Call

To get a better understanding of SIP and how it works, an example of a call flow between a user agent, a proxy server, and a voice gateway is described (see *Figure 1*).

The user agent initiates a call by sending an INVITE message to the proxy server. The INVITE message contains the information necessary for the target endpoint to open a media channel to the user agent. This information includes the IP address and port of the user agent, as well as the codecs that the user agent supports. The proxy forwards the INVITE message to the voice gateway. (When the proxy receives the INVITE message from the user agent, and when the voice gateway receives the INVITE from the proxy, a 100 Trying response is returned, but that is not shown in the call-flow diagram in *Figure 1*.) The voice gateway sends out a signal initiating the call to the PSTN and informs the proxy (which in turn informs the user agent) that it is ringing the destination. When the call is answered, the voice gateway sends a 200 OK back to the proxy. This message contains the gateway's information that the user agent needs in order to set up a media stream back to the gateway. When the user agent receives the 200 OK, it responds directly to the gateway with an ACK. At that point, the call is in session, and the two endpoints pass media directly between each other. When either side wants to terminate the call, a BYE is sent from one endpoint to the other, and an ACK is returned.

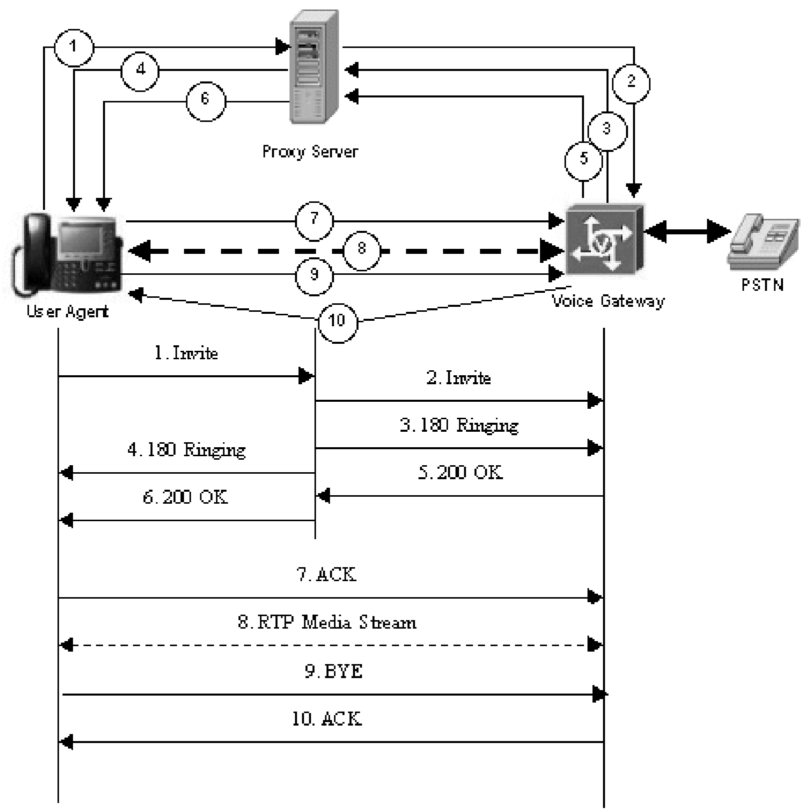
In this example, once the proxy facilitated the call between the user agent and voice gateway, it dropped out of the call flow, and the two endpoints continued the session management directly between themselves. In some cases, it may be desirable for all session management to flow through the proxy. This may be for security reasons (i.e., the voice gateway is configured to accept messages only from the proxy) or because the proxy needs to be aware of all messages in order to supply certain functionality. SIP defines a "record-route" tag that is inserted in the SIP message by the proxy for such situations. All subsequent messages must then flow through the entity (or entities) addressed in the "record-route" tag(s).

3.2. Registration

SIP defines a method for a user agent to inform a server of its location. The user agent "registers" with the registrar of

FIGURE 1

Simple SIP Call Flow



its domain, so that when a SIP message headed for that user reaches the domain, the registrar knows where to forward the message. The registration message contains a "TO" field, which defines the SIP address for which messages are intended, and a "CONTACT" field, which holds the forwarding address where the user can currently be reached. The registration is valid for an amount of time defined in the EXPIRES parameter.

The following scenario (see *Figure 2*) shows an example of a user agent registering with a registrar, and then being contacted by another user agent via that registrar.

The first user agent (*baruch@deltathree.com*) registers with a registrar and sets its contact information to baruch@123.1.2.3. Another user sends an INVITE over the Internet to *baruch@deltathree.com*, and that message is routed to the SIP proxy/registrar for the domain deltathree.com. The proxy/registrar looks up the user *baruch* in its registration database and forwards on the INVITE message to the user agent at IP address 123.1.2.3. From then on, the call flow continues as in the previous section.

3.3. Authentication

To deny service to any request that does not come from an authorized user, SIP defines an authentication protocol that allows users to identify themselves with a username and password in a secure manner. SIP supports both basic and digest authentication; basic sends the username and password in clear text while digest passes the password in encrypted form. When a user agent attempts to register or sends an INVITE to a proxy, the proxy/registrar responds with a 401 (or 407) response, indicating that authorization is required (see *Figure 3*). (If digest authentication is used, that response also contains the information necessary to build a secure transmission, which includes the encrypted password.) When the user agent receives the response, it will reissue the REGISTER or INVITE, but this time it will include the necessary authentication information (incorporating the security information just received, in the case of digest authentication). The proxy/registrar will test the username and password against its own data, and if they are valid, it will process the request accordingly.

3.4. Additional SIP Capabilities

SIP was designed to be open and flexible, and as a result it can be used for many diverse applications. One can build on SIP's location and session negotiation capabilities and apply them to various situations. In some cases, extensions have been defined that stretch SIP's functionality even further. Also, SIP is still very much a work in progress, and various additions and subtle add-ons are being suggested and worked on.

Some additional applications where SIP is being used include the following:

FIGURE 2

Registration and Inbound Call

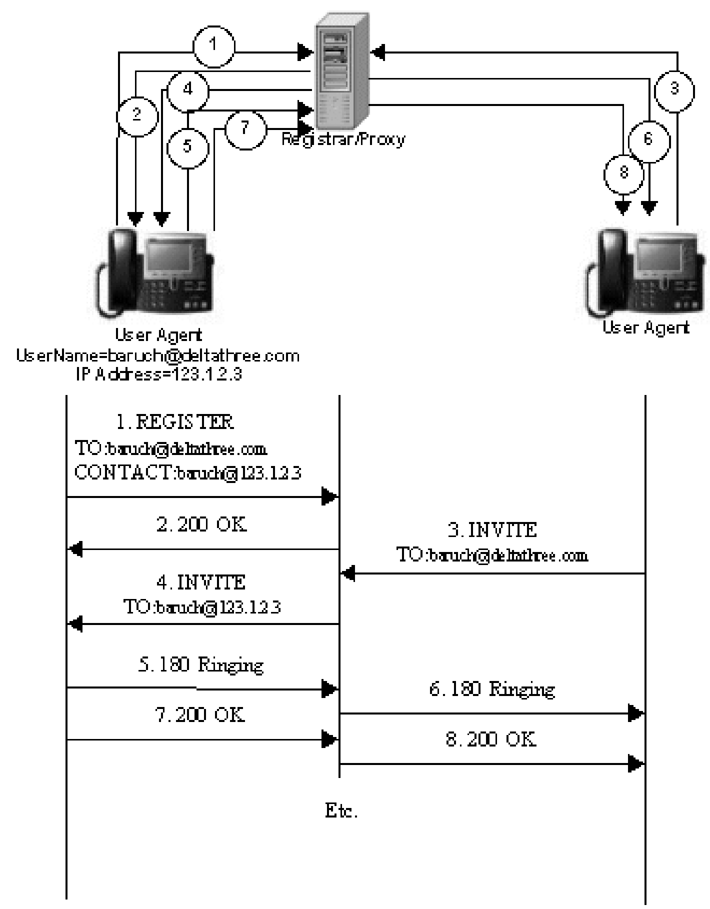


FIGURE 3

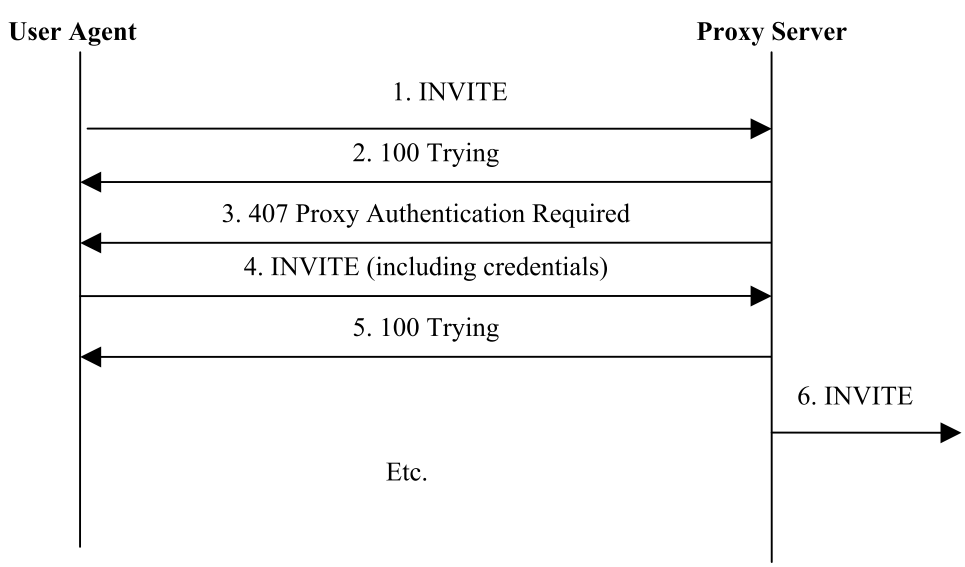
Authentication Flow



- *Presence:* SIP's registration infrastructure provides the foundation for centralized tracking of users' location and status. SIP can be used to build buddy lists and other presence-based programs.
- *Instant Messaging:* Instant messaging applications typically send short text messages between parties. SIP can accomplish this easily, since it already has a location mechanism and supports text attachments to the SIP message.
- *Event Notification:* SIP defines a Subscribe/Notify message header that is used by a user agent to request that a server or user agent inform it when certain events occur. One example of this might be an IP phone subscribing to a voice-mail server and requesting that it be notified when a message comes in. The IP phone would receive a message in the event that mail is received, and the phone might then switch on a "message waiting" indicator to let the user know that the voice mailbox should be checked.

There are numerous other examples of SIP–based applications. Any situation that requires communication over the Internet between two or more endpoints might be implemented using SIP. As SIP matures and is more widely deployed, and as developers become more aware of its capabilities, we can expect to see SIP–based applications becoming ubiquitous.

4. Pre-Paid Billing

In February of 2001, I attended a SIP conference where a well-respected expert was discussing SIP–based Internet telephony. I stood up and asked him how SIP intended to deal with billing, specifically with per minute charges. Since SIP deals mainly with sessions, per-session billing is not a problem. But, as an Internet telephony service provider (ITSP) that bridges calls between IP–based endpoints and the PSTN, our costs are based on the PSTN billing model (per minute), and so we need to charge our customers accordingly. The speaker explained that within a few years, the legacy telephony system would be completely replaced by VoIP and that, just as no one thinks of billing per e-mail, so too telephone calls would be bundled in a flat monthly service charge for IP connectivity.

Needless to say, I was not convinced, and that night proceeded to write an Internet draft that proposed a method of interfacing SIP calls with RADIUS (remote authentication dial-in user service, a standard protocol used by many billing systems). A few months later, Microsoft came out with their requirements for ITSPs wishing to terminate SIP–based traffic from their Messenger client, and per-minute charges were an essential component. As long as telephony costs are linked to usage, Internet telephony must reflect that in its billing model and must bill in real time. If not, the potential fraud risk will be enormous, as clever hackers will find ways to take advantage of loopholes, to exploit the reliance on statistical methods (such as building a rate plan based on assumed average usage), and to use any delay in updating or processing billing information to overuse an account's resources.

4.1. Real-time Billing Considerations

The majority of retail sales for VoIP applications come from personal computer (PC)–to-phone (a software client running on a PC) or phone-to-phone (via interactive voice response [IVR] gateways). Users typically sign up for these services via the Web or purchase calling cards with account information already provisioned. In either case, the model is normally a pre-paid one, where a defined amount is credited to an account and the balance is updated immediately upon termination of a call. It is essential that debiting the account balance occur as close to real time as possible, since an account must have the updated balance information available for the follow-on call. Before each call, a user's account balance is queried to make sure that there is enough credit to authorize the call. The balance is translated into duration based on the destination/origination rates for that particular user and call, and a timer is set to tear down the call if the user goes beyond the allotted duration available.

The algorithm for processing this type of billing structure is often broken into three steps: authentication, authorization, and accounting (AAA).

4.1.1. Authentication

The first stage involved in processing a call request is to retrieve an account identifier (e.g., a username) and password. In IVR systems, these are digits entered from the telephone keypad. In the case of IP–based clients, they must be passed to the server in a secure manner (in SIP this is accomplished through basic or digest authentication). Authentication means verifying that the account is valid and open for making calls and that the password matches one stored and associated with that account.

4.1.2. Authorization

The second stage verifies that the user is authorized to make this specific call (after the destination, or B-number, for the call is provided). Given a user's rate plan, account balance, and the explicit rates based on the origination and destination associated with this particular call, the billing server will return a maximum duration available. With this duration value available, the system (trusted user agent or network server) will start a timer and terminate the call if the call goes beyond the allotted duration. In the case of IVR–based calls, the voice gateway will typically have the timer functionality and the ability to close a call. In the case of IP–based clients, call teardown poses a more complicated problem, since the client usually cannot be trusted to terminate a call when funds run out.

It is imperative that the data available to the billing server for this calculation be current. If there is a delay between the end of one call and the account balance update, a user placing a follow-on call immediately after a previous one will have more credit available than should be the case. The maximum duration set for the follow-on call will allow the user's balance to run below zero, creating a liability in terms of collecting the funds owed.

I would like to stress the critical nature of fraud associated with IP–based calling products. On the one hand, the automated, on-line (and somewhat anonymous) nature of the provisioning process makes these applications particularly vulnerable to hackers and credit-card thieves. On the other hand, the costs incurred by the ITSP are real in that every minute originating from the ITSP's network and terminating on the PSTN will be charged to the ITSP.

So there is an immediate liability in terms of real money as soon as an account is opened, and a system that allows any loophole whereby a user can spend money without proper coverage will be exploited to the benefit of rogue IP telephony hackers.

4.1.3. Accounting

The last stages involved in the billing process are the recording of the call detail (CDRs), the final rating of the call, and updating the account balance. Again, this accounting must be done quickly in order for the follow-on balance to be accurate. To accurately determine the duration of the call, either the call start and stop information must be recorded and then correlated, or else at least one element in the network that can be trusted to know precisely the start and stop of a call must keep state and track the duration.

4.2. Centralized Authentication: Digest Authentication to RADIUS Mapping

SIP has no preferred method for implementing AAA functionality or billing. Indeed, since SIP is meant to manage the call session, set up, and tear down the call, it could be argued that billing is completely orthogonal to the scope and functionality of SIP. However, even in the earliest drafts, the authors of SIP began to address certain issues relating to AAA—namely authentication. Sessions originating on the Internet or other IP networks do not have the same trusted stature of a call coming from a dedicated twisted pair of copper wires that are physically attached to a device located at a definite address. In fact, the idea that authentication of the originating user is essential, and the notion that only trusted users will have access to certain services and applications available through SIP, implies either that those services may involve confidential information or that those services are billable. (Note that generally, e-mail does not require authentication of the sender, because the outbound-only nature of e-mail means that the sender is not accessing private information—only the receiving party has that constraint and so must provide a password. Also, e-mail is virtually never billed for on a per–e-mail basis.)

Whereas authentication was always considered part of SIP, authorization and accounting were not addressed. Most commercially available proxies have logging functionality that can usually be adapted for the purpose of CDR creation. Reading logs, however, implies a "batch" mindset where records are processed off-line at a later time. They are not especially suited for real-time billing applications. The fundamental requirements for real-time billing as described are a central billing service where each of the three As read from and write to the same data repository, and that information is updated transactively, that is, a follow-on call is available only once the previous call's information is processed and the balance updated. Systems working in this way need to "push" the information to the billing server at the termination of a call and not rely on writing the call information to some file or queue and waiting for the server to "pull" that information and process it.

Many legacy systems implementing real-time AAA use a protocol called RADIUS [3][4]. RADIUS is meant to provide the following functionality:

- Passing a user's password securely, not in clear text.
- Verifying that the RADIUS client is a trusted entity.
- Verifying that the RADIUS server is a trusted entity.
- Passing additional information between the client and server in a secure manner, ensuring that no one in between can tamper with the data.

To accomplish this, RADIUS makes use of a shared secret between the client and server. That shared secret must be specified to each party in a prearranged manner that is outside the scope of the RADIUS protocol.

Note that confidentiality is assured only to the password field; all other communication is guaranteed reliability (i.e., no one can change the data), but theoretically someone sniffing the data going back and forth could read the information.

RADIUS defines (among some other ancillary things) two messages: the authentication message and the accounting message. A client sends an authentication request including the username and password to the server, which responds with an accept or reject message. The accounting message has two subtypes: accounting start, sent at the beginning of a call, and accounting stop, sent on termination of a call, which includes all the information needed to create a CDR. All of these messages may also include vendor-specific attributes (VSAs), and, in that way, the client and server can pass information between them in a reliable manner. The RADIUS server will pass the information over to a billing service that reads and writes to a database and processes the information for the RADIUS server in order to determine how the server should respond to requests and what information it should pass back to the client.

The second A—authorization—requires the destination or B-number of the called party and, based on that information, determines the duration available to the user for the call. This can be implemented through the use of VSAs in either the authentication message or in the accounting start message.

As previously mentioned, in SIP, the username and password are verified using digest authentication (when security is a necessity). However, due to the different encryption and hashing (one way encryption) mechanisms used by digest and by RADIUS, there is no direct way of using the digest information and translating it to RADIUS. (The details of this are beyond the scope of this paper and can be found in [5].) We have proposed a mapping between SIP digest authentication and RADIUS that requires no changes to the SIP client but necessitates modification of the SIP proxy and RADIUS server. (These modifications have already been implemented in commercially available SIP proxies, such as Cisco Systems' CSPS product.) In this manner, a SIP proxy can authenticate a user from the data provided through RADIUS to a centralized server. Other SIP network elements may take care of authorization and accounting, again via RADIUS, to that same centralized server. Such a set-up will take care of the fundamental requirements for a real-time interface between a SIP network and a billing service.

4.3. Call Teardown and CDR Creation

Now that a real-time interface between the SIP network and billing service has been defined, the only thing still required in order to realize a pre-paid model is call teardown when the call reaches the maximum duration allotted. There are two suggested approaches as to where the element that is responsible for call teardown should be located. Each option has advantages and disadvantages, and the ultimate decision will depend on the specific network topography and other considerations.

4.3.1. Control at the Edge

The first model places the responsibility for tearing down a call at the edge—in the voice gateway that either terminates the call to the PSTN or originates the call from the PSTN. Many gateways (such as Cisco's voice gateways) have the functionality already in place to communicate via RADIUS and set timers and to tear down a call when the maximum duration is reached. The reason that this functionality has already been implemented in the gateways is that they are often used as IVR gateways for pre-paid calling-card (phone-to-phone) applications. Very minor modifications are necessary to get the same functionality to work from a SIP–based VoIP call, since all the necessary information is already present in the SIP message, including the B-number or destination, and the user information. When the call terminates, the accounting stop message is issued to the RADIUS server by the gateway passing all the CDR information back to the centralized billing service in real time.

An advantage of keeping this functionality at the edge is that the gateway is one network element that must always, in any case, keep state for the entire length of the call. It will, therefore, always be able to know the final duration of the call and can pass that information back to the billing service for processing. Without the duration, the billing process would need to correlate accounting start and accounting stop messages, adding to the processing time and resources required by the billing service.

A second advantage is that this solution scales with the gateways: As the number of ports required within a network grows, the number of gateways increases proportionally and the increased processing power needed for keeping state of all those calls is distributed over the gateways.

The major disadvantage of this scheme is that it requires that gateways be trusted elements not only within the SIP network, but also as billing entities. An ITSP may not be able to live with such a constraint if it wants to leverage least-cost routing to various partner termination (or origination) networks. If the gateway does not belong to the ITSP, then it may not be compatible with the RADIUS protocol implemented by the ITSP, or it may not be trusted to pass secure information across network boundaries. Along the same lines, there can be no billing for calls where both endpoints are untrusted entities or do not speak RADIUS. Calls from IP devices or software clients to each other—or to services such as conference servers, voice-mail programs, etc. that do not have built in RADIUS support and in any event would hardly be considered trusted entities—would not be able to be billed.

4.3.2. Centralized Call Control

The second model places the responsibility for call teardown in a centralized network element: the call controller. All SIP messages must pass through this element, which is responsible for authorization of the call (via RADIUS), for setting a timer that fires an event when the maximum duration is reached, and for sending out the SIP BYE messages to both parties when that event fires in order to tear down the call. The call controller would keep state of the call (from INVITE and 200 OK through to the BYE or timer firing) and write the accounting stop to the RADIUS server, including the call duration.

The advantage of this scheme is that any SIP call passing through the call controller can be billed regardless of the termination or origination characteristics of the endpoint. The disadvantage is that as a centralized network element, it is a single point of failure for network traffic and must be redundant, highly available, and scaleable in order to process and keep state on every call running through the network.

5. Conclusion

SIP stands poised as the method of choice for management of media transport sessions between Internet-based endpoints. Its advantages are numerous: It is highly extensible and flexible, easy to program and troubleshoot, and particularly well suited for the Internet. As such, important bodies and companies have already adopted it as their communications protocol; device manufacturers are building it into their products; and software developers are busy implementing applications and services that interoperate using native SIP.

The challenge for the service provider is to integrate SIP devices and software clients with the services and applications available and to bill for them. SIP by itself does not adequately address the problems and requirements associated with billing, specifically real-time billing in a pre-paid model that fits the particular demands and constraints of Internet users. An interface between SIP and legacy billing services is required. RADIUS offers a good prospect as the protocol for that interface, since many billing services already support it and the required mapping between SIP messages and RADIUS can be defined in a relatively straightforward manner. Development of specific billing entities that sit within the SIP network, or else some modification of existing network elements, may be required to achieve full integration between SIP devices and applications, and a real-time, pre-paid billing model.

Introduction

Virtually everything in life is governed by standards of some kind, and most people would agree that standards are a necessary part of working and living. However, standards are rendered worthless if they are not implemented and followed. And that is exactly what is happening in the telecom industry today.

For example, there are rigorous standards in place for signaling system 7 (SS7) that are not being followed. The SS7 signaling standard—established by the New York–based American National Standards Institute (ANSI), the primary body for handling telecommunications standards—was based on many months of study by numerous review boards composed of industry experts. These industry representatives found that, to ensure reliable service, diversity of many components of SS7 are required. SS7 has various reliability features for the same reason a 737 airplane has two engines—for backup. If an airplane had only one engine (and it can be airborne with only one), most passengers probably would be quite resistant to flying in it.

The primary SS7 standard relating to diversity—these standards are readily available either directly from ANSI or from the Alliance for Telecommunications Industry Solutions (ATIS) document center (www.atis.org)—is ANSI T1.111-1996. This standard was reaffirmed last year and will be ANSI T1.111-2000 when it is published. However, there are companies implementing SS7 without putting the required diversity in place, thereby rendering the standard meaningless.

Arguments Against Standards Compliance

A common argument against compliance with the established standards is that they are "voluntary." And this is true. In fact, the voluntary nature of standards is common over all industries, not just telecommunications. The concern, then, becomes whether these companies are selling products or services, such as toll telephone service based on a standard, even though they are not following the reliability aspects of the standard. That is misrepresentation. Moreover, such violations are not immediately visible. No one can tell just by picking up a telephone that a certain standard has or has not been followed. It is only when a failure occurs and customers are not able to make or receive toll calls that light is shed.

Some also argue that these standards may not be cost-effective. Many carriers are making a conscious business decision not to implement the standard requirements for diversity, using this reason (of not being cost-effective) to justify their decision. Considering some of the problems carriers are having, cost-effectiveness depends on what costs are included. Some costs, after all, are difficult if not impossible to quantify. For example, what is the cost to the public of not having the telephone service they are paying for? What is the cost to people that are unable to dial 911 and reach an emergency center?

Best Practices

The industry also has what are called "best practices." Following some severe SS7 signaling outages around 1990–1991, the Federal Communications Commission (FCC) asked the industry to meet, examine existing outages, and develop best practices that would, if followed, eliminate common problems. They have done and still do this. Best practices are not official standards, in that they do not have to go through the rigorous review process required for ANSI standards. No rules state that best practices must be followed. Best practices represent the industry's own consensus as to what would help make a reliable network.

One of the industry organizations is the Network Reliability Interoperability Council (NRIC), a two-year federal advisory committee. As an example of their work, Focus Group 3/Subcommittee 1 of NRIC–4 examined all of the existing best practices that had been established over the years, weeded out the ones that were obsolete because of technological changes, and developed new best practices where there were gaps. This was done in response to some network outages where obvious failures had taken place.

Another group, ATIS, was formed right at divestiture by the local telephone companies. It has since expanded, taking in a host of other groups, including manufactures, interexchange carriers, and others. It sponsors the Network Interconnection Interoperability Forum (NIIF), which has developed a reference document ("Installation, Testing, and Maintenance Responsibilities for SS7 Links and Trunks—Attachment G: Link Diversity Validation Guidelines," which is also available from the ATIS document center) that covers many aspects of network reliability that should be managed. It basically outlines a set of best practices to achieve the SS7 diversity requirements spelled out in the ANSI T1-111 standard. This document was put together by the industry, not by the FCC.

Outage Reports

Per Section 63.100 of FCC rules, any carrier that experiences an outage of at least 30,000 lines for 30 minutes or more must report that outage to the FCC. These are just telecommunications outages, not Internet or packet switching outages. The newest NRIC, NRIC–5, is working on what reports should be required for packet-switching networks. Many best practices are identical between regular telephone and packet networks.

Organizations that experience an outage must file a preliminary report within hours of the occurrence and a final report 30 days later. The preliminary report need only say something to this effect: "We have a problem. We do not know why. We do not know how long it will last." While this initial report may not seem to be particularly useful, it alerts the FCC if someone from Congress were to call and ask if they knew there was an outage in such and such a place. Reports on all the outages that have occurred since 1996 are posted on the Web at www.fcc.gov/oet/outage and available to the public. There is no summary or analysis available there, but there is a scan of the actual paper reports that were filed by the carriers.

There are approximately 200 outage reports filed every year, which averages out to be nearly four per week. These are not isolated instances, and there is great concern that many outages are not being reported. For example, if there were 29,000 lines out for a week, or 10,000 lines out for a month, they would not be reported because they are below the 30,000 line/30-minute requirement. The few exceptions to this rule are when outages occur from fires that affect more than 1,000 lines, outages at major airports, and outages affecting nuclear power plants.

Common Causes of Outages

A common industry scapegoat reason for outages is backhoes—road workers digging up the street and cutting the cables. In reality, though, the majority of outages are caused by problems inside the carrier's building, not out in the street. In other words, the majority of outages are caused by human errors—employees of the reporting company or contractors putting in new equipment or modifying existing equipment. These kinds of outages are called procedural outages, and they have been increasing in frequency.

Many of the outages are directly related to the lack of diversity in the network. The SS7 standards and best practices call for diversity in almost all aspects of SS7—digital timing supplies, power supplies, digital cross-connect machines, cables, cable routes, etc. If that diversity is not there, the standard suggests that the maximum annual downtime requirements will not be met. A lack of diversity does not cause outages, but it does significantly contribute to the extent of the outage (number of customers affected). In other words, when something fails and there is little to no diversity, there is a far greater chance that a much wider area will be affected by the outage than if there had been diversity. Again, the single-engine 737 analogy works here: the fact that it only has one engine will not cause a problem in and of itself, but this will make the plane more vulnerable to other problems.

Many outages are single-point failures. This means that one point in the network has a problem—one cable gets cut, one switching machine goes down, one network component fails, etc.—and the resulting problem affects a very wide area.

Another common failure is the simplex-duplex failure. In other words, many telephone network components are built with duplexed components, so that if one fails, it automatically switches to a backup, and service is not affected. Synchronous optical network (SONET) rings provide a good example of this type of failure. If a SONET ring has a failure on it, it automatically switches. No customers are affected by a SONET ring going into a simplex mode; in fact, that is the whole point of this kind of architecture. However, if the simplex problem is not repaired in a timely fashion and there is another failure, whatever or whoever was served by that component will be out of service. In one case, two and a half months elapsed between the time a SONET ring went into a simplex mode and when another failure occurred elsewhere on that same SONET ring. Since the first failure had not been repaired, all services provided over the SONET ring were affected.

Network Architecture

Figure 1 offers an illustration of telephone-company buildings (represented as the dots) and the connections between those buildings (the solid lines). This is a physical network, not a logical network. Logically, there could be a connection between the two upper dots. Physically, the traffic route goes down and through two other buildings.

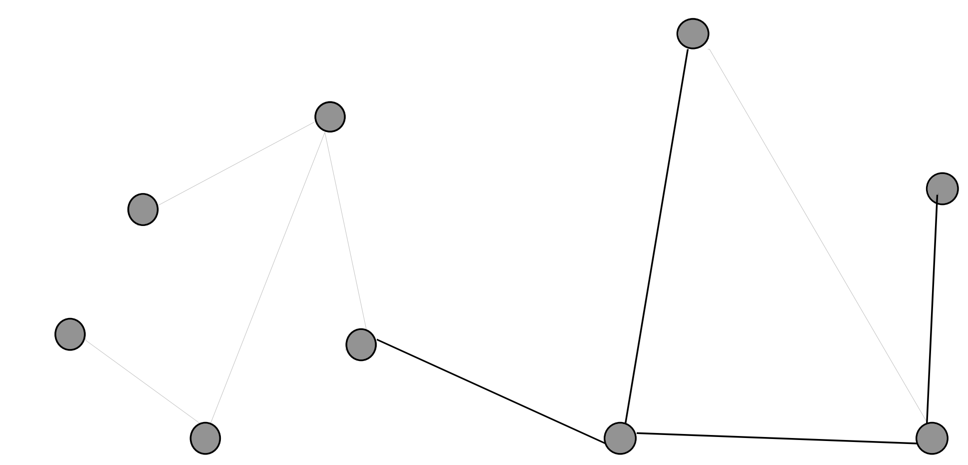
This kind of configuration does not apply to rural areas only. The diagram in *Figure 1*, in fact, is a simplistic version of the Second Avenue fire that occurred in New York City back in the 1970s. The dot on the left-hand side of the line connecting the two halves of the drawing could represent the Second Avenue Building in Manhattan, through which most traffic between Manhattan and Brooklyn traveled. The building burned up. And though it did not affect the rest of the network, little traffic went between Manhattan and Brooklyn until other paths could be established.

It also must be remembered that an entire building does not have to be destroyed for an outage to occur; it could be just one common piece of equipment. And with this old architecture, if one dot (building) goes out, the rest of the network is still fine: calls can still be completed between customers served by any of the buildings that were not directly impacted.

Figure 2, representing SS7 architecture, is another simplistic diagram. This shows only one end office, toward the bottom of the diagram. The dotted lines represent packet-switching circuits. They go up through one of two mated signal transfer points (STP), and these are all interconnected. There is total diversity between these paths—or there is supposed to be—and the STPs are connected with diverse routes to two service control points (SCP). The SCP

FIGURE 1

Architecture (Old)



is sometimes called "The Godfather." No traffic moves unless The Godfather says it can. If no one can talk to The Godfather, traffic will not move between buildings. This is how SS7 should work. Furthermore, none of these components should have more than 40-percent utilization. This way, if anything fails, the mated component can carry the entire load without a problem.

Today's architecture is represented in *Figure 3*. The building (dot) in the diagram on the left with the arrow would have two diverse paths (dotted lines), assuming the two STPs are on the right-hand side. Obviously, the administrators of the network provide as much diversity as possible; but there are two buildings that are common, as well as the path between them. In fact, the signaling paths from all five buildings on the left side of the diagram would have to go through the same two buildings and the common path between them to reach the STPs. Thus, there exists several places where there is a single-point failure potential that could restrict the customers in all five buildings on the left from the ability to make or receive calls from any other building in the network. In other words, with today's architecture, the signaling control messages for all inter-building traffic must be able to reach the SCP (The Godfather) before traffic can flow.

Notes on Common Channel Signaling

Some valuable points for better understanding common channel signaling (CCS) can be gleaned from *Bellcore Notes in the Networks*. A few of the most noteworthy quotations from this report are included in the following sections.

On CCS Architecture
"A crucial part of designing an SS7 network is including sufficient equipment redundancy and physical-route diversity so that stringent availability objectives are met" (section 6, page 255).

On CCS Availability Objectives
"Each network access segment should be down (an average of) no more than 2 minutes per year" (section 4, page 50).

"The backbone network segment should be down a negligible amount of time (that is, close to 0 minutes downtime per year)" (section 4, page 50).

On CCS Diversity
"The above allocation assumes an ANSI–based reference architecture with two-way diversity for the A-link sets and three-way diversity for the B-/D-link sets." (section 4, page 50)

FIGURE 2

Architecture (SS7)

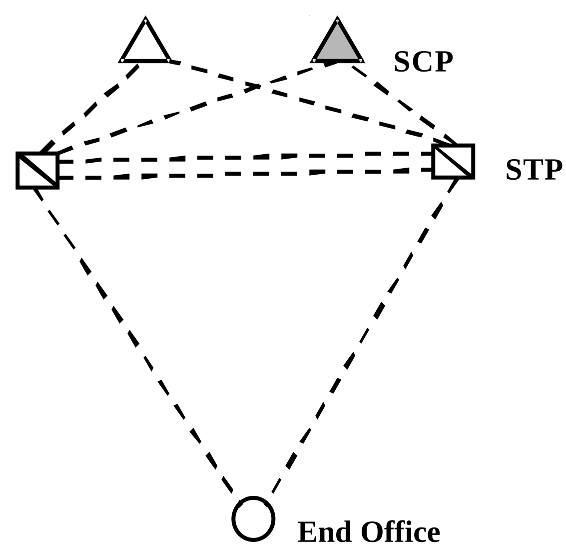


FIGURE 3

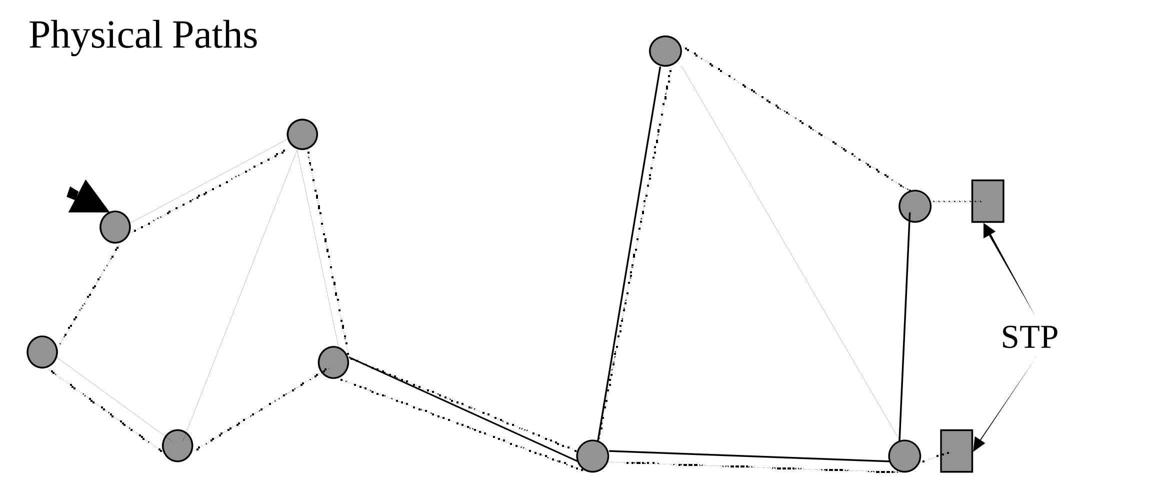
Architecture (Today)



Problems with Diversity

Diversity problems are twofold. First, there may be only a single physical path available for part or all of a route. Because it is only a single physical path, everything goes over that path just like on the previous diagrams. There is no way to provide diversity even though the standard calls for it until such time as a diverse physical path is established.

The second problem with diversity is administrative. The tools that the carriers use to assign circuits to the various network components were not designed to handle diversity, making it difficult for the people who assign circuits to place and maintain them in a diverse fashion. In many cases, circuits are moved from one path to another without recognition of the diversity implications.

Case Studies

The following section offers a few illustrations from the 2000 fourth-quarter outages. The full reports are available on the FCC Web site at http://www.fcc.gov/oet/outage.

- ***Outage 00-168: Houston, Texas:*** More than 718,000 customers in 17 wire centers [that is, telephone-company buildings] suffered more than 2.6 million blocked calls. Both E-911 and SS7 links were knocked out of service for two hours and twelve minutes. It was a hardware failure in one building. It was also a simplex-duplex failure. So when the initial trouble was not repaired, the duplex side failed, and everything was lost.
- ***Outage 00-191: Silver Spring, Maryland:*** On November 13, almost two million customers were cut off for almost four hours due to digital cross-connect bay failure. It knocked out almost 200 DS–3 or T3 circuits. Everything went through one piece of equipment in one building and had a very wide impact. After a momentary power failure, a surge blew the fuses, which were the wrong size.
- ***Outage 00-192: Nashville, Tennessee:*** The following is a good example of the STP diversity. The power supply to the STP failed, so the STP went down. This would not have disrupted service if the links were loaded to 40 percent of their capacity, but somebody had grossly overloaded the links. It was a simplex-duplex failure because the initial overload was not fixed. When Nashville failed, the STP in Atlanta could not handle the load, resulting in nearly 185,000 blocked calls for over seven hours.
- ***Outage 00-194: Montgomery, Alabama:*** A tandem switch serving eight wire centers plus independents failed. This made 34 public-service answering points (PSAPs) not available to answer E-911 calls for 42 minutes. This was the result of another fuse problem: the power-transfer switch fuses were the wrong size.
- ***Outage 00-219: Miami, Florida:*** Cellular traffic is not immune to such outages either. Cellular traffic goes from the tower to a cellular switch, which is connected to a traditional network tandem switch. The links went down here between the cellular switch and the tandem switch for almost three hours. A SONET multiplexer went bad.
- ***Outage 00-220: Klamath Falls, Oregon:*** Thirty-one thousand customers ended up losing E-911 service because there was no diversity for the E-911 circuits—something that violates best practices. However, there was diversity in the SS7 circuits. Thus, customers did have long-distance service for making and receiving calls, but they could not call 911 for more than 16 hours. The cause: vandals had cut a fiber cable.

Introducing Software Paradigms to Hardware Design

Kjell Torkelsson
Vice President, Engineering
Celoxica Ltd.

Background

With today's complex systems and high-performance silicon, the worlds of hardware and software engineering are converging fast. Traditional processor-based solutions start with a high-level design, which is partitioned into hard and soft components.

For hardware engineers, taking complex functions and describing them in hardware description language (HDL) to produce a high-performance field programmable gate array (FPGA) or application-specific integrated circuit (ASIC) design can be extremely challenging and time consuming.

For software engineers, these same functions are relatively simple to implement in code that can easily be integrated with the overall system. However, the sequential nature of processors and their reliance on high clock speeds to perform fast calculations often imposes limits on performance.

The ideal would be a middle ground, with the performance advantages of parallelism gained though hardware and the ease of design and integration of software. A few years ago, this would have been a pipe dream, but advances in software tools and the growing functionality and capability of field-programmable devices now enable software concepts to be implemented on hardware, without getting involved in a time-consuming and costly HDL design loop.

By using modern, multimillion gate FPGA technology, software components can be realized in silicon faster than traditional methods, enhancing the time-to-market opportunities. What is more, such solutions can extend the lifetime of hardware, as new functions or efficiencies can simply be reprogrammed on devices out in the field. Programmable gate arrays can even be modified over the Internet.

Bridging the Gap from Software to Silicon

Celoxica's recently launched DK1 design suite compiles from Handel-C to an FPGA net list without requiring an intermediate HDL step. It allows system developers and software engineers to accelerate algorithms by expressing them in parallel and mapping them directly in hardware. The benefits are especially acute in areas such as broadband networking, third-generation (3G) base stations, or Internet backbone routers, where complex software algorithms such as encryption or compression need to be run at higher and higher speeds.

For example, in networks or high-traffic Web sites, the slow throughput available with software-based encryption is a major performance bottleneck in completing secure on-line transactions. Implementing the triple data encryption standard (DES) algorithm in FPGA-based hardware using the DK1 design suite provided throughput in excess of 6 gigabits per second (Gbps). What is more, a single software engineer was able to complete this project from specification to hardware in only one week.

Sequential algorithms are frequently best performed by software implementations using conventional central processing unit (CPU) architectures. Optimal hardware acceleration comes most often from functions performed in parallel, typically in the physical form of a hardware co-processor closely coupled with the CPU.

Celoxica's specially developed programming language, Handel-C, takes this into account, providing the extensions required for hardware development. It is firmly grounded in ISO/ANSI-C but with an additional statement for parallel processing (par) as well as constructs for communication between parallel elements. The language also provides flexible data path widths, versatile memory architectures, and interfaces to external hardware.

Other C-based design methods have emerged to support the need for high-productivity, system-level design at the algorithmic level. These fall into two camps: behavioral methodologies and RTL–based methodologies.

Behavioral compilers give the user little control, automating the processes between input and output in a way that has been likened to a "long, dark tunnel" that has a tendency to generate code that is too big and too slow.

C-based RTL methodologies tend to provide more control but wrap VHDL and Verilog functions in clumsy versions of

C or C++ and hence do little to remove the low-level complexity of RTL design.

In contrast, Handel-C delivers a level of abstraction over RTL but maintains manual control for more efficient code than behavioral approaches allow. Design engineers need both sequential and parallel expression of functions from their tools. RTL, which expresses parallelism by default, require low-level coding of state machines to implement sequential expressions-a laborious and verbose process. Handel-C combines these two worlds more elegantly with a sequential language, able to express parallelism by using simple par statements to add parallelism where it is needed.

Handel-C and the DK1 development environment allow designers to use software paradigms and library code and even to import legacy HDL blocks. In exactly the same way as newly written code, these can be simulated within DK1 and co-simulated with other tools. These facilities provide huge flexibility, speeding design by code reuse, and make a modular approach to design practical. In addition, because it is so simple to change code and re-simulate or even update the target FPGA, engineers can work using the familiar process of iterative improvement to individual functional blocks and are free to try creative approaches to gain improved performance, without the fear of dramatically extending delivery time.

Timing and Control

Handel-C is designed around a simple timing model that makes it highly accessible to system architects and software engineers. Each assignment in the program takes one clock cycle to execute, giving the programmer full control over what is happening in the design at any point in time. Results are predictable and controllable, as easily in software as in the final hardware.

Use of the par statement is illustrated by the following program extract:

```
/*******************
* The main program *
*******************/
void main (void)
{
   par
   {
      SyncGen();
      Display();
      PerFrameUpdate();
   }
}
```

The program described might be the core of a video "bat-and-ball" game. The screen consists of a background color surrounded by a border and a moving square (the "ball"), which moves in straight lines and bounces off the border. At the top level, the program consists of the parallel composition of three processes.

This fragment highlights the aforementioned major difference between Handel-C and conventional sequential languages such as C-that of parallelism. This program calls for three separately executing processes to run concurrently. The first one is the SyncGen process, which is responsible for producing standard video graphic array (VGA) video sync signals and for updating the ScanX and ScanY variables, which track the current pixel position both during display and during the hidden parts of the video signal, namely the horizontal and vertical blank intervals. The other two processes synchronize themselves to this one by inspecting the values of these two variables. The Display process is responsible for producing the video output signal, and the PerFrameUpdate process changes the variables used by the display process to advance the state of the "game."

There are many other features that make Handel-C a highly relevant language for developing functionality that will be deployed in FPGA co-processors. Firstly, it supports complex C functionality, including structures, pointers, and functions (shared and inline), thus ensuring a shallow learning curve for software engineers and allowing rapid implementation of very complex, modular systems. With extended operators for bit manipulation, and high-level mathematical macros (including floating point), it allows rapid translation of digital signal processor (DSP) algorithms to efficient hardware.

With Handel-C, there are no state machines to design. Control flow comes from C statements such as if, case, and while, so complex sequential control flows can be designed simply, in a way that is intuitive to software engineers. And the simple and consistent syntax extensions for specific hardware features such as RAMs/ROMs, signals, and external pin connections provide for efficient use of available hardware without cumbersome syntax.

Handel-C programs can automatically deal with clocks, clock enables, and synchronized data transfers across clock domain boundaries. The result is a major reduction in complexity, plus the use of the optimal clock rate for each part of the design enables increased speed and reduced power consumption.

Once the algorithm has been optimized, it is simply a matter of compiling the software down to hardware. Celoxica's DK1 produces an architecture-optimized EDIF netlist, targeted on either Xilinx or Altera programmable logic layout tools. Tests have shown that the compiler is efficient both in terms of synthesis time and the area and delay of generated designs. Benchmarks against typical VHDL designs show comparable, if not superior results, on designs produced with Handel-C. *Tables 1* and *2* show a few such examples.

DK1 includes a profiling tool that gives area and delay estimates, which are presented as color-coded annotations of the source code. This makes optimizing the generated hardware extremely simple, even for relatively inexperienced engineers. In addition, users can supply timing constraints at the source level, which are automatically translated for the target technology. At the lowest level, DK1 generates readable signal names for tracing back through post-layout timing analysis.

As well as timing analysis, the debugging environment provides in-depth features normally found only in software environments. These include symbolic debugging using breakpoints, single stepping, watched variables, and the ability to follow parallel threads of execution.

TABLE 1

Benchmark 1-DES Encryption Block

Design	Language	Clock (MHz)	CLB Slices	Rate (Mbps)
Sequential DES (16-cycle latency; one 64-bit block/16 cycles)	Handel-C	105	267	420
	VHDL	101	255	404
Fully Pipelined DES (16-cycle latency; one 64-bit block/cycle)	Handel-C	101	3025	6464
	VHDL	32.5	2528	3,052

TABLE 2

Benchmark 2-A Time Domain Multiplexer for a Multimedia Gateway

Language	Clock (MHz)	CLB Slices	Logic Depth	Lines of Code	Development Time (Days)
Handel-C	39.9	694	7	1,499	24
VHDL	34.9	1,032	9	1,748	43

Co-simulation and verification facilities are built into the Celoxica tool chain, facilitating co-design with instruction set simulators, VHDL simulators such as ModelSim, and external C test benches. A key benefit is that hardware/software partitioning decisions can be made much later in the design cycle.

In the Real World

Whether for rapid prototyping or first-generation final products, this approach gives a head start in time to market, with lower risk and the potential to upgrade products in the field. So much for the theory, but what about practical experience?

One customer halved the time it took to implement a signaling system 7 (SS7) protocol, used in telecommunications systems, using Handel-C rather than VHDL, producing more compact and efficient FPGA code in 24 days, compared with 43 days. Another company, designing an IPv6 router, developed core components in just four man-months of software-engineering effort with DK1, while its team of hardware engineers worked for 12 man-months using Verilog and still failed to produce a working design-the working Handel-C code ran to 40 pages; the incomplete Verilog design had reached 200 pages. A third customer ran a competition between a traditional hardware design team and a small group of software engineers using the Celoxica technology, with the aim of creating an MP3 audio processor. In only seven weeks, the latter successfully converted existing software and produced optimized working hardware that beat design specifications. In the same time period, the hardware group using HDL had not even finished writing the specification.

Success in these and other trials is providing the confidence for software engineers to seize the opportunity and, where appropriate, extend their domain into the hardware field. With technologies such as this, there is little to lose and a great deal to be gained.

Appendix: Writing Code for Optimized Hardware

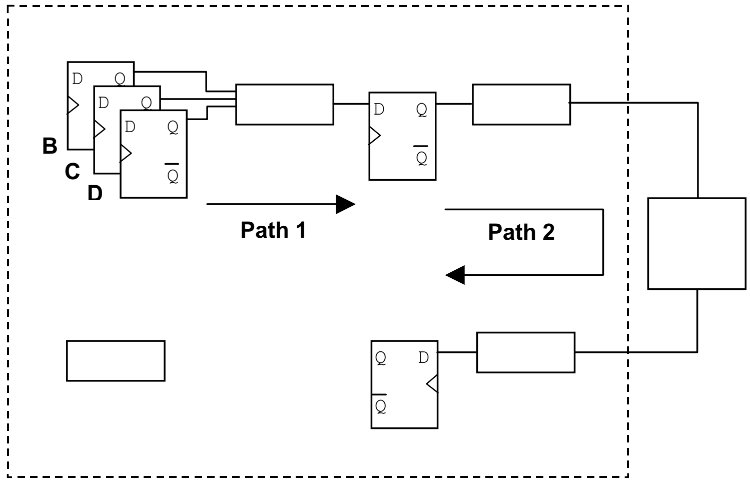
In Handel-C registers are implemented using flip-flops and all other circuitry (forming the logic making up the content of assignments) is made up of logic gates. Each of the gates in the circuit has delay associated with it as the inputs propagate through the gate to the outputs (there is also a delay associated with the interconnecting wiring on programmable logic). An average delay for a four-input gate on a modern FPGA is of the order of a few nanoseconds, which seems very quick. However, it is important to ensure that the total logic delay for each assignment does not exceed the period of the circuit clock. We have chosen 20 MHz as the rate for a boat game, resulting in a maximum propagation delay of 50 ns.

Understanding the Logic in an Assignment

Figure 1 is a simplified diagram of an FPGA with some internal circuitry, interfaced to an external RAM. Paths 1 and 2 correspond to the following two statements in Handel-C:

FIGURE 1

Simplified Diagram of an FPGA



```
seq
{
A = B * C + D; /* Statement One */
E = SSRAM0[ A+1 ] - 1; /* Statement Two */
}
```

The first statement is implemented entirely in logic internal to the FPGA. This form of statement allows the most complex expressions, but the delay through the logic must never exceed 50 ns. The second statement involves an external RAM access. Variable A passes through logic to increment it by one, and the resulting value forms the address input to the external RAM.

There is then a fixed propagation delay through the external RAM from address pins to data pins (typically about 10 ns). The data re-enters the FPGA, has one subtracted from it, and is finally latched into another register. This total path must also not exceed 50 ns. To ensure that you write logic that is sufficiently fast for your chosen clock rate, it is important that each expression being assigned is kept relatively simple.

RAM Access

To minimize the logic for external and block RAM accesses, the RAM address is supplied directly from a register, and the data from the RAMs is put into a second register. If the same RAM is accessed from many places, Handel-C builds logic to multiplex the address lines for each access out to the RAM address pins. This logic has its associated delay, so the number of places at which RAM (or any shared resource) is accessed should be kept to a minimum.

Reducing Logic Depth

The code fragment

```
seq
{
A = B * C + D; /* Statement One */
E = SSRAM0[ A+1 ] - 1; /* Statement Two */
}
```

would have shorter logic paths written as

```
seq
{
X = B * C;
A = X + D + 1;
Y = SSRAM0[ A ];
E = Y - 1;
}
```

The second code fragment would then take four clock cycles rather than two. In most cases, however, we need to be able to perform one complete calculation every clock cycle. The number of clock cycles can be reduced to one by using *pipelining*.

Pipelining

The following code snippet illustrates an expression that is potentially too complicated for the application constraints.

```
a = (b + c + d) * (e + 1);
```

As before, this can be split into a number of sequential assignments, each with a logic depth shallow enough for the timing requirements. To get a single calculation per clock cycle, the statements can all be evaluated simultaneously by using *par*.

```
while(1)
{
par
{
/* First clock cycle */
sum1 = b + c + d;
sum2 = e + 1;

/* Second clock cycle */
a = sum1 * sum2;
}
}
```

After the first clock cycle:

- Correct values for sum1 and sum2 are calculated.
- The value in a depends on their previous values.

After the second clock cycle:

- The full result is available in register a (*simultaneously* the sums have been calculated for the next values of b, c, d, e).

By the next clock cycle:

- There is a new value for the calculation.

This shows that after a delay (or *latency*) of one clock cycle, a result for the calculation is available every cycle.

Pipeline Coding Requirements

Pipelined code can be slightly larger than equivalent simple code, but the logic delay should always be considerably lower. Pipelining allows you to perform very complex operations at high clock rates. However, pipelined code is marginally harder to write because there is a delay before the data is available. When a pipeline is started, the first few cycles of output must be discarded until the true data propagates through.

When writing code that uses the output from the pipeline, you must take care not to use some of the junk data or discard some of the initial valid data.

Operator Complexity

There is a hierarchy of complexity for Handel-C operations, with (for a given bit width) division being more complex than multiplication and multiplication being more complex than addition. Moreover, the < and > operators are more complex than an == comparison. Thus, divisions should be avoided unless absolutely essential. Wide multiplications should, whenever possible, be the only operation in a particular assignment. It is also best to use == rather than < or > for any Boolean operations.

Conversion to Fixed Point

Wherever possible, it is more efficient to use fixed rather than floating-point operations in hardware. In most cases, floating-point hardware is easily replaced with fixed-point, where a fixed number of the bits in the representation are to the left of the decimal point and a fixed number are to the right. You can set the number of bits to the left and right of the decimal point to different values for different stages in an algorithm to provide the accuracy required as efficiently as possible. In cases where high accuracy is required, it is important to calculate the possible error incurred by converting from floating-point to fixed.

New OSS Software Can Help Service Providers Regain Control of Their Businesses

Catharine Trebnick
Senior Vice President, Marketing
CPLANE, Inc.

The telecommunications services market has certainly experienced its share of growing (and contracting) pains over the last 12 months. The marketing promises of the late 20th century have given way to the business realities of the 21st century, and many carriers and service providers have been sacrificed along the way. It is not surprising then that those who have survived are taking a more cautious and conservative approach to managing and growing their businesses.

Nowhere is this more evident than in the carrier spending plans tracked by industry observers. In 2000, according to a recent report from Salomon Smith Barney, U.S. carriers spent more than $97 billion in capital expenditures (CAPEX), with most of it going to network infrastructure upgrade and expansion. In 2002, CAPEX spending will likely fall to around $55 billion—a $40 billion decrease. There are two primary reasons for this reduction. The obvious one is current economic conditions, but the more interesting one is the shift in business focus from operational expansion to operational efficiencies.

If you look more closely at CAPEX spending plans, you'll also see plans for increased spending on software—particularly operations support system (OSS) applications that will help to improve operational efficiencies and extract greater value from the business. These applications do a great job handling discrete processes such as order management, service assurance, and fault management.

Unfortunately, these applications do not address a fundamental control problem that service providers must solve—that is, the ability to effectively control both service and network resources. After all, optimal service performance for the end customer and optimal use of network resources for the service provider are both essential to the survival and growth of the business.

The good news is that a new class of OSS software—which combines service activation with network optimization—is emerging to address this issue. Available from several legacy OSS vendors and next-generation upstarts, the software is already generating a lot of interest from regional Bell operating companies (RBOCs) and next-generation carriers alike. Unlike many other OSS applications, these new activation/control applications provide a more holistic level of control by bridging the gap between three layers of the telecommunications management network (TMN) model: the service-management layer (SML), the network-management layer (NML), and the element-management layer (EML) (see *Figure 1*). The software's appeal is that it empowers service providers with the ability to effectively control both service and network resources in a way that is consistent with strategic business policies and objectives. And that means control of their business.

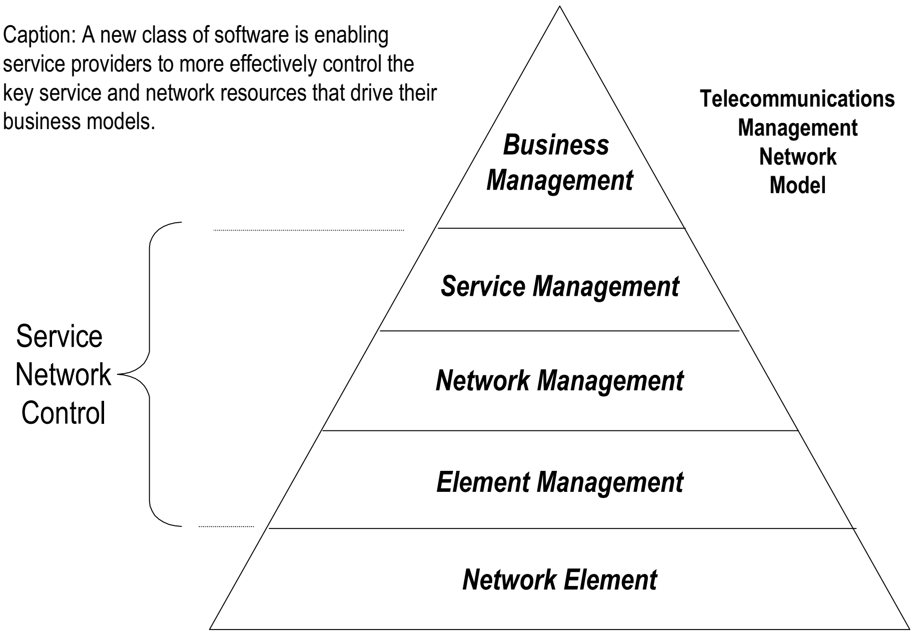
In the remainder of this article, we'll briefly look at how this software bridges these layers and provides a complete OSS activation and control solution. Let's start with the SML and the requirement to rapidly create new revenue-generating services.

In the past, the definition of new services was most often tied to changes in the underlying network infrastructure; in fact, investments in the infrastructure typically drove the creation of new services. As a result, the process involved in developing new services could be complex, time consuming, and expensive. This process also tended to stifle service innovation and prevented service providers from being able to quickly prototype and test new service offerings. The new software promises to empower carriers with the tools to respond faster to market opportunities with new services.

The software allows providers to directly develop their own service-level specification (SLS) as a high-level extensible markup language (XML) document. The SLS document typically contains information on the customer, service type, service termination points, and service connectivity attributes—things such as bandwidth, response time, latency, security, etc. Some or all of this information may be

FIGURE 1

Caption: A new class of software is enabling service providers to more effectively control the key service and network resources that drive their business models.



retrieved from or shared with other OSS applications handling order management or service assurance.

These SLS connectivity attributes are often key components of customer service-level agreements (SLAs), and customers pay a premium to ensure that their SLAs are met. That means that the service provider must work hard to meet those expectations. So, while operations at this layer focus on "what" the service will deliver, it is even more important that the software understand "how" the network will deliver it.

It is at the NML that an understanding of the network comes into play. In fact, this intersection of the service and the network is where the issue of control becomes business-critical, and this is one of the critical gaps in the TMN model that service network control software helps to bridge. One of the main objectives of this software is to enable service providers to better understand the impact of new services on the network, so that they are better able to determine how best to use expensive network resources to support revenue-generating services.

Therefore, at the NML, the service network control software must be able to translate the high-level service request into a set of instructions that the network can perform to ensure that the customer SLA is met. That's the real objective—not just blind activation of a service request, but optimal delivery of the service across a complex network infrastructure.

Getting control of network resources would be difficult enough if the network was composed of equipment from one vendor or one technology But many service-provider networks have been built over many years with new and legacy equipment operating at multiple network layers (optical, asynchronous transfer mode [ATM], Ethernet, Internet protocol [IP], etc.).

The software addresses this complex problem by first extracting data from other OSS tools—such as topology information from a network-management system (NMS)—to build a comprehensive information model that provides real-time data on the physical and logical topology of the network and on how resources are currently being used. This information, combined with analytical intelligence built into the software and the vendor-independent control-plane architecture of the software itself, allows the service provider to determine which technologies and resources are available to fulfill the requirements of the service.

For example, assume that a carrier was rolling out an IP virtual private network (IP–VPN) service to link multi-site enterprises between various metro networks across the United States. In that case, it may wish to perform traffic engineering within the core of the network to set up multiprotocol label switching (MPLS) label-switched paths (LSPs) between each metro network. That level of traffic engineering would enable the carrier to configure specific MPLS–enabled network elements to ensure that they are individually tuned to support the IP–VPN service. That, in turn, ensures optimal use of key resources *and* performance of the service, *and* satisfaction of the customer.

Preparing the network for optimal delivery of premium services obviously requires more than just engineering the core of the network. To begin with, any request for network resources must be evaluated against admission criteria—policies established by the service provider. Based on these policies, the software can determine whether or not a request is authorized to use the resources and, if so, whether resources are available to support it. This is a service-layer extension of well-understood "on-the-box" control functions found in protocols such as private network-to-network interface (PNNI) or resource reservation protocol (RSVP). It gives the provider the power to arbitrate access to resources directly through high-level business rules, rather than rely on arbitrary decisions made by devices that are unaware of a network-wide provider goal. If a request is admitted, it must be mapped onto appropriate resources in the network.

Implementing any service requires resource controls in the data path. For example, traffic entering the network might need to be policed to an agreed rate or shaped for injection into the network—this is known as "traffic conditioning." Deeper into the network, shared resources must be partitioned between multiple traffic types to ensure that each receives the appropriate service level (bandwidth and quality of service [QoS])—this is known as "bandwidth management." And, as discussed, in the core of the network, fat pipes (trunks, or wavelengths) must be in place to deliver sufficient capacity to the aggregate traffic load.

The output of the various operations in the NML is a "network-level specification" that is linked to the EML. In the past, a specification like this was created by hand and delivered to an army of network engineers responsible for manually configuring each network element along the data path. This was a time-consuming operation obviously prone to human error. When the configuration work was complete, the next step was often troubleshooting to identify the source problems that would no doubt occur along the way.

With this new OSS software, this process is largely automated, with network engineers involved at critical checkpoints. Instead of a human-controlled process, it becomes a software-controlled process where the software works directly with the vendor element-management systems (EMSs) to ensure that specific network elements are configured to support specific connectivity attributes of specific data services. Errors are minimized, if not eliminated, because the network specification is based on real-time data extracted from the information model. As mentioned earlier, this database tracks resource availability and service traffic flows, and then determines how best to use available network resources to support service requirements.

Once the appropriate set of network elements have received instructions on how to behave, the new service is then deployed across the network. Customers can then be activated in near real-time and feel confident that the performance of the service will be in line with their expectations and SLAs. In fact, data in the information model can be provided to other OSS applications—such as service assurance and billing—to "close the loop" with the customer and provide evidence that the SLA has been met.

The flexibility of this new breed of software also allows enterprise customers to gain direct, Web-based access to their service orders, so they can make instant changes and upgrades to their services and have those changes activated in near real time.

Now more than ever before, service providers are looking for ways to achieve the "faster, better, cheaper" objectives of any successful company. This new software is capable of helping carriers achieve all three of these objectives. It will deliver the level of service *and* network control that carriers need as they move forward with their strategies to deliver premium, profitable, data connectivity services. By gaining control of these strategic assets, they will be better able to truly regain control of their businesses.

Availability Measurement

Craig Tysdal
President and Chief Executive Officer
NetSolve, Inc.

The networking community has understood for years that a network must exceed a certain availability, and reliability, standard to have business value. That explains why the concept developed that very cheap bandwidth has little value to a business because it either breaks down frequently or takes too long to repair. This de facto standard was applied with more anecdotal evidence than real science. Still, it became an easy excuse for an understaffed networking organization to shrug and exclaim, "We have a choice here—we can fix the problem, or we can document the outage." Such excuses are inexcusable today. With networks being the backbone of today's business, measurement systems are critical to effective network management.

The Internet's growth, the dependence of businesses on a network for revenue and customer satisfaction, and the advent of new technologies will increase the requirement that enterprises better understand and measure availability. In particular, technologies such as voice over Internet protocol (VoIP), digital subscriber line (DSL), and cable modems represent opportunities for business to become more cost-effective, provided that the availability of these subsystems exceeds business requirements. This paper discusses the general concepts of availability measurement, and it offers five critical questions that availability-measurement systems should address.

1. What availability metrics are meaningful?
2. What is the availability of the network to our internal and external customers?
3. Are vendors meeting the availability expectations agreed upon?
4. What factors, including people, tools, training, process, vendors, and subsystems, must be improved to increase availability?
5. How does my network availability compare with that of my peers/competitors?

These questions are meaningful when examined from multiple perspectives, including those of the enterprise, networking vendors, and management service providers. This paper's intent is not to examine the technical issues, but rather to understand the completeness of a solution from a business perspective.

What Availability Metrics Are Meaningful?

For availability metrics to become a business tool, it is crucial to understand and define the set of metrics that is truly important. This will avoid at least two common mistakes. First, that a lack of focus and specificity will yield too much data. Too much data will elongate the analysis cycle and often prevent or rush the most important step: corrective action. Second, that an incorrect choice or focus on a metric may produce counter-productive behavior. Focusing solely on mean time to repair (MTTR), for example—outside the context of availability and number of incidents per device/application—could mean that success or a better metric is achieved by a large number of small outage situations. Therefore, chronic sites may exist that are not obvious by examining the MTTR metric without additional data. Consequently, a frame-relay provider may achieve a significant competitive advantage in marketing a lower MTTR number when, actually, the network is less stable, and the MTTR metric is "enabled" by excessive PVC/Port bounces or cleared during test incidents.

NetSolve focuses on six key metrics: managed availability, unmanaged availability, proactive notification, number of incidents per subsystem per month, mean time to identify problems, and MTTR. Rather than define each of these metrics in detail, we will outline the business thinking and intent integrated into their definitions.

Managed Availability

The concept of a "managed" device, subsystem, or application is familiar to a management service provider. It is the set of components necessary for operating and maintaining. This concept also applies to the enterprise, with good definitions setting expectations. Great customer service is impossible without solid expectations.

Once a clear understanding of responsibility has been set, the concept of availability depends on simple arithmetic and the definition of downtime. The guiding principle to defining downtime is simply whether the application or the network is available to the customer. Typically, from an industry perspective, downtime does not include time for scheduled maintenance or time associated with the failure of a primary link as long as a redundant link is operating correctly. Such times should be reported, trended, and managed. For example, redundant links in a wide-area network (WAN) may have significant performance and cost implications important to the business and user experience. Scheduled maintenance can increase to be more proactive in your management techniques. This is especially true when diagnosing a network condition that has not completely failed. Many troubleshooting techniques and processes center around a "hard down" condition. Additionally, scheduled maintenance frequently occurs when there will be minimal business impact (if such a thing exists in your business). So, although these times typically are excluded from a "managed" metric, including them in an availability calculation is meaningful to ascertain trends and to manage.

Finally, the dynamics of defining downtime changes, depending on whether you are proactive or reactive in reporting it. In a reactive scenario, when capturing downtime using a trouble-ticket system, the downtime typically starts when a user notifies a help desk or vendor. This time may significantly differ from the time when the actual failure occurred. Ignoring the somewhat-academic argument about whether the network is down if no user or machine requires its use, the reality is that proactive management tends to capture more downtime and more incidents of downtime. Therefore, comparisons of availability calculations require additional information.

Unmanaged Availability

Unmanaged availability metrics attempt to define the entire user experience regardless of whether the management service provider, vendor, or internal support organization operates and supports it. We maintain that any measurement system must create metrics that closely parallel the total customer experience. For example, if the network runs perfectly, but poorly trained mobile users struggle with correctly connecting or using it, the business purpose is thwarted and customer satisfaction significantly hurt. Defining the network-system components that accurately reflect the customer impression requires thought. Additionally, the natural inclination would be to increase complexity. But that should be avoided. Customer responses on their own experience tend to be fairly simple; "it works great," "it stinks," "it works better," "it operates the same," or "it's worse than last month."

Proactive Notification

While this metric has no real implication to network availability, it does save time for customers and users—and improves their mental health. The faster a customer or user understands that there's a problem with the network and when it is expected to be fixed, the quicker that business contingency plans can be made. In addition, in those instances when responsibility for information technology (IT) is divided, i.e., network/application or voice/data, proactive notification by the responsible party to the business partner can save troubleshooting time and, hence, money.

Number of Incidents per Subsystem per Month

This metric is useful to detect situations where there are numerous interruptions of service, but they require little time to repair, known as MTTR. Thus, user dissatisfaction may not be high, since repairs are made quickly. Converting this metric into mean time between failure (MTBF) will allow some consistency of language in discussions with software and hardware vendors. Capturing this metric has an additional benefit: Networking equipment and services providers will devote different troubleshooting processes and resources to situations that have a documented history of repeated failure. Finally, this metric can help us to understand the quality of our network-design and configuration-management practices.

Mean Time to Identify Problems

The time required to identify the cause of a failure is only a component of MTTR and, in and of itself, is not that meaningful in a business sense. Nonetheless, this is an important element to managed service providers and internal IT organizations wanting to measure effectiveness, efficiency, and return on investment (ROI) of people, tools, and processes.

Mean Time to Repair

MTTR is the mean time interval between a failure's detection and the time it takes to repair it and restore service to the user. Calculations of this metric and its importance depend on understanding what is included in downtime and incident-failure analysis. Histograms of this metric as well as breakouts of this information to appropriate subsystem and supplier are very important.

The highlighted metrics are not the inclusive list that we internally monitor and/or publish for customers. They are an excellent place to begin the discussion about availability, and they prepare us to move to the second important question.

What Is the Availability of Our Network to Internal and External Customers?

Our customers tell us that different applications and different users require different levels of availability. Additionally, designing in high levels of availability in networks traditionally increases cost. Finally, when considering customer service, it helps to look at availability the same way that a customer might. We should allow customers to determine many of the business rules that define an availability calculation. For example, a customer might want to look at only one site or device in the last week or two. This same customer may believe that something less than an around-the-clock, seven-day-a week calendar is critical to truly understand the impact of associated outages on the business. Under this approach, the customer is free to make commitments to internal and external customers (read service-level agreements [SLAs], if you will) and maintain a flexible reporting system for appropriate measurement of those commitments. But can vendors then tailor their respective SLAs so that SLAs made from the customer to its customers conveniently flow down? This is the preferred situation.

These same market dynamics have prompted some software vendors to provide tools that correlate applications with users, thus defining availability from an application perspective. A high degree of automation is required in this approach to ensure that the underlying integrity of the database yields meaningful results that are cost-effective to gather and maintain.

Are My Vendors Meeting the Agreed-Upon Availability Expectations?

The availability system, to the highest degree possible, must reflect the availability and responsiveness of the responsible vendors. The Internet's value proposition for virtual private networks (VPNs) degrades significantly if the availability in the local loop or in a multicarrier long-haul environment is significantly more fragile than such private network technologies as private line or frame relay. Similarly, robust implementation of VoIP should not be tainted in any way if on-or-off net-wide area network links fail.

To answer this question, the enterprise or management service provider will measure certain important metrics such as downtime at higher degrees of granularity. For example, a component of downtime for an MTTR calculation when a network hardware failure occurs is the time it takes the vendor to respond to a dispatch. Clearly, if a customer has purchased four-hour response time, then it is critical that the vendor arrives within four hours of notification. It is assumed, of course, that the vendor has the correct replacement part and that it works. Availability systems need to measure this responsiveness as well as the underlying assumption of effective resolution.

What Factors—Including Training, Process, Vendors, and Subsystems—Do I Need to Improve to Increase Availability?

The requirement for measuring availability to help answer this question is the ability to trap, trend, and report on elements of availability with a high degree of specificity. Key to this are the error codes and the accurate reporting of the same. This process has some natural enemies. When critical systems are down and multiple vendors are working on a problem, it is not unusual that more than one component will be analyzed or changed simultaneously. If this works, then it is difficult to determine the problem's true cause. Subsequent failure analysis does not always unwind this problem and, given the repair-and-replacement cost of networking components today, many times it is not even seriously considered. Accurate reporting also assumes integrity among customer employees, vendors, and management service providers. In our business, we believe the customer should have control over their network even though they have hired us to operate it. As a result, we many times will share password control of configuration management. We have found that the use of authorization systems, nightly archives, and exception reporting is invaluable to determining where our processes and individual training require improvement.

How Does My Network Availability Compare with Peers/Competitors?

Once a customer has reported and trended availability, the obvious question becomes: How good is it? Is meeting our internal and vendor SLAs sufficient? Is a competitor's IT organization beating our brains out? The advantage of a management service provider with a solid availability reporting system is access to statistically significant amounts of comparative data. This data—when available in easy to understand formats—will answer the central question. In addition, it potentially becomes very useful for vendor management and evaluation. Are there availability costs to a free Internet service? What are the comparative results of different DSL vendors or different broadband access technologies? The networking industry has embraced published results on lab tests and some Internet-related operations data. Significant opportunity exists to increase this information and augment or replace marketing claims with operational reality.

Conclusion

The availability of our network last month was 99.98%. This is a simple statement. The purpose of this white paper is to provide a perspective on defining a robust availability reporting system. If properly designed, understood, and delivered, this reporting system will help enterprises to answer simple questions so they, too, can define their network availability just as easily.

What Does Redundancy Mean, Really...

James Wilson
Product Marketing and Program Manager
General Bandwidth

The technology that powers the public switched telephone network (PSTN) has been designed, refined, and optimized over the last several decades. At the heart of PSTN reliability is redundancy. Redundancy in carrier-class networks, simply defined, is the ability of telecommunications equipment to continue operation without service outages in the case of failure of any component of the telecommunications equipment.

The convergence of voice and data networks is making it possible to deliver voice, data, and multimedia over a single broadband network, driving the transformation of the PSTN from a circuit-switched network to an end-to-end packet network dubbed the new voice infrastructure (NVI).

The challenge is to provide the same level of redundancy in the NVI that has come to be expected of the PSTN.

Redundancy Defined

Carrier-class redundancy is built into every facet of packet-based voice networking equipment that guarantees the same level of reliability in NVI equipment as that offered by existing PSTN equipment. For example, in voice over digital subscriber line (VoDSL) and voice over Internet protocol (VoIP) applications, products with carrier-class redundancy are able to maintain active calls and minimize the impact to calls in the process of being set up when a component of the equipment fails.

While important to service providers for every application, carrier-class redundancy is critically important for equipment delivering derived voice over broadband networks. Voice gateways, which provide the center point for linking the packet- and circuit-switched networks are particularly susceptible to any failure, making redundancy that much more critical. The loss and retransmission of voice packets directly affects voice quality. If voice packets arrive out of sequence or with some packets missing, the end result is garbled communication. Because VoDSL and VoIP gateways have to work as faultlessly as the PSTN, they must be held to a higher redundancy standard than data networks. As a further requirement, services enabled by voice over broadband gateways must be completely transparent to the end user in terms of availability, reliability, and quality. *Figure 1* summarizes data from a Bellcore study on factors affecting telephone network downtime.

Software, Hardware, and Environmental Conditions

Outages due to software, hardware, and environmental conditions contribute to 45 percent of telephone network downtime. In a carrier-class redundant system, the software design leverages the hardware redundancy model to minimize the impact to system availability during outage periods and maintenance activities. A distributed, modular architecture is typically employed to ensure reliable system operation. This architecture includes well-defined software components and interfaces that clearly delineate control and status functions. A well-defined software architecture greatly assists in the management of system resources and will quickly direct redundancy resources when necessary.

Hardware redundancy typically involves using one or more spare devices to compensate for a failed active component during normal system operation. Upon failure of the primary device, the secondary device assumes operation with no interruption in service. This combination of a primary device and a secondary device comprise the minimum set for a protection group. Redundant devices in voice gateway products include module, port, timing system, and power-system redundancy.

Module Redundancy

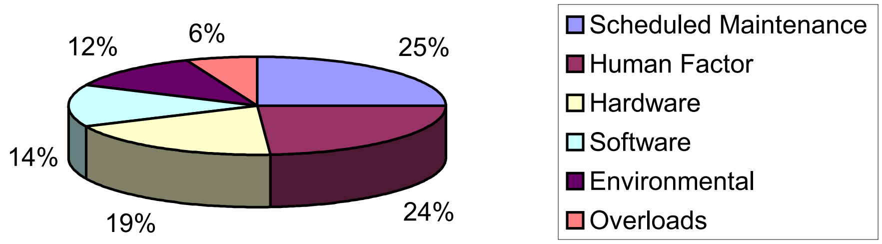
Modules, or cards, provide system control and input/output (I/O) functionality in voice gateway equipment. Each module must be redundant in order to guarantee carrier-class redundancy. There are different redundancy techniques used depending on the type of module.

1:1

1:1 redundancy is typically used for system controller modules and I/O interfaces. In a 1:1 redundancy scheme, one primary module and one secondary module comprise one protection group. There are three service state models for 1:1 protection groups. VoDSL and VoIP gateways must employ Active/Hot Standby or Active/Active Standby to be considered carrier-class products.

FIGURE 1

Factors Affecting Telephone Network Downtime



With Active/Hot Standby, both static and dynamic data is maintained in the Hot Standby secondary module. The Hot Standby card queues all activity and is in synchronicity with the primary card but does not act on requests or transactions. If the primary module fails, the secondary module can quickly assume traffic responsibilities because of its dynamic data synchronicity with the primary module. Active/Hot Standby facilitates quicker switchover times than Active/Cold Standby and is used in carrier-class redundant systems.

In Active/Active Standby, both the primary and secondary modules are active and both act on requests and transactions. The active card is designated the primary card and transmits data, while the standby card processes but does not transmit data. This approach minimizes switchover times and is used in carrier-class redundant systems.

1:N

1:N redundancy is used to maximize the number of in-service I/O interfaces because one secondary module can back up N primary modules in a protection group. This is especially relevant in trunking applications, as duplication of interface modules can be expensive and 1:N redundancy minimizes the cost of leasing spare lines.

In 1:N configurations, the spare module cannot be fully configured because its exact configuration is not completely known until one of the primary modules in the protection group fails. At that time, the secondary card is updated and begins to transmit traffic. For this reason, 1:N systems typically are Active/Cold Standby.

Hot Swappability

Another carrier-class requirement involving module redundancy is hot swappability, which is the ability to replace defective modules with non-defective modules while not impacting active traffic through the system. Modules that are hot swappable must also have the ability to automatically download their proper configuration when plugged into the slot.

Port Redundancy

In some instances, it is important to provide redundancy at the port level in addition to the card level. This is especially critical in situations where a large percentage of traffic is flowing over a handful of ports and loss of a single port can have a substantially negative impact on overall system availability. *Figure 2* details an example of this type of redundancy.

In this diagram a digital signal (DS)–3 Y-cable provides port redundancy. Both transmit signals are connected through a Y-cable to a transmit line, while both receive signals are connected through a Y-cable to a receive line. 75-ohm splitters determine which port is primary and which is secondary. Upon failure of the primary port, the secondary port begins transmission with no signal loss. Port redundancy is critical for VoDSL and VoIP gateways to provide a degree of fault tolerance above and beyond module-level redundancy.

Timing System Redundancy

To ensure fault tolerance and flexibility, multiple timing sources must be available for carrier-class voice gateways. This must include both internally generated timing sources as well as externally generated timing sources. Common timing sources include BITS and CC clocks. Upon failure of all internal and external timing sources, a Stratum Holdover clock must be available on carrier-class voice gateways.

Power System Redundancy

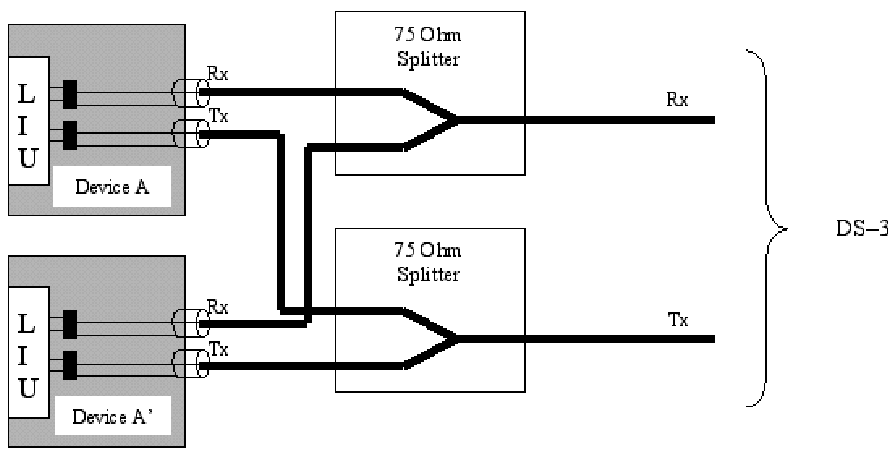
Some networking equipment includes internal power supplies. This equipment cannot be considered carrier class, as it introduces another potential point of failure that could adversely impact the system's overall mean time between failure (MTBF). Carrier-class VoDSL and VoIP gateways typically use a remote redundant power source and two 48-volt direct current (DC) redundant power inputs. In the case of failure of one power input, the second input is available to ensure the equipment remains powered.

Scheduled Maintenance

Scheduled maintenance (25 percent) represents a significant contributor to network downtime. Equipment design not only influences how often equipment must be serviced, in terms of reliability, but how the scheduled maintenance procedure actually occurs. For voice over broadband gateways, system availability during scheduled maintenance is especially critical. Carrier-class products employ split mode operation, a feature that allows equipment to be upgraded in the field without service interruption. Split mode is typically used to facilitate new software loads or hardware replacement. While a software or hardware update is made on one side of the split, normal transactions occur on the other side of the split. Split mode allows carrier-class gateways to continue processing active calls and set up new call connections during the maintenance process. Because of this capability, split mode is a necessary component for carrier-class voice gateways.

FIGURE 2

DS–3 Y-Cable Redundant Device Configuration



Human Factors

Human factors (24 percent) are another major cause of downtime. In addition to split mode, the ability to maintain equipment in a straightforward manner influences carrier-class service. Every field replaceable unit on a gateway should be clearly labeled to minimize confusion during installation and upgrades. Gateway design should be modular enough that removal of unrelated hardware or cables is minimized. Carrier-class gateway products typically employ a midplane architecture that allows service technicians to replace faulty components while not affecting the remainder of the system.

Another important human factor consideration is the design and appearance of the gateway element-management system (EMS). The EMS should be clearly organized to allow for easy fault, performance, and configuration management of the gateway. An intuitive point-and-click graphical user interface (GUI) is a necessary feature. Another important feature of an EMS is its event notification process. All equipment state changes should be propagated from the gateway to the EMS and clearly identify to the user what is happening on the gateway under management in real time. Diagnostic tools should be available to monitor and measure gateway performance from the EMS. Further, the EMS should allow the user the same degree of management control remotely as a user on site with the equipment.

Traffic Overloads

Traffic overloads contribute another 6 percent to network downtime. Carrier-class gateways have the ability to directly control packetized voice traffic. In VoDSL applications, carrier-class gateways are able to shape and police traffic on multiple levels: virtual path (VP), virtual circuit (VC), and channel identifier (CID). This gives users the maximum amount of flexibility to manage traffic across their voice over broadband networks.

In voice gateways, system bus capacity can also impact traffic conditions. Carrier-class gateways are based on asynchronous transfer mode (ATM) bus architectures that provide in excess of 10 gigabits per second (Gbps) backplane/midplane capacity. These ATM–based designs provide sufficient excess bandwidth that the system bus does not become a bottleneck, even in high-traffic conditions. This design is superior to compact peripheral component interconnect (PCI)–based architectures, which are limited to 1 Gbps or less capacity and become bottlenecks in high-traffic situations. Another limitation of compact PCI–based voice gateways is that they require special PCI bridge circuitry to extend beyond eight slots, which introduces another potential point of failure in the system.

Conclusion

Through more than 100 years of development, the PSTN in the United States has been the most reliable network in the world. Unlike the Internet and corporate local-area networks (LANs), where network outages invariably occur from time to time, phone service has to be error-free. Reliable phone service is of paramount importance because telephony service plays such a critical role in the everyday life of business and residential subscribers.

Carrier-class redundancy in VoDSL and VoIP gateways plays a critical role in ensuring the system reliability and availability that enables packet voice services to meet the requirements of traditional voice services.

QoS Metrics for SLA Management

Eric Yam
Chief Technology Officer
ECtel

The telecommunications industry is a dynamically changing environment. New technologies, such as Internet protocol (IP), wireless, and digital subscriber lines (DSL), are rapidly emerging, and new servers and new business models are being introduced. This paper discusses quality of service (QoS) for service-level agreement (SLA) management for new services from the perspective of service management and business management.

New QoS Challenges

QoS was traditionally an operations and engineering tool used by QoS experts for a relatively static, well-established connection-based network environment. Today it has become a business management tool with immediate commercial implications.

Meeting Emerging Telecommunications Business Transactions

QoS is now being used to formulate and enforce the compliance of SLAs. Telecommunications capacity is being traded among alternative carriers as if it were a stock market commodity, and price is determined by volume and quality. Best-value routing (BVR) is replacing the traditional least-cost routing by using a value criteria, which is the cost weighted by quality.

Requirements for SLAs

The market should be allowed to provide different service grades at different price levels, and QoS metrics should be used for the formulation of SLAs and subsequent compliance confirmation.

Industrially standardized QoS methodology is needed to characterize true customer-perceived QoS, and that should be applicable to different services and technologies. In addition, the tool should be an automated, hands-free quality measurement of live traffic, supported by near-real-time reporting and information distribution.

Also needed are short- and long-term quality statistics, which can be measured against target QoS benchmarks, and this requires metrics.

QoS Metrics

Metrics is an index to represent true customer perception of call quality, and it is based on well-researched and well-tested models. It is used for quantifying abstract quality attributes in simple numbers that are easy to interpret and use by experts and amateurs alike. Metrics is a standard for industry-wide use that enables everyone to speak the same language.

Call-Quality Metrics

Telephone call quality is based on four factors: the call-connection success rate, call-connection delay, conversation and voice quality, and fax transmission quality.

Call-Connection Success Rate

The call-connection success rate includes the answer-seizure ratio (ASR) and the call-completion ratio (CCR). It is based on the number of attempts made before a connection is completed.

Call-Connection Delay

The call-connection delay includes the post-dial delay (PDD) and the call setup time—i.e., how long it takes to get a successful connection. This is an important measurement to the service provider because call-connection delay is not billable time. It is important to the user because waiting can lead to frustration.

Conversation and Voice Quality

The conversation and voice quality is a value measured by the call clarity index (CCI), the perceptual analysis measurement system (PAMS), and the perceptual evaluation of speech quality (PESQ). The CCI is now the new International Telecommunications Union–Telecommunication Standardization Sector (ITU–T) Rec. P.562, and the new standard for speech quality is the ITU–T P.862.

Fax Transmission Quality

The fax transmission quality includes the number of page sends, the data rate, and image quality. The new standard for fax transmission quality is ITU–T Rec. E.458.

Call-Quality Measurement

There are two basic approaches to measuring call quality. One method is to measure live traffic, and the other is to generate test calls. A hybrid of these two approaches is also possible.

Live-Traffic Measurement

Measuring live traffic is nonintrusive. It is a high-volume per-call measurement per the ITU–T Rec. P.561, which could amount to measuring tens of millions of call records a day and storing up to a year's worth of data.

With the information in a call-record database, statistics can be generated per carrier or per destination over a selected time interval, such as hourly, daily, or weekly, with centralized control and scheduling. It will also provide a macroscopic view of network health.

The high-level metrics involved in live-traffic measurement include the call connectivity and PDD, CCI, or ITU–T Rec. P.562, and the fax performance index.

Test Calls
Generating test calls is intrusive. It requires centralized control of strategically located remote test units (RTU) to make test calls via the network being tested. The microscopic view of the system that intrusive testing provides is complementary to the macroscopic view provided by the nonintrusive method.

The test call measures call connectivity and setup delay as well as user-perceived quality for voice over IP (VoIP), using the psycho-acoustic model PAMS/PESQ. The test call also has to measure IP network parameters.

The Hybrid Approach
The hybrid approach to call-quality measurement makes use of both nonintrusive and intrusive methods. An RTU is strategically located for the generation of intrusive test calls, and the traffic center houses the nonintrusive live-traffic measurement devices (see *Figure 1*).

Mapping of Network Parameters into User-Perceived Quality
Call-quality measurement results in a high volume of data. Measurements must be taken for speech level or loudness, noise, echo loss and delay, voice compression effects, and absolute delay, which includes transmission and processing. The latency, delay variation or jitter, packet loss percentage, errored packet percentage, and the signal enhancement scheme must also be measured.

To use all these measurements for service-level management, they need to be mapped into user-perceived quality. The user-perceived mean opinion score (MOS) ranges from five to one, where five is excellent and one is bad. For each call there must actually be two MOSs, one to represent each direction of the call.

Average CCI for All Calls
The average CCI for many carriers falls between four, which is good, and three, which is fair. *Figure 2* shows the actual measurements of live traffic, using the CCI for 14 different carriers, labeled A through N. There is some variation among these carriers, but not much.

Average CCI for Bad Calls
Looking at only the bottom 20 percent of bad calls for the same carriers reveals a large amount of variation (see *Figure 3*). The CCI of carrier B has dropped from about 3.3 (better than fair) to below 2.5 (midway between fair and poor). That of carrier F has dropped from almost 3.5 (midway between good and fair) to about 2.9 (less than fair but not as poor as carrier B).

Customers who placed the poor-quality calls shown for carriers B and F would most likely complain and ask for a refund.

The CCR
The CCR can be measured hourly for a 24-hour period and then charted to show the distribution of completed, incomplete, and rejected calls. *Figures 4* and *5* illustrate the hourly

FIGURE 1

Hybrid Approach Combining Nonintrusive and Intrusive Methods

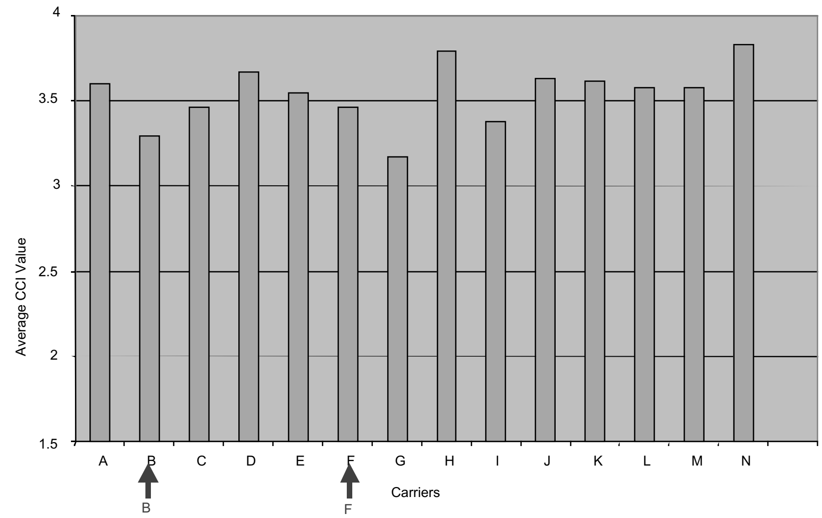
WAN wide-area network

FIGURE 2

Average CCI Values by Carrier



breakdown of calls for a single carrier on a single day, first for phone calls and then for fax calls. Based on the ratio of completed calls to incomplete and rejected calls, the shown carrier's record is not very good.

Voice-Quality Benchmarking

Intrusive tests, especially for listening quality (LQ), would be even more revealing. A comparison of LQ MOS, measured by the PAMS intrusive test, was done for a local public switched telephone network (PSTN), an international PSTN, and a VoIP phone-card service (see *Figure 6*).

The international carrier in *Figure 6* did slightly worse than the local carrier, but the quality of both was nonetheless very consistent and good. Not only is the average VoIP quality poorer than the international carrier, there are also some very bad calls.

Industrial Standardization

The ITU–T study group is doing a lot of work in the area of industrial standardization, and the QoS of VoIP is being worked on. The QoS Development Group (QSDG) and the ITU–T are very active in this area, as is the Internet Engineering Task Force (IETF).

ETSI TIPHON QoS Classes

The European Telecommunications Standards Institute (ETSI) Telecommunications and Internet Protocol Harmonization over Networks (TIPHON) considers the call

FIGURE 3

Worst 20 Percent Average CCI Values by Carrier

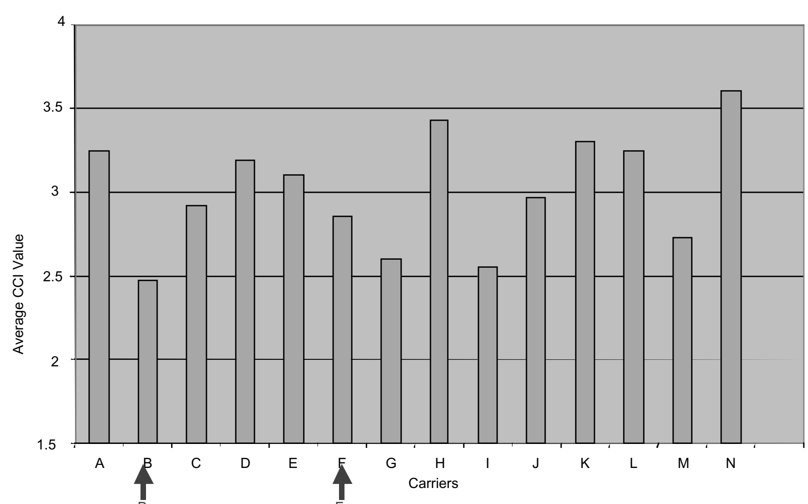


FIGURE 4

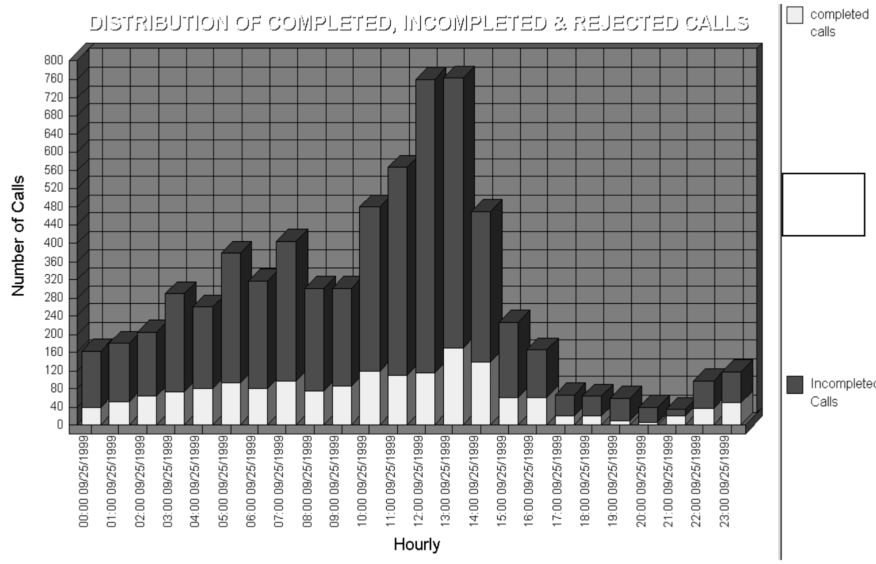
CCR for 24 Hours



as a service and defines four QoS classes, per DTS-101-512, March 2000:

- 4 = Best
- 3 = High
- 2 = Medium
- 1 = Best effort

These classes are expressed in terms of several measurable parameters, including overall transmission quality, speech quality, end-to-end delay, and call setup time.

IPDR.org

IPDR.org is an industrial organization for facilitating practical implementation of interchange of usage data among service elements of IP–based services, which include the following:

- Session-based calls (versus call-based records)
- Content-based billing (versus connection-based billing)
  - QoS–based billing (versus best effort)
  - Multiple services such as VoIP, video on demand (VOD), e-mail, wireless application protocol (WAP), and multimedia conferencing

FIGURE 5

Fax Success Rate for 19 Hours

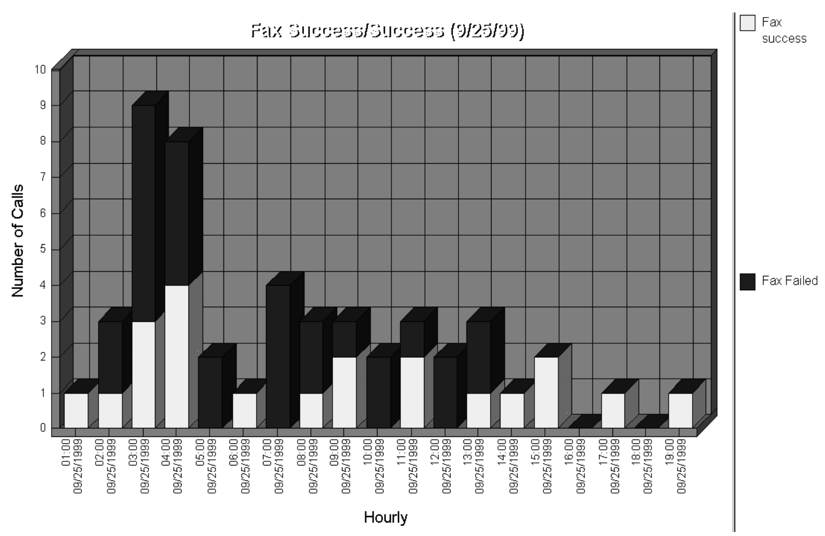


FIGURE 6

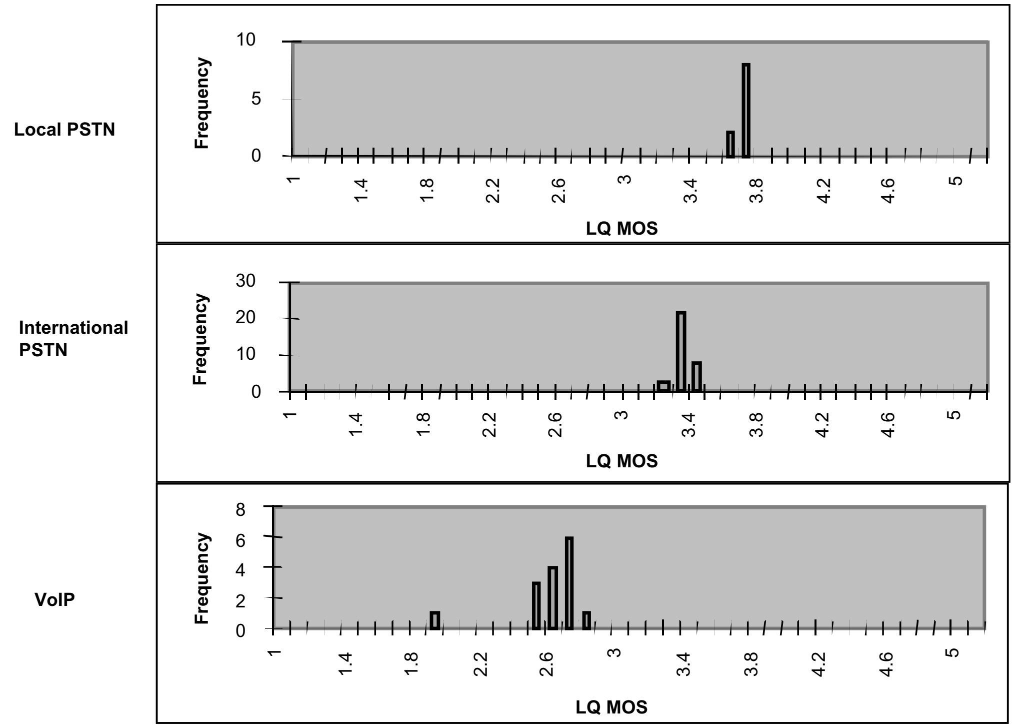
Voice-Quality Benchmarking



Network data management–usage (NDM–U) version 2.5, scheduled for release in first quarter 2001, will include VoIP and VOD IP data record (IPDR) specifications with QoS attributes. IPDR work will be essential for SLA management for IP–based services.

Looking Ahead

Fundamental QoS tool sets will be available for SLA management of emerging services, such as IP–based voice service. New tools will be needed for specific new services, such as a multimedia opinion model.

It will be an evolutionary and collaborative process to apply the tools to fit different business scenarios and industry standardization efforts by the ITU–T, QSDG, TIPHON, and IPDR.org.

Acronym Guide

2B1Q	two binary, one quaternary
2G	second generation
3DES	triple data encryption standard
3G	third generation [also G3]
3GPP	third-generation partnership project
3R	regeneration, reshaping, and retraining
4B3T	four binary, three ternary
4F/BDPR	four-fiber bidirectional dedicated protection ring
4F/BSPR	four-fiber bidirectional shared protection ring
AAA	authentication, authorization, and accounting
AAL–[x]	ATM adaptation [layer x]
ABC	activity-based costing
ABR	available bit rate
AC	alternating current OR authentication code
ACD	automatic call distributor
ACH	automated clearinghouse
ACL	access control list
ACLEP	adaptive code excited linear prediction
ACM	address complete message
ACR	alternate carrier routing OR anonymous call rejection
ADM	add/drop multiplexer OR asymmetric digital multiplexer
ADPCM	adaptive differential pulse code modulation
ADS	add/drop switch
ADSI	analog display services interface
ADSL	asymmetric digital subscriber line
AFE	analog front end
AGW	agent gateway
AIM	advanced intelligent messaging
AIN	advanced intelligent network
ALI	automatic location identification
AM	amplitude modulation
AMA	automatic messaging account
AMI	alternate mark inversion
AMPS	advanced mobile phone service
AN	access network
ANI	automatic number identification
ANM	answer message
ANSI	American National Standards Institute
ANX	Automotive Network Exchange
AOL	America Online
AON	all-optical network
AP	access point OR access provider
APC	automatic power control
API	application programming interface
APON	ATM passive optical network
APS	automatic protection switching
ARCNET	attached resource computer network
ARI	assist request instruction
ARM	asynchronous response mode
ARMS	authentication, rating, mediation, and settlement
ARP	address resolution protocol
ARPANET	Advanced Research Projects Agency Network
ARPU	average revenue per customer
A-Rx	analog receiver
AS	application server OR autonomous system
ASAM	ATM subscriber access multiplexer
ASC	Accredited Standards Committee
ASCII	American Standard Code for Information Interchange
ASE	amplified spontaneous emission
ASIC	application-specific integrated circuit
ASIP	application-specific instruction processor
ASON	automatically switched optical network
ASP	application service provider
ASR	access service request OR answer-seizure rate OR automatic service request OR automatic speech recognition
ASSP	application-specific standard part
ASTN	automatically switched transport network OR analog switched telephone network
ATC	automatic temperature control
ATIS	Alliance for Telecommunications Industry Solutions
ATM	asynchronous transfer mode OR automated teller machine
ATMF	ATM Forum
ATP	analog twisted pair
ATU-C	ADSL transmission unit-CO
ATU-R	ADSL transmission unit-remote
A-Tx	analog transceiver
AUI	attachment unit interface
AVI	audio video interleaved
AWG	American Wire Gauge OR arrayed waveguide grating
AYUTOS	as-yet-un-thought-of services
B2B	business-to-business
B2C	business-to-consumer
BAF	Bellcore automatic message accounting format
B-Box	breakout box
BBS	bulletin board system
BCSM	basic call state model
BDCS	broadband digital cross-connect system
BDPR	bidirectional dedicated protection ring
BE	border element
BER	bit-error rate
BERT	bit error–rate test
BGP	border gateway protocol
BH	busy hour
BHCA	busy hour call attempt
BI	bit rate independent
BICC	bearer independent call control
BID	bit rate identification
BIP	bit interactive parity
B–ISDN	broadband ISDN
BLEC	broadband local-exchange carrier OR building local-exchange carrier
BLES	broadband loop emulation services
BLSR	bidirectional line-switched ring
BML	business management layer
BOC	Bell operating company

BOF	business operations framework
BOND	back-office network development
BOSS	broadband operating system software
BPON	broadband passive optical network
BPSK	binary phase shift keying
B–RAS	broadband–remote access server
BRI	basic rate interface
BSA	business services architecture
BSPR	bidirectional shared protection ring
BSS	base-station system OR business support system
BTS	base transceiver station
BVR	best-value routing
BW	bandwidth
CA	call agent
CAC	call admission control OR carrier access code OR connection admission control
CAD	computer-aided design
CAGR	compound annual growth rate
CALEA	Communications Assistance for Law Enforcement Act
CAM	computer-aided manufacture
CAMEL	customized application of mobile enhanced logic
CAP	competitive access provider OR carrierless amplitude and phase modulation
CAPEX	capital expenditures
CAR	committed access rate
CARE	customer account record exchange
CAS	channel-associated signaling OR communications applications specification
CAT	conditional access table OR computer aided telephony
CATV	cable television
C-band	conventional band
CBDS	connectionless broadband data service
CBR	constant bit rate
CBT	core-based tree
CC	control component
CCB	customer care and billing
CCF	call-control function
CCI	call clarity index
CCITT	Consultative Committee on International Telegraphy and Telephony
CCK	complementary code keying
CCR	call-completion ratio
CCS	common channel signaling
CD	chromatic dispersion OR compact disc
cDCF	conventional dispersion compensation fiber
CDD	content delivery and distribution
CDDI	copper-distributed data interface
CDMA	code division multiple access
CDMP	cellular digital messaging protocol
CDMS	configuration and data management server
CDN	control directory number
CDPD	cellular digital packet data
CDR	call detail record OR clock and data recovery
CD–ROM	compact disc–read-only memory
CDWDM	coarse wavelength division multiplexing
CE	customer edge
CEI	comparable efficient interface

CEO	chief executive officer
CER	customer edge router
CES	circuit emulation service
CERT	computer emergency response team
CES	circuit emulation service
CESID	caller emergency service identification
CEV	controlled environment vault
CFB/NA	call forward busy/not available
CFO	chief financial officer
CFP	contention free period
CGI	common gateway interface
CHCS	composite health care system
CHN	centralized hierarchical network
C–HTML	compressed HTML
CIC	circuit identification code
CID	caller identification
CIMD2	computer interface message distribution 2
CIM	common information model
CIO	chief information officer
CIP	classical IP over ATM
CIR	committed information rate OR Communications Industry Researchers
CIT	computer integrated telephone
CLASS	custom local-area signaling services
CLE	customer-located equipment
CLEC	competitive local-exchange carrier
CLI	command line interface
CLLI	common language location identifier
CLR	circuit layout record
CM	cable modem
CM&B	customer management and billing
CMIP	common management information protocol
CMISE	common management information service element
CMOS	complementary metal oxide semiconductor
CMRS	commercial mobile radio service
CMTS	cable modem termination system
CNAM	calling name (also defined as “caller identification with name” and simply “caller identification”)
CNAP	CNAM presentation
CO	central office
CODEC	coder-decoder
COI	community of interest
COO	chief operations officer
COPS	common open policy service
CORBA	common object request broker architecture
CORE	council of registrars
CoS	class of service
COT	central office terminal
COTS	commercial off-the-shelf
COW	cellsite on wheels
CP	connection point
CPAS	cellular priority access service
CPC	calling-party category (also calling-party control OR calling-party connected)
CPE	customer-premises equipment
CPI	continual process improvement
CPL	call processing language
CPLD	complex programmable logic device
CPN	calling-party number
CPU	central processing unit
CR	constraint-based routing

CR–LDP	constraint-based routed–label distribution protocol
CRC	cyclic redundancy check OR cyclic redundancy code
CRM	customer-relationship management
CRS	capacity, reach, and speed
CRTP	compressed real-time transport protocol
CRV	call reference value
CS	client signal
CS–[x]	capability set [x]
CSA	carrier serving area
CSCE	converged service-creation and execution
CSCW	computer supported collaborative work
CS–IWF	control signal interworking function
CSF	critical success factors
CSM	customer-service manager
CSMA/CA	carrier sense multiple access with collision avoidance
CSMA/CD	carrier sense multiple access with collision detection
CSN	circuit-switched network
CSP	communications service provider OR content service provider
CSR	customer-service representative
CSU	channel service unit
CSV	circuit-switched voice
CT	computer telephony
CT–2	cordless telephony generation 2
CTI	computer telephony integration
CTIA	Cellular Telecommunications & Internet Association
CTM	Center for Telecommunications Management
CTO	chief technology officer
CUG	closed user group
CWD	centralized wavelength distribution
CWDM	coarse wavelength division multiplexing
CWIX	cable and wireless Internet exchange
DAC	digital access carrier
DACS	digital access cross-connect system
DAM	DECT authentication module
DAMA	demand assigned multiple access
DARPA	Defense Advanced Research Projects Agency
DAVIC	Digital Audio Video Council
dB	decibel(s)
dBrn	decibels above reference noise
DB	database
DBMS	database management system
DBS	direct broadcast satellite
DC	direct current
DCC	data communications channel
DCF	discounted cash flow OR dispersion compensation fiber
DCLEC	data competitive local-exchange carrier
DCM	dispersion compensation module
DCN	data communications network
DCOM	distributed component object model
DCS	digital cross-connect system OR distributed call signaling
DCT	discrete cosine transform
DDN	defense data network
DDS	dataphone digital service
DECT	Digital European Cordless Telecommunication
demarc	demarcation point
DEMS	digital electronic messaging service
DES	data encryption standard
DFB	distributed feedback
DFC	dedicated fiber/coax
DGD	differentiated group delay
DGFF	dynamic gain flattening filter
DHCP	dynamic host configuration protocol
DiffServ	differentiated services
DIN	digital information network
DIS	distributed interactive simulation
DITF	Disaster Information Task Force
DLC	digital loop carrier
DLCI	data-link connection identifier
DLE	digital loop electronics
DLEC	data local-exchange carrier
DLR	design layout report
DM	dense mode
DMD	dispersion management device
DMS	digital multiplex system
DMT	discrete multitone
DN	distinguished name
DNS	domain name server OR domain naming system
DOC	department of communications
DOCSIS	data over cable service interface specifications
DOD	Department of Defense
DOJ	Department of Justice
DoS	denial of service
DOS	disk operating system
DOSA	distributed open signaling architecture
DOT	Department of Transportation
DOW	day of week
DP	detection point
DPC	destination point code
DPE	distributed processing environment
DPT	dial pulse terminate
DQoS	dynamic quality of service
D-Rx	digital receiver
DS–[x]	digital signal [level x]
DSAA	DECT standard authentication algorithm
DSC	DECT standard cipher
DSCP	DiffServ code point
DSF	dispersion-shifted fiber
DSL	digital subscriber line [also xDSL]
DSLAM	digital subscriber line access multiplexer
DSLAS	DSL–ATM switch
DSP	digital signal processor OR digital service provider
DSS	decision support system
DSSS	direct sequence spread spectrum
DSU	data service unit OR digital service unit
DTMF	dual-tone multifrequency
DTV	digital television
D-Tx	digital transceiver
DVB	digital video broadcast
DVC	dynamic virtual circuit
DVD	digital video disc
DVMRP	distance vector multicast routing protocol
DVOD	digital video on demand
DVR	digital video recording
DWDM	dense wavelength division multiplexing
DXC	digital cross-connect
E911	enhanced 911

EAI	enterprise application integration
EBITDA	earnings before interest, taxes, depreciation, and amortization
EC	electronic commerce
ECD	echo-cancelled full-duplex
ECRM	echo canceller resource module
ECTF	Enterprise Computer Telephony Forum
EDA	electronic design automation
EDF	electronic distribution frame OR erbium-doped fiber
EDFA	erbium-doped fiber amplifier
EDGE	enhanced data rates for GSM evolution
EDI	electronic data interchange
EDSX	electronic digital signal cross-connect
EFM	Ethernet in the first mile
EFT	electronic funds transfer
EJB	enterprise Java beans
ELAN	emulated local-area network
ELEC	enterprise local-exchange carrier
EM	element manager
EMI	electromagnetic interference
EML	element-management layer
EMS	element-management system OR enterprise messaging server
ENUM	telephone number mapping
E–O	electrical-to-optical
EO	end office
EoA	Ethernet over ATM
EOC	embedded operations channel
EoVDSL	Ethernet over VDSL
EPD	early packet discard
EPON	Ethernet PON
EPROM	erasable programmable read-only memory
ERP	enterprise resource planning
ESCON	enterprise system connection
ESS	electronic switching system
ETC	establish temporary connection
EtherLEC	Ethernet local exchange carrier
ETL	extraction, transformation, and load
eTOM	e-telecom operations map
ETSI	European Telecommunications Standards Institute
EU	European Union
EXC	electrical cross-connect
EURESCOM	European Institute for Research and Strategic Studies in Telecommunications
FAB	fulfillment, assurance, and billing
FAQ	frequently asked question
FBG	fiber Bragg grating
FCAPS	fault, configuration, accounting, performance, and security
FCC	Federal Communications Commission
FCI	furnish charging information
FCIF	flexible computer-information format
FDA	Food and Drug Administration
FDD	frequency division duplex
FDDI	fiber distributed data interface
FDF	fiber distribution frame
FDM	frequency division multiplexing
FDMA	frequency division multiple access
FDS–1	fractional DS–1
FE	extended framing
FEC	forward error correction
FEPS	facility and equipment planning system
FEXT	far-end crosstalk
FHSS	frequency hopping spread spectrum
FICON	fiber connection
FITL	fiber-in-the-loop
FM	fault management OR frequency modulation
FOC	firm order confirmation
FOT	fiber-optic terminal
FOTS	fiber-optic transmission system
FP	Fabry-Perot [laser]
FPB	flex parameter block
FPGA	field programmable gate array
FPLMTS	future public land mobile telephone system
FPP	fast-packet processor
FR	frame relay
FRAD	frame-relay access device
FSAN	full-service access network
FSC	framework services component
FSN	full-service network
FT	fixed-radio termination
FT1	fractional T1
FTC	Federal trade Commission
FTE	full-time equivalent
FTP	file transfer protocol
FTP3	file transfer protocol 3
FTTB	fiber-to-the-building
FTTC	fiber to the curb
FTTCab	fiber-to-the-cabinet
FTTEx	fiber-to-the-exchange
FTTH	fiber-to-the-home
FTTN	fiber-to-the-neighborhood
FTTS	fiber-to-the-subscriber
FTTx	fiber-to-the-x
FWM	four-wave mixing
FX	foreign exchange
G3	[see 3G]
GA	genetic algorithm
Gb	gigabit
GbE	gigabit Ethernet [also GE]
GBIC	gigabit interface converter
Gbps	gigabits per second
GCRA	generic cell rate algorithm
GDIN	global disaster information network
GDMO	guidelines for the definition of managed objects
GE	[see GbE]
GEO	geosynchronous Earth orbit
GETS	government emergency telecommunications service
GFF	gain flattening filter
GFR	guaranteed frame rate
Ghz	gigahertz
GIF	graphics interface format
GIS	geographic information services
GKMP	group key management protocol
GMII	gigabit media independent interface
GMLC	gateway mobile location center
GMPCS	global mobile personal communications services
GMPLS	generalized MPLS
GNP	gross national product
GOCC	ground operations control center
GPIB	general-purpose interface bus
GPRS	general packet radio service

GPS	global positioning system
GR	generic requirement
GRASP	greedy randomized adaptive search procedure
GSA	Global Mobile Suppliers Association
GSM	Global System for Mobile Communications
GSMP	generic switch management protocol
GSR	gigabit switch router
GTT	global title translation
GUI	graphical user interface
GVD	group velocity dispersion
GW	gateway
HBO	Home Box Office
HCC	host call control
HD	home domain
HDLC	high-level data-link control
HDML	handheld device markup language
HDSL	high–bit rate DSL
HDT	host digital terminal
HDTV	high-definition television
HDVMRP	hierarchical distance vector multicast routing protocol
HEC	head error control OR header error check
HEPA	high-efficiency particulate arresting
HFC	hybrid fiber/coax
HIDS	host intrusion detection system
HLR	home location register
HN	home network
HOM	high-order mode
HomePNA	Home Phoneline Networking Alliance [also HomePNA2]
HomeRF	Home Radio Frequency Working Group
HPC	high probability of completion
HPO	high-performance option
HQ	headquarters
HSCSD	high-speed circuit-switched data
HSD	high-speed data
HSIA	high-speed Internet access
HSP	hosting service provider
HTML	hypertext markup language
HTTP	hypertext transfer protocol
HVAC	heating, ventilating, and air-conditioning
HW	hardware
IAD	integrated access device
IAM	initial address message
IAS	integrated access service OR Internet access server
IAST	integrated access, switching, and transport
IAT	inter-arrival time
IBC	integrated broadband communications
IC	integrated circuit
ICD	Internet call diversion
ICDR	Internet call detail record
ICL	intercell linking
ICMP	Internet control message protocol
ICP	integrated communications provider OR intelligent communications platform
ICS	integrated communications system
ICW	Internet call waiting
IDC	Internet data center OR International Data Corporation
IDE	integrated development environment
IDES	Internet data exchange system
IDF	intermediate distribution frame
IDL	interface definition language
IDLC	integrated digital loop carrier
IDS	intrusion detection system
IDSL	integrated services digital network DSL
IEC	International Electrotechnical Commission OR International Engineering Consortium
IEEE	Institute of Electrical and Electronics Engineers
I-ERP	integrated enterprise resource planning
IETF	Internet Engineering Task Force
IFITL	integrated [services over] fiber-in-the-loop
IFMA	International Facility Managers Association
IFMP	Ipsilon flow management protocol
IGMP	Internet group management protocol
IGP	interior gateway protocol
IGRP	interior gateway routing protocol
IGSP	independent gateway service provider
IHL	Internet header length
IIS	Internet Information Server
IKE	Internet key exchange
ILA	in-line amplifier
ILEC	incumbent local-exchange carrier
ILMI	interim link management interface
IM	instant messaging
IMA	inverse multiplexing over ATM
IMRP	Internet multicast routing protocol
IMSI	International Mobile Subscriber Identification
IMT	intermachine trunk OR International Mobile Telecommunications
IMTC	International Multimedia Teleconferencing Consortium
IN	intelligent network
INAP	intelligent network application part
INAP AU	INAP adaptation unit
INE	intelligent network element
InfoCom	information communication
INM	integrated network management
INMD	in-service, nonintrusive measurement device
INT	[point-to-point] interrupt
InterNIC	Internet Network Information Center
IntServ	integrated services
IOF	interoffice facility
IOS	intelligent optical switch
IP	Internet protocol
IPBX	Internet protocol private branch exchange
IPcoms	Internet protocol communications
IPDC	Internet protocol device control
IPDR	Internet protocol data record
IPe	intelligent peripheral
IPG	intelligent premises gateway
IPO	initial public offering OR Internet protocol over optical
IPoA	Internet protocol over ATM
IPQoS	Internet protocol quality of service
IPSec	Internet protocol security
IPTel	IP telephony
IPv6	Internet protocol version 6
IPX	Internet package exchange
IR	infrared
IRU	indefeasible right to user
IS	information service OR interim standard
IS-IS	intermediate system to intermediate system

ISA	industry standard architecture
ISAPI	Internet server application programmer interface
ISC	integrated service carrier OR International Softswitch Consortium
ISDF	integrated service development framework
ISDN	integrated services digital network
ISDN–BA	ISDN basic access
ISDN–PRA	ISDN primary rate access
ISEP	intelligent signaling endpoint
ISM	industrial, scientific, and medical OR integrated service manager
ISO	International Organization for Standardization
ISOS	integrated software on silicon
ISP	Internet service provider
ISUP	ISDN user part
ISV	independent software vendor
IT	information technology OR Internet telephony
ITSP	Internet telephony service provider
ITTP	information technology infrastructure library
ITU	International Telecommunication Union
ITU–T	ITU–Telecommunication Standardization Sector
ITV	Internet television
IVR	interactive voice response
IVRU	interactive voice-response unit
IWF	interworking function
IWU	interworking unit
IXC	interexchange carrier
JAIN	Java APIs for integrated networks
JCAT	Java coordination and transactions
JCC	JAIN call control
JDBC	Java database connectivity
JDMK	Java dynamic management kit
JMAPI	Java management application programming interface
JMX	Java management extension
JPEG	Joint Photographic Experts Group
JSCE	JAIN service-creation environment
JSIP	Java session initiation protocol
JSLEE	JAIN service logic execution environment
JTAPI	Java telephony application programming interface
JVM	Java virtual machine
kbps	kilobits per second
kHz	kilohertz
km	kilometer
L2F	Layer-2 forwarding
L2TP	Layer-2 tunneling protocol
LAC	L2TP access concentrator
LAI	location area identity
LAN	local-area network
LANE	local-area network emulation
LATA	local access and transport area
L-band	long band
LBS	location-based services
LC	local convergence
LCD	liquid crystal display
LCP	link control protocol
LCUG	Local Competition User Group
LD	laser diode OR long distance
LDAP	lightweight directory access protocol
LD–CELP	low delay–code excited linear prediction
LDP	label distribution protocol
LDS	local digital service
LE	line equipment OR local exchange
LEAF®	large-effective-area fiber
LEC	local-exchange carrier
LED	light-emitting diode
LEO	low Earth orbit
LEOS	low Earth-orbiting satellite
LER	label edge router
LES	loop emulation service
LIDB	line information database
LL	long line
LLC	logical link control
LMDS	local multipoint distribution system
LMN	local network management
LMOS	loop maintenance operation system
LMP	link management protocol
LMS	loop-management system OR loop-monitoring system OR link-monitoring system
LNNI	LANE network-to-network interface
LNP	local number portability
LNS	L2TP network server
LOI	letter of intent
LOL	loss of lock
LOS	line of sight OR loss of signal
LPF	low-pass filter
LQ	listening quality
LRN	local routing number
LSA	label switch assignment OR link state advertisement
LSB	location-sensitive billing
LSMS	local service management system
LSO	local service office
LSP	label-switched path
LSR	label-switched router OR leaf setup request OR local service request
LT	line terminator OR logical terminal
LTE	lite terminating equipment
LUNI	LANE user network interface
LX	local exchange
M2PA	message transfer protocol 2 peer-to-peer adaptation
M2UA	message transfer protocol 2–user adaptation layer
M3UA	message transfer protocol 3–user adaptation layer
MAC	media access control
MADU	multiwave add/drop unit
MAN	metropolitan-area network
MAP	mobile applications part
MAS	multiple-application selection
MB	megabyte
Mb	megabit
MBAC	measurement-based admission control
MBGP	multicast border gateway protocol
MBone	multicast backbone
Mbps	megabits per second
MC	multipoint controller
MCC	mobile country code
MCU	multipoint control unit
MDF	main distribution frame
MDSL	multiple DSL

MDTP	media device transport protocol
MDU	multiple-dwelling unit
MEGACO	media gateway control
MEMS	micro-electromechanical system
MExE	mobile execution environment
MFJ	modified final judgment
MG	media gateway
MGC	media gateway controller
MGCP	media gateway control protocol
MHz	megahertz
MIB	management information base
MII	media independent interface
MIME	multipurpose Internet mail extensions
MIN	mobile identification number
MIPS	millions of instructions per second
MIS	management information system
MITI	Ministry of International Trade and Industry (in Japan)
MLT	mechanized loop testing
MM	Mobility Management
MMDS	multichannel multipoint distribution system
MMPP	Markov-Modulated Poisson Process
MMUSIC	Multiparty Multimedia Session Control [working group]
MNC	mobile network code
MOM	message-oriented middleware
MON	metropolitan optical network
MOP	method of procedure
MOS	mean opinion score
MOSFP	multicast open shortest path first
MOU	minutes of use OR memorandum of understanding
MPC	mobile positioning center
MPEG	Moving Pictures Experts Group
MPI	message passing interface
MPLambdaS	multiprotocol lambda switching
MPLS	multiprotocol label switching
MPOA	multiprotocol over ATM
MPOE	multiple point of entry
MPOP	metropolitan point of presence
MPP	massively parallel processor
MPx	MPEG–Layer x
MRC	monthly recurring charge
MRS	menu routing system
MRSP	mobile radio service provider
ms	millisecond
MSC	mobile switching center
MSF	Multiservice Switch Forum
MSIN	mobile station identification number
MSNAP	multiple services network access point
MSO	multiple-system operator
MSP	management service provider
MSS	multiple-services switching system
MSSP	mobile satellite service provider
MTA	message transfer agent
MTBF	mean time between failures
MTP–[x]	message transfer part–[x]
MTTR	mean time to repair
MTU	multiple-tenant unit
MVL	multiple virtual line
MWIF	Mobile Wireless Internet Forum
MZI	Mach-Zender Interferometer
NA	network adapter
NAFTA	North America Free Trade Agreement
NANC	North American Numbering Council
NANP	North American Numbering Plan
NAP	network access point
NARUC	National Association of Regulatory Utility Commissioners
NAS	network access server
NASA	National Aeronautics and Space Administration
NAT	network address translation
NATA	North American Telecommunications Association
NBN	node-based network
NCF	National Communications Forum
NCP	network control protocol
NCS	national communications system OR network connected server
NDA	national directory assistance
NDM–U	network data management–usage
NDSF	non-dispersion-shifted fiber
NE	network element
NEBS	network-equipment building standards
NEL	network-element layer
NEXT	near-end crosstalk
NFS	network file system
NG	next generation
NGCN	next-generation converged network
NGDLC	next-generation digital loop carrier
NGF	next-generation fiber
NGN	next-generation network
NGOSS	next-generation operations system and software OR next-generation OSS
NHRP	next-hop resolution protocol
NI	network interface
NIC	network interface card
NID	network interface device
NIDS	network intrusion detection system
NIIF	Network Interconnection Interoperability Forum
NIS	network information service
NIU	network interface unit
nm	nanometer
NML	network-management layer
NMS	network-management system
NND	name and number delivery
NNI	network-to-network interface
NOC	network operations center
NOMAD	national ownership, mobile access, and disaster communications
NP	number portability
NPA	numbering plan area
NPAC	Number Portability Administration Center
NPN	new public network
NP–REQ	number-portable request query
NPV	net present value
NRC	Network Reliability Council OR nonrecurring charge
NRIC	Network Reliability and Interoperability Council
NRRI	National Regulatory Research Institute (The Ohio State University)
NRSC	Network Reliability Steering Committee
NRZ	non–return to zero
NS/EP	national security and emergency preparedness

NSAP	network service access point
NSAPI	Netscape server application programming interface
NSCC	network surveillance and control center
NSDB	network and services database
NSP	network service provider OR network and service performance
NSTAC	National Security Telecommunications Advisory Committee
NT	network termination OR new technology
NTN	network terminal number
NTSC	National Television Standards Committee
NVP	network voice protocol
NZ–DSF	nonzero dispersion-shifted fiber
O&M	operations and maintenance
OADM	optical add/drop multiplexer
OA&M	operations, administration, and maintenance
OAM&P	operations, administration, maintenance, and provisioning
OBF	Ordering and Billing Forum
OBLSR	optical bidirectional line-switched ring
OC–[x]	optical carrier–[level x]
OCBT	ordered core-based protocol
OCD	optical concentration device
OCh	optical channel
OCR	optical character recognition
OCU	office channel unit
OCX	open compact exchange
OD	origin-destination
ODBC	open database connectivity
ODSI	optical domain services interface
O–E	optical-to-electrical
O–EC	optical–electrical converter
OECD	Organization for Economic Cooperation and Development
OEM	original equipment manufacturer
O–E–O	optical-to-electrical-to-optical
OEXC	opto-electrical cross-connect
OFC	Optical Fiber Conference
OFDM	orthogonal frequency division multiplexing
OIF	Optical Internetworking Forum
OLA	optical line amplifier
OLAP	on-line analytical processing
OLI	optical link interface
OLT	optical line termination OR optical line terminal
OLTP	on-line transaction processing
OMC	Operations and Maintenance Center
OMG	Object Management Group
OMS SW	optical multiplex section switch
OMS	optical multiplex section
OMSSPRING	optical multiplex section shared protection ring
ONA	open network architecture
ONE	optical network element
ONMS	optical network-management system
ONI	optical network interface
ONT	optical network termination
ONTAS	optical network test access system
ONU	optical network unit
OP	optical path
OPEX	operating expenses
OPS	operator provisioning station
OPTIS	overlapped PAM transmission with interlocking spectra
OPXC	optical path cross-connect
ORB	object request broker
ORT	operational readiness test
OS	operating system
OSA	open service architecture
OSC	optical supervisory panel
OSD	on-screen display
OSGI	open services gateway initiative
OSI	open systems interconnection
OSMINE	operations systems modification of intelligent network elements
OSN	optical-service network
OSNR	optical signal-to-noise ratio
OSP	outside plant
OSPF	open shortest path first
OSS	operations support system
OSS/J	OSS through Java
OSU	optical subscriber unit
OTM	optical terminal multiplexer
OTN	optical transport network
OUI	optical user interface
O-UNI	optical user-to-network interface
OUSP	optical utility services platform
OVPN	optical virtual petabits network OR optical virtual private network
OWSR	optical wavelength switching router
OXC	optical cross-connect
PABX	private automatic branch exchange
PACA	priority access channel assignment
PACS	picture archiving communications system
PAL	phase alternate line
PAM	Presence and Availability Management [Forum] OR pulse amplitude modulation
PAMS	perceptual analysis measurement system
PAN	personal access network
PANS	pretty amazing new services
P&L	profit and loss
PBN	point-to-point–based network OR policy-based networking
PBX	private branch exchange
PC	personal computer
PCF	physical control field
PCI	peripheral component interconnect
PCM	pulse code modulation
PCN	personal communications network
PCR	peak cell rate
PCS	personal communications service
PDA	personal digital assistant
PDD	post-dial delay
PDE	position determination equipment
PDH	plesiochronous digital hierarchy
PDN	public data network
PDP	policy decision point
PDSN	packet data serving node
PDU	protocol data unit
PE	provider edge
PERL	practical extraction and report language
PESQ	perceptual evolution of speech quality
PFD	phase-frequency detector
PHB	per-hop behavior
PHP	personal home page
PHY	physical layer

PIC	point-in-call OR predesignated interexchange carrier OR primary interexchange carrier
PICS	plug-in inventory control system
PIM	personal information manager OR protocol-independent multicast
PIN	personal identification number
PINT	PSTN and Internet Networking [IETF working group]
PINTG	PINT gateway
PKI	public key infrastructure
PLA	performance-level agreement
PLC	planar lightwave circuit OR product life cycle
PLCP	physical layer convergence protocol
PLL	phase locked loop
PLMN	public land mobile network
PLOA	protocol layers over ATM
PM	performance monitoring
PMD	physical-medium dependent OR polarization mode dispersion
PMDC	polarization mode dispersion compensator
PMO	present method of operation
PMP	point-to-multipoint
PN	personal number
PNNI	private network-to-network interface
PnP	plug and play
PO	purchase order
PODP	public office dialing plan
POET	partially overlapped echo-cancelled transmission
POF	plastic optic fiber
POH	path overhead
POIS	packet optical interworking system
PON	passive optical network
POP	point of presence
POP3	post office protocol 3
POS	packet over SONET OR point of service
PosReq	position request
POT	point of termination
POTS	plain old telephone service
PP	point-to-point
PPD	partial packet discard
PPP	point-to-point protocol
PPPoA	point-to-point protocol over ATM
PPPoE	point-to-point protocol over Ethernet
PPTP	point-to-point tunneling protocol
PP–WDM	point-to-point–wavelength division multiplexing
PQ	priority queuing
PRI	primary rate interface
ps	picosecond
PSAP	public safety answering point
PSC	Public Service Commission
PSD	power spectral density
PSDN	public switched data network
PSID	private system identifier
PSN	public switched network
PSPDN	packet-switched public data network
PSQM	perceptual speech quality measure
PSTN	public switched telephone network
PTE	path terminating equipment
PTN	personal telecommunications number service
PTP	point-to-point
PTT	Post Telephone and Telegraph Administration
PUC	public utility commission
PVC	permanent virtual circuit
PVM	parallel virtual machine
PVN	private virtual network
PWS	planning workstation
PXC	photonic cross-connect
QAM	quadrature amplitude modulation
QOE	quality of experience
QoS	quality of service
QPSK	quaternary phase shift keying
QSDG	QoS Development Group
RADIUS	remote authentication dial-in user service
RADSL	rate-adaptive DSL
RAM	remote access multiplexer
RAN	regional-area network
RAP	resource allocation protocol
RAS	remote access server
RBOC	regional Bell operating company
RCP	remote call procedure
RCU	remote control unit
RDBMS	relational database management system
RDC	regional distribution center
RDSLAM	remote DSLAM
REL	release
RF	radio frequency
RFC	request for comment
RFI	request for information
RFP	request for proposal
RFPON	radio frequency optical network
RFQ	request for quotation
RGU	revenue-generating unit
RGW	residential gateway
RHC	regional holding company
RIAC	remote instrumentation and control
RIM	research in motion
RIP	routing information protocol
RISC	reduced instruction set computing
RJ	registered jack
RLL	radio in the loop
RM	resource management
RMA	request for manual assistance
RMI	remote method invocation
RMON	remote monitoring
ROADM	reconfigurable optical add/drop multiplexer
ROBO	remote office/branch office
ROI	return on investment
ROW	right of way
RPC	remote procedure call
RPF	reverse path forwarding
RPR	resilient packet ring
RPRA	Resilient Packet Ring Alliance
RPT	resilient packet transport
RQMS	requirements and quality measurement system
RRQ	round-robin queuing or registration request
RSU	remote service unit
RSVP	resource reservation protocol
RSVP–TE	resource reservation protocol–traffic engineering
RT	remote terminal

RTCP	real-time conferencing protocol
RTOS	real-time operating system
RTP	real-time transport protocol
RTSP	real-time streaming protocol
RTU	remote test unit
RxTx	receiver/transmitter
RZ	return to zero
SAM	service access multiplexer
SAN	storage-area network
SAP	service access point
SAR	segmentation and reassembly
S-band	short band
SBS	stimulated Brillouin scattering
SCAN	switched-circuit automatic network
SCCP	signaling connection control part
SCCS	switching control center system
SCE	service-creation environment
SCF	service control function
SCL	service control language
SCM	service combination manager OR station class mark OR subscriber carrier mark
SCN	service circuit node OR switched-circuit network
SCP	service control point
SCR	sustainable cell rate
SCSP	server cache synchronization protocol
SCTP	simple computer telephony protocol OR simple control transport protocol OR stream control transmission protocol
SD	selective discard
SDA	separate data affiliate
SD&O	service development and operations
SDB	service design bureau
SDC	service design center
SDF	service data function
SDH	synchronous digital hierarchy
SDM	service-delivery management OR shared data model
SDN	software-defined network
SDP	session description protocol
SDRP	source demand routing protocol
SDSL	symmetric DSL
SDTV	synchronous digital hierarchy
SDV	switched digital video
SE	service element
SEC	Securities and Exchange Commission
SEE	service-execution environment
SEP	signaling endpoint
ServReq	service request
SET	secure electronic transaction
SFA	sales force automation
SFD	start frame delimiter
SFF	small form-factor
SFGF	supplier-funded generic element
SG	signaling gateway
SG&A	selling, goods, and administration OR sales, goods, and administration
SGCP	simple gateway control protocol
SGSN	serving GPRS support node
SHLR	standalone home location register
SHV	shareholder value
SI	systems integrator
SIBB	service-independent building block
SIC	service initiation charge
SICL	standard interface control library
SID	silence indicator description
SIF	SONET Interoperability Forum
sigtran	Signaling Transport [working group]
SIM	subscriber identity module OR service interaction manager
SIP CPL	SIP call processing language
SIP	session initiation protocol
SIP–T	session initiation protocol for telephony
SITA	Société Internationale de Télécommunications Aéronautiques
SIU	service interface unit
SIVR	speaker-independent voice recognition
SKU	stock-keeping unit
SL	service logic
SLA	service-level agreement
SLC	subscriber line carrier
SLEE	service logic execution environment
SLIC	subscriber line interface circuit
SLO	service-level objective
SM	sparse mode
SMC	service management center
SMDI	simplified message desk interface
SMDS	switched multimegabit data service
SME	small-to-medium enterprise
SMF	single-mode fiber
SML	service management layer
SMP	service management point
SMPP	short message peer-to-peer protocol
SMS	service-management system OR short message service
SMSC	short messaging service center
SMTP	simple mail transfer protocol
SN	service node
SNA	service node architecture OR service network architecture
SNAP	subnetwork access protocol
SNMP	simple network-management protocol
SNPP	simple network paging protocol
SNR	signal-to-noise ratio
SO	service objective
SOA	service order activation
SOAC	service order analysis and control
SOAP	simple object access protocol
SOCC	satellite operations control center
SOE	standard operating environment
SOHO	small office/home office
SON	service order number
SONET	synchronous optical network
SOP	service order processor
SP	service provider OR signaling point
SPC	stored program control
SPE	synchronous payload envelope
SPF	shortest path first
SPIRITS	Service in the PSTN/IN Requesting Internet Service [working group]
SPIRITSG	SPIRITS gateway
SPM	self-phase modulation OR subscriber private meter
SPOP	service point of presence
SPX	sequence packet exchange
SQL	structured query language
SRF	special resource function
SRP	source routing protocol
SRS	stimulated Raman scattering
srTCM	single-rate tri-color marker

SS	softswitch
SS7	signaling system 7
SSE	service subscriber element
SSF	service switching function
SSG	service selection gateway
SSL	secure sockets layer
SSM	service and sales management
SSMF	standard single-mode fiber
SSP	service switching point
STE	section terminating equipment
STM	synchronous transfer mode
STN	service transport node
STP	shielded twisted pair OR signal transfer point OR spanning tree protocol
STR	signal-to-resource
STS	synchronous transport signal
SUA	SCCP user adaptation
SVC	switched virtual circuit
SW	software
SWAN	storage wide-area network
SWAP	shared wireless access protocol
SWBT	Southwestern Bell Telephone
SWOT	strengths, weaknesses, opportunities, and threats
SYN	IN synchronous transmission
TALI	transport adapter layer interface
TAPI	telephony application programming interface
TAT	terminating access trigger OR termination attempt trigger OR transatlantic telephone cable
Tb	terabit
TBD	to be determined
Tbps	terabits per second
TC	tandem connect
TCAP	transactional capabilities application part
TCB	transfer control block
TCIF	Telecommunications Industry Forum
TCM	time compression multiplexing
TCO	total cost of ownership
TCP	transmission control protocol
TCP/IP	transmission control protocol/Internet protocol
TC–PAM	trellis coded–pulse amplitude modulation
TDD	time division duplex
TDM	time division multiplex
TDMA	time division multiple access
TDMDSL	time division multiplex digital subscriber line
TDOA	time difference of arrival
TDR	time domain reflectometer OR transaction detail record
TE	traffic engineering
TEAM	transport element activation manager
TED	traffic engineering database
TEM	telecommunications equipment manufacturer
TFD	toll-free dialing
THz	terahertz
TIA	Telecommunications Industry Association
TIMS	transmission impairment measurement set
TINA	Telecommunications Information Networking Architecture
TINA-C	Telecommunications Information Networking Architecture Consortium
TIPHON	Telecommunications and Internet Protocol Harmonization over Networks
TIWF	trunk interworking function
TL1	transaction language 1
TLDN	temporary local directory number
TLS	transparent LAN service OR transport-layer security
TLV	tag length value
TMF	TeleManagement Forum
TMN	telecommunications management network
TMO	trans-metro optical
TN	telephone number
TNO	telecommunications network operator
TO&E	table of organization and equipment
TOD	time of day
TOM	telecom operations map
ToS	type of service
TP	twisted pair
TPM	transaction processing monitor
TPS–TC	transmission control specific–transmission convergence
TR	technical requirement OR tip and ring
TRA	technology readiness assessment
TRIP	telephony routing over Internet protocol
trTCM	two-rate tri-color marker
TSB	telecommunication system bulletin
TSI	time slot interchange
TSP	telecommunications service provider
TSS	Telecommunications Standardization Section
TTC	Telecommunications Technology Committee
TTCP	test TCP
TTL	transistor-transistor logic
TTS	text-to-speech OR TIRKS® table system
TUI	telephone user interface
TUP	telephone user part
TV	television
UA	user agent
UADSL	universal ADSL
UAK	user-authentication key
UAWG	Universal ADSL Working Group
UBR	unspecified bit rate
UBT	ubiquitous bus technology
UCP	universal computer protocol
UCS	uniform communication standard
UDP	user datagram protocol
UI	user interface
ULH	ultra-long-haul
UM	unified messaging
UML	unified modeling language
UMTS	Universal Mobile Telecommunications System
UN	United Nations
UNE	unbundled network element
UNH–IOL	University of New Hampshire–Interoperability Laboratory
UNI	user network interface
UOL	unbundled optical loop
UPC	usage parameter control
UPI	user personal identification
UPS	uninterruptible power supply
UPSR	unidirectional path-switched ring
URI	uniform resource identifier
URL	universal resource locator

USB	universal serial bus
USTA	United States Telephone Association
UTOPIA	Universal Test and Operations Interface for ATM
UTS	universal telephone service
V&H	vertical and horizontal
VAD	voice activity detection
VAN	value-added network
VAR	value-added reseller
VAS	value-added service
VASP	value-added service provider
VBNS	very–high-speed backbone network service
VBR	variable bit rate
VBR–nrt	variable bit rate–non–real-time
VBR–rt	variable bit rate–real time
VC	virtual circuit OR virtual channel
VCC	virtual channel connection
VCI	virtual channel identifier
VCLEC	voice CLEC
VCO	voltage-controlled oscillator
VCR	videocassette recorder
VCSEL	vertical cavity surface emitting laser
VD	visited domain
VDM	value delivery model
VDSL	very-high–data rate DSL
VeDSL	voice-enabled DSL
VGW	voice gateway
VHE	virtual home environment
VHS	video home system
VITA	virtual integrated transport and access
VLAN	virtual local-area network OR voice local-area network
VLR	visitor location register
VLSI	very–large-scale integrated
VM	virtual machine
VMS	voice-mail system
VoADSL	voice over ADSL
VoATM	voice over ATM
VOD	video on demand
VoDSL	voice over DSL
VoFR	voice over frame relay
VoIP	voice over IP
VON	voice on the Net
VoP	voice over packet
VOQ	virtual output queuing
VoT1	voice over T1
VP	virtual path
VPDN	virtual private dial network
VPI	virtual path identifier
VPIM	voice protocol for Internet messaging
VPN	virtual private network
VPR	virtual path ring
VPRN	virtual private routed network
VRE	Virtual Radiology Environment
VRU	voice response unit
VSAT	very-small–aperture terminal
VSI	virtual switch interface
VSM	virtual services management
VSN	virtual service network
VSR	very short reach
VT	virtual tributary
VTN	virtual transport network
VToA	voice traffic over ATM
VVPN	voice virtual private network
VXML	voice extensible markup language
W3C	World Wide Web Consortium
WAN	wide-area network
WAP	wireless application protocol
WATS	wide-area telecommunications service
WB DCS	wideband DCS
WCDMA	wideband CDMA
WCT	wavelength converting transponder
WDCS	wideband digital cross-connect
WDM	wavelength division multiplexing
WECA	wireless Ethernet compatibility alliance
WEP	wired equivalent privacy
WFA	work and force administration
WFQ	weighted fair queuing
WIM	wireless instant messaging
WIN	wireless intelligent network
WLAN	wireless local-area network
WLL	wireless local loop
WMAP	wireless messaging application programming interface
WML	wireless markup language
WNP	wireless local number portability
WRED	weighted random early discard
WS	work station
WSP	wireless session protocol
WTA	wireless telephony application
WUI	Web user interface
WVPN	wireless VPN
WWCUG	wireless/wireline closed user group
WWW	World Wide Web
XA	transaction management protocol
XC	cross-connect
XD	extended distance
xDSL	[see DSL]
XML	extensible markup language
XNS	Xerox network system
XPM	cross-phase modulation
XPS	cross-point switch
xSP	specialized service provider
XT	crosstalk
XTP	express transport protocol
Y2K	Year 2000

Index
