Annual Review of Communications

International Engineering Consortium

Volume 55

The *Annual Review of Communications, Volume 55* includes papers from educational forums sponsored by the International Engineering Consortium, a nonprofit organization affiliated with more than 70 universities worldwide.

Quality Publications from the International Engineering Consortium:

- IP and the Intelligent Network: The Road to Convergence
- Next-Generation Optical Networks: Advanced Technologies and Market Opportunities
- Operations Support Systems 2002: Enabling the Next-Generation Network
- The Evolution of Broadband: DSL and Beyond
- Optical Networks: Architectures and Advances
- Optical Access: Next-Generation Technology and Services in the First Mile
- Telecom Outlook Report: Millennial Edition
- DSL's Next Chapter: Packaging Access, Adding Voice and Video
- The Market for IP Enhanced Services
- Broadband Access and Services in the Local Loop: A Comprehensive Report

For more information on any of these titles, please contact the IEC publications department at +1-312-559-3730 (phone), +1-312-559-4111 (fax), publications@iec.org, or via our Web site (http://www.iec.org).

This *Annual Review of Communications,* together with subsequent editions, may be purchased from the International Engineering Consortium.

Volume 1, 1944, through Volume 43, 1989, are out of print. Microfilm copies of these volumes may be obtained from University Microfilms, Inc., Ann Arbor, Michigan 48106.

About the International Engineering Consortium

The International Engineering Consortium (IEC) is a nonprofit organization dedicated to catalyzing positive change in the information industry and its university communities. Since 1944, the Consortium has provided high-quality educational opportunities for industry professionals, academics, and students.

In conjunction with the industry, the IEC has developed free, on-line, Web-based tutorials. The IEC conducts industry-university programs that have substantial impact on curricula. Every year, the IEC provides grants to professors and students to participate in the IEC educational forums. The IEC also conducts research and develops publications, conferences, and technological exhibits that address major opportunities and challenges of the information age.

More than 70 leading, high-technology universities are currently affiliated with the Consortium. The industry is represented through substantial corporate support and through the involvement of many thousands of executives, managers, and professionals.

University Program Sponsors

Through the University Program, sponsoring organizations provide grants for full-time faculty members and their students to attend IEC Forums. The generous contributions of the following sponsoring organizations make this valuable program possible. For more information about the program, please call +1-312-559-4103 or send an e-mail to *universityprogram@iec.org*.

This past year, the University Program has provided more than 400 grants to professors to attend the educational opportunities offered at IEC Forums. Because of their participation in IEC Forums, professors created or updated 600 university courses; more than 10,000 students were impacted by these new and upgraded courses, and more than 12,000 students benefited from improvements made in university laboratories. Since its inception in 1984, the University Program has enhanced the education of more than 500,000 students worldwide.

Media Sponsors and Partners

The IEC's Media Sponsors and Partners program was established as a means for the Consortium and the leading industry publications to provide reciprocal support for the many service programs throughout the year. The IEC thanks these publications for their efforts in keeping the industry up to date on the Consortium's events, publications, and Web-based educational programs.

Media Sponsors

Publications participating as Media Sponsors provide substantial support of and exposure to the Consortium's overall programs and are intimately involved in specific events and publications as Official Publishing Sponsors.

Executive Perspectives

The Light Bulb, the PC, and Broadband

Duane Ackerman
Chairman and Chief Executive Officer
BellSouth Corporation

As recently as two years ago, not many folks were interested in what communications companies from the "old economy" had to say about the Internet. Nor did they want to hear our take on the digital revolution more generally. After all, we were old economy. All we had were customers and revenue, strong balance sheets, big networks, billing operations, and a long heritage of service.

And it didn't seem to matter that, for a more than a century, we had been taking the latest in communications technology, and turning it to the advantage of customers—while also delivering earnings to our shareholders. As a business writer for "The New York Times" said in the spring of 2001, "old economy measures looked hopelessly quaint" back then.

That was then, this is now. Today, traditional measures such as earnings are back. Likewise, it is understood once more that the ultimate discipline is imposed by the customer—the products and services they'll use, the price they'll pay, the level of service they demand. And folks think companies such as BellSouth might actually be the ones to deliver on the digital revolution. But they're not sure.

They ask: Who's got a business model that will work? They know the race is on to deploy broadband—"fast access." And they recognize the growing consensus on what will ultimately determine the success of broadband: "It's the applications, stupid."

And while they know BellSouth and others are committed to enabling the broadband network, they ask: Where are the applications? Can anyone make money on them? Or is all of this just more hype, like so much hype we've heard for more than 10 years, ever since talk about the "information highway" became the rage?

Good questions all. I can answer them emphatically: No, broadband and the rest are not all hype. Someone does know how to separate the practical from the hype, the profitable from the hype.

Even in an economic slump, we see the promise of substantial growth ahead of the industry. Customers are adapting a new generation of digital appliances and services, and in typical digital fashion: Costs are going down; performance is going up. Convergence is changing network economics, creating a new competitive dynamic.

The pending arrival of broadband/Internet protocol (IP) infrastructure, through digital network convergence, coupled with applications, will drive increased customer demand. We see this supply-side effect as a potent driver of demand, including demand for full packages of service. And just as the personal computer (PC) ushered in a new era, so too will broadband—a new era for the economy, a new era for the industry. The fact is we have reached the limits of narrowband Net growth—broadband" will spur the next wave of growth.

The Applications Story

The PC is a powerful example of what will happen with broadband applications. For many of us, the PC started as a glorified typewriter—a word processor. Applications followed. Applications followed when the PC was a standalone device. Applications followed when it was used with local-area networks (LANs) and wide-area networks (WANs), and more applications came with the Net. They're still coming. The applications story will continue in that vein with broadband.

The story has been the same for other technologies: television, radio, and electricity applications—successful mass applications. Of course, there were always skeptics. Darryl Zanuck, the head of 20th Century Fox, said this about television back in 1946: "Television won't be able to hold on to any market it captures after the first six months. People will soon get tired of staring at a plywood box every night."

And back in 1977, a computer executive—who I won't name—said this: "There is no reason for any individual to have a computer in their home." I suppose he was right—in 1977. But we know that the increase in the power of computers, the decline in price—and the development of applications—made a shambles of that 1977 projection.

As we see the world, the skeptics on broadband will be just as wrong. We at BellSouth see substantial promise for growth in broadband, in communications generally.

Now, as you here know, the prevailing mood in the industry isn't optimistic; it sure doesn't feel like we're an industry with growth on the horizon. We're all watching that stock ticker more closely, following the Fed and Alan Greenspan more closely, looking at manufacturing stats, sales of durable goods, new housing starts, unemployment—all those tea leaves. We know the market is edgy. But as we look at market demand and as we look at the prospects for broadband, we have reason to be more optimistic than today's glum mood indicates. Overall, data growth is running at 30 to 40 percent. In BellSouth's case, with some specific data products, we're seeing 50, 60, 70 percent growth on what are now significant bases. The same is true for other companies.

Digital Story Still a Good Story

People like the power and flexibility that digital devices allow them. They're using them; they want more.

The nub of the matter is this: Even as the short term concerns everyone, the digital story looks good for the long term.

In the emerging broadband/IP world, different parts of the industry will have new and somewhat differing advantages as we pursue high-value customers of network services. These advantages will differ especially depending on the specific assets with which each of us starts. And hence our digital stories will differ.

The BellSouth story includes some big numbers that touch all of you as well—numbers on growth in the total volume of information. These give us a better sense of what's happening in the big picture of data. These numbers come from the School of Information Management and Systems at the University of California at Berkeley. And while we now need to view these numbers in light of this economic slump, they nevertheless suggest the scale of data growth that we need to be thinking about.

The school estimates that the world's total information at close of 2000 was roughly 15 billion gigabytes. By the end of 2002, the school projects total information will be 33 billion gigabytes. In other words, in just two years, there'll be a doubling of the amount of information the human race has accumulated since humans first daubed paint on cave walls. By 2003, the amount will stand at 57 billion gigabytes.

No wonder digital customers are clamoring for data products.

All of this information has to be generated—perhaps processed, manipulated some way, maybe with other information in other media. It has to be transported, stored, retrieved. In other words, not only is there a lot more data in our future, but more of it is being moved more often and at ever-higher speeds.

That's a lot of work for everyone in the information-communications industries—a lot of applications to develop.

With this continuing explosion of information, storage and storage-related solutions are projected to be a near $100 billion market within three years. Businesses need new efficiencies, new ways to increase productivity. Consumers always want more convenience, new ways to gain control of their time. Give them broadband applications that deliver on these—applications that are practical, powerful and affordable—and they'll use them.

Practical, Profitable Broadband

The following are several areas we at BellSouth believe are the most promising, the most practical, the most profitable.

The first is what we call "productivity-enhancing" applications for small and mid-size businesses: enterprise resource planning (ERP), customer-relationship management (CRM), and front- and back-office applications.

Our long economic boom has been driven by these applications for large businesses. Now, we can address medium to small businesses. Such applications would be in areas where small and mid-size businesses simply cannot afford the information technology (IT) infrastructure to do the work, but where they want some of the same services available to big companies. By 2004, this is expected to be a $15 billion market in the United States, a third of that in small and mid-size businesses.

Video is another promising area. Training for corporations is of course a "videoconferencing" kind of opportunity. Training falls under the label of "distance learning." Originally, we thought of distance learning as being for K-12 education as well as some higher education. As it turns out, 75 percent of the distance-learning market is corporate training. By 2004, this market will be around $30 billion in the United States.

We all recognize the growing challenge that training presents to us right now—new people plus new technology. Companies are increasingly turning to a video solution for training—especially when, as is so often the case, employees are dispersed in many locations.

And there are practical video applications for consumers. "Instant" videoconferencing can be used for security. From the office you might use video to check things at home or to see if the delivery driver left the package in the right place. Similarly, as your parents age, you can use video to check with them throughout the day. Likewise, if you have a weekend house, a boat stored at a lake, or a new babysitter that you're not yet sure of.

We see instant video messaging as a promising area for broadband, for instance through sharing files with family members. Grandparents get the latest videotape of the grand babies, the tape of the school play, and so on.

Video programs on demand are another area, as well as interactive video games. On-line games alone are expected to be a $10 billion market by 2004. And we're looking at various devices for the home in which an assortment of movies and other programs might be downloaded overnight, rather than playing in real time. We believe this is a promising interim solution.

We expect customers to take to unified messaging (UM): Bringing together all the devices, all the networks, so someone can sit down at their PC and listen to their voice-mail—with one mailbox for wireline and wireless—as well as read their e-mail. Or someone can use their wireless phone or Palm Pilot, or other devices to retrieve other messages and information.

And then there's growth in what we're all calling the "enablement layer," that being the additional capabilities the network requires. To offer video on demand (VOD), for example, takes this enablement layer. We have to have distribution networks with the broadband capacity to transmit video. And we have to have storage to cache movies—or other content—near the edge of the network. At BellSouth, we see this enablement layer as a major opportunity. We're making such "enablement" an integral part of our network as we transition our network from circuit to packet, from analog to digital, from narrowband to broadband.

And here's another bright spot for broadband: Reliable, secure broadband access to all the existing applications that reside on enterprise networks—a "remote access" VPN.

These are just a few examples of some specific, practical broadband applications that we believe are promising.

Such applications, of course, beg the question of who profits from them—in particular, how will network companies benefit? Can we construct a win/win solution? At BellSouth, we're committed to various kinds of alliances and partnerships in this regard. In fact, we're working with many on just such matters.

Mass Technologies and Applications

We can all take additional encouragement from the long experience already alluded to, the history of earlier technologies. Take the development of the PC from standalone to now, when, through the Internet, it can be hooked to other computers and to databases around the world. Applications were key; the PC became not only powerful, but also practical.

Applications drove success in other mass technologies.

Anyone of a certain age can remember when television went off at 10 o'clock in the evening. After that, all you could get was a test pattern. In Meridian, Mississippi, the local television station filled much of the airtime with a man sitting there playing the organ live. Look at the content now.

Or electricity. It's a useful analogy. Initially, the primary "application," if you will, was the light bulb. Simple as that was, it revolutionized how people lived. Folks such as Edison, of course, knew there was far more in electricity than light. And indeed, there came a long line of "applications": refrigerators, record players, pumps, stoves, washers, air conditioners—"applications" of electricity that reduced the amount of sheer drudgery in work, improved health, and delivered comfort and convenience. The light bulb was just the first step.

Today, people see broadband as fast access to the Internet; that's all. But fast access is just the first step. We can't foresee all of the transforming types of applications that will emerge from broadband—the practical, multimedia applications. Those will come. We'll see hundreds of them—some of which will change work and leisure as much as did electric pumps, refrigerators, air conditioners, television, and all the rest.

I have faith in that assertion. It is faith built on experience. It is not "build it, and they will come." It is "Make it practical, make it powerful, make it affordable—and they will pay." Real value generates real revenue.

The sum total of our experience tells us that this is the case.

A New Competitive Dynamic

Convergence will deliver much more powerful products and services. Our own view is that convergence, as it moves us toward integrated broadband/IP networks, is also producing a new competitive dynamic. We also believe that convergence remains the most powerful force at work in our industries. Consider wireless, and, more specifically, the fate of local and long-distance service in the wireless arena. We all know what happened. With AT&T's One Rate Plan as the precipitating event, local and long distance merged. They converged.

AT&T radically altered the landscape. Everyone had to adjust: rate plans, bundles, and joint ventures such as Cingular.

Another measure of the power of convergence can be seen in the recording industry. Not long ago, only big companies could distribute music worldwide. Today, a 10-year old kid in, say, Dothan, Alabama, can be a worldwide distributor—much to the chagrin of recording artists and the recording industry.

Convergence is not a single destination. It is a journey—a complex journey, a continuum. Its way stations are network technology platforms, protocols, and services. As we pass the various way stations, each of them interacts with the others, creating still more powerful convergence—and more powerful services for customers.

It's this broader force of convergence that I believe is the key to future growth. Convergence is what makes more powerful packages of services less expensive and, therefore, attractive to customers.

Contrary to much of the current conventional wisdom, we at BellSouth believe that "the package" is alive and well. But we believe that the package is alive and well for a different reason than made the idea so popular during the past few years. Then the idea was that the convenience of "one-stop shopping" would prompt consumers to buy full packages. The new competitive dynamic being created by convergence will give consumers a more potent incentive for buying full packages: lower costs. In other words, the changing supply-side dynamic, not so much demand-side, is the real driver of demand for packages.

We see tremendous opportunities here. There is a place for a full package of services, a big place. These will be highly successful with many segments of customers, particularly those who use the most services. Yes, there'll also be places for players that are not providing full packages. Some will be major players, and some will be niche players. But in the world of integrated broadband/IP networks, we see the offerings of full-service providers becoming more attractive to an increasing range of customers.

And we believe we're positioned to be a full-service provider; our local network, we believe, will be at the heart of delivering integrated, broadband/IP capabilities to consumers and businesses. In BellSouth's case, our existing local network makes us a primary enabler in the digital revolution.

The Digital Challenges

The challenges for our related industries are clear: We know we have to deliver an integrated broadband/IP network. We know we have to deliver the new architectures, which include storage and caching facilities at the network's edge. We know we have to deliver facilities for Web hosting. We know we have to deliver carrier-quality reliability and security. We know we have to deliver applications that are practical, powerful, and affordable. We have to help customers be more productive. We have to find business models that work. We have to construct win/win relationships with our partners. And we have to help the digital customer with the complexity that we've pushed to the edge of the network.

To deliver on all of these requires all of those traditional or "old economy" virtues that we talked about at the start—the knowledge and skills that we've developed over the years and our ability to deliver to customers and to shareholders.

The digital story is a great story, and we're in a great business. When the world is creating a digital economy, an increasingly networked economy, it's pretty good to be in our business. I always tell our employees that we're in the most exciting industry in the world. We're an enabler of the most basic forces driving the economy and driving changes in society—an enabler of forces of historic power and reach.

The opportunities are immense. Our challenge is to execute and deliver, and I believe we can. When we do, we will have earned our spot in history.

This paper was adapted from a speech delivered to the Accenture Global Communications Forum in Miami, Florida on April 2, 2001.

Architecture for Multifunction Application Server

Shankar Allimatti
Corporate Head, Centre of Excellence–Intelligent Networks
Mahindra British Telecom Limited

Introduction

The revolutionary change and the growth in the telecommunication industry is witnessed today in the quest for achieving universal communication—anywhere, any time, anyone. This exponential change phenomenon is basically driven by the new emerging technologies, increased customer demands for better services, global competition across the industry, and time to market leading to mergers and acquisitions (M&A). Above all, the economic compulsions are driving network/service providers and equipment suppliers to increase operational efficiencies and cut down on costs.

With such competitive compulsions and the fact that the existing networks with very large investments are here to stay for some time to come, the network/service providers are aptly choosing the path of orderly migration. This orderly migration means the evolution of existing public switched telephone networks (PSTNs) with a time division multiplexing (TDM)/time division multiple access (TDMA)–based infrastructure optimized for voice to the flexible, convergent, multimedia next-generation networks and the service business evolution from a monopoly-based single network to a entrepreneurial, multiservice, customer-driven environment.

In the converged world, enterprises define themselves not by their network, but by the needs of the customer. The convergence looking at all of the above is very complex and multifaceted, encompassing the domain (information technology (IT) and telecom), networks, and technologies.

Convergence is driving the radical changes in telecommunications systems and services. In the passage to converged, multimedia new-generation networks, very few legacy network systems will survive. The systems that will prevail will be those with open architectures supporting multiple technologies not only for optimization, but also for reconfiguration.

The new software systems enabling convergence and supporting multiple emerging technologies should be adaptable without being completely re-engineered. They should combine the qualities of a voice network and the opportunities of data network and provide service providers with efficient scalable growth, allowing economical expansion of the networks through the simple addition of services/up-gradations. In addition, they should enable networks and the services to be interactive and interoperable.

The intelligent network (IN) is one such interactive medium that enables users to access a large range of applications and services. It could be possible to redefine this technology to provide the consistent framework that defines the relationship between converging networks and services. This paper attempts to address one such IN technology component—the service control point (SCP). The following sections address how SCP could be redefined or re-engineered to work as a multifunction application server.

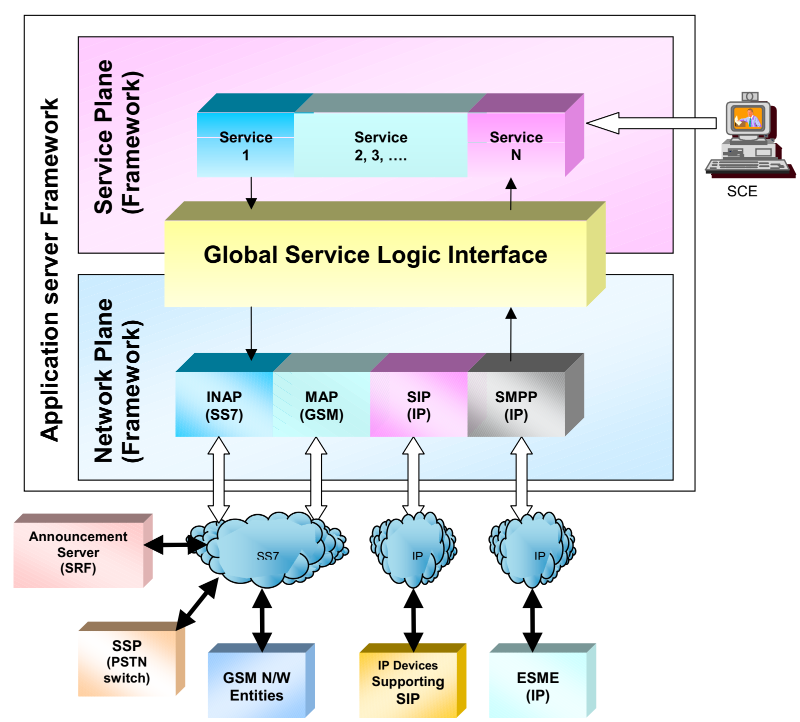
The service plane in the conventional IN could be provided as a service-oriented abstraction of network resources. The services can be considered as single distributed software objects. The Java and common object request broker architecture (CORBA) technologies would provide an advantage in building such systems.

In this suggested architecture, the service plane hosts service objects. These objects may be shared across multiple service groups. Connectivity to the network is established through the network plane. The network plane hosts network or domain-specific objects and communicates with other entities in the specific network. The architecture diagram is show in *Figure 1*.

Architecture

The architecture of a multifunction application server could be the evolution of the SCP architecture as described in International Telecommunication Union–Telecommunication Standardization Sector (ITU–T) Q12XX standards. The conceptual IN model could be re-engineered to be a more generic, network, or domain transparent model. The refined architecture comprises two major planes: the service plane and network plane. These planes interact through a set of events. These are briefly described in the following paragraphs.

FIGURE 1



Service Plane (Framework)

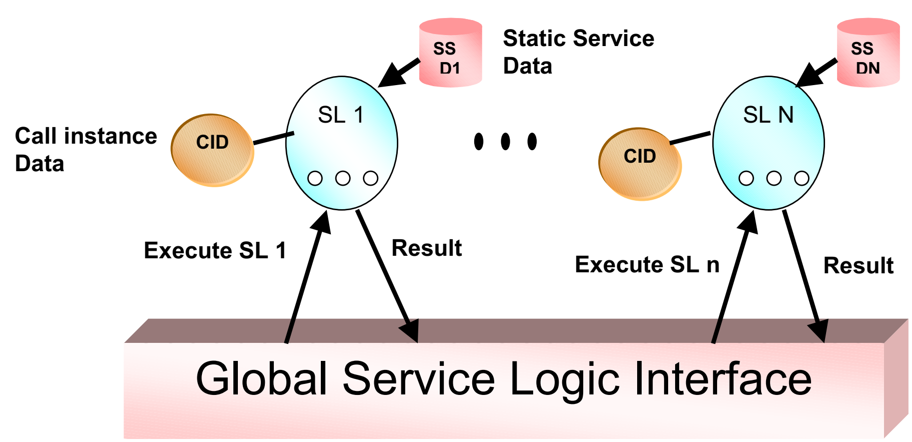
The service plane and global functional plane as defined by ITU–T Q12XX could be re-engineered to a domain-independent service framework. This framework would host and execute the services transparently in the converged network environments.

The service-plane design logic is a combination of service-independent building blocks (SIBS). The ITU–T Q12X3 SIBs are re-engineered to define the services in converged networks.

The SIB is a standard reusable component having a discrete, non-interruptible operation. The SIBs can be implemented as Enterprise Java Beans (EJB). A Bean builder framework can be used to integrate and deploy the same. This integrated Java Bean logic is termed *service logic*, as shown in *Figure 2*.

The service logic may be implemented as distributed objects (using CORBA/EJB technologies) that could be shared across the service-provider boundaries, providing the distinct advantage in terms of load sharing and redundancy of services across the network. This functionality could be

FIGURE 2



achieved through use of the service-creation environment (SCE). This design tool supports the service design across domains and protocols. The output of the SCE would be a service-logic script that can have a generic format in form of extensible markup language (XML)/Java, deployable on the application server platforms.

The execution of the service is triggered by the service request from the user on the network. The global service-logic interface enables the service instance-specific message (CID) exchange between the service logic and the network. The global service-logic interface supports the simultaneous operations of multiple services across the network domains enabling multiple services being executed from the single platform. Global service logic interacts with the network through a network plane supporting multiple protocols.

Network Plane (Framework)

The network plane is the enhanced version of the distributed and physical plane as described in Q12XX. The architecture of the framework, as shown in *Figure 3*, would support the incorporation of multiple protocols such as signalling system 7 (SS7), short message peer-to-peer (SMPP), session initiation protocol (SIP), customized applications for mobile network enhanced logic (CAMEL) application part (CAP), mobile application part (MAP) (Global System for Mobile Communications [GSM]), H.323, etc. These stacks in turn provide the connectivity with the respective network. The message converter converts the messages from the stack into the generic events understandable by the service logic and vice versa.

This type of architecture enables flexibility to add or delete any protocol interface with incremental efforts.

Advantages of Multifunction Application Server

- Services interoperable across network domains
- Easily adaptable to changing network needs
- Open framework supporting service design as per customer requirements

Applications and Services

Tele-Voting Service

The tele-voting service to support subscribers from Internet protocol (IP) and PSTN domains can be implemented on the multifunction application server. The PSTN subscribers access the service through intelligent network application part (INAP) protocol whereas subscribers on an IP network access the same through an SIP interface.

Short Message Service Center (SMSC)

The multifunction application server can be used to provide the SMSC functionality in the mobile network by interfacing with the SS7 and IP networks through the MAP and SMPP interfaces respectively. The application-management function provides the interface to database management.

Gateway Application

The multifunction application server can work as a gateway by converting the messages of different protocols. The translation of messages is implemented as service logic in the application server.

Home Location Register (HLR)

The application server can serve as a HLR toward a mobile network using SS7 protocol. HLR procedures can be implemented as service logic, and an entire HLR application would consist of coordinating service logics. The application-management function can provide the database interface.

VoDSL Market Overview

Claudia Bacco
Executive Vice President
TeleChoice

This paper presents an overview of the digital subscriber line (DSL) market and focuses on current video over digital subscriber line (VoDSL) status and vendor efforts.

North American Deployment Status

The actual numbers for the second quarter show that the incumbent local-exchange carriers (ILEC) are still very much in the lead in the deployment of DSL, with residential customers being its primary users (see *Figure 1*). It should be noted that many of the service providers, if they are connecting to a business that is physically in a house such as a telecommuter or a home office, count it as a residence and not a business. These numbers are therefore not substantially skewed, but there are probably more businesses in the total number than these represent.

The first quarter of 2001 was actually the first that showed any overall slowing in the growth of DSL. One reason for that is the collapse of Northpoint. Not all of the Northpoint customers were able to reconnect with another provider, and not all of those that did were able to do it within the same quarter. So there was a downturn based on the number of people that actually went without service. The service providers that implemented price increases in the first quarter also showed a comparable percentage reduction in DSL adoption. Where prices increased there was definitely a correlation to the number of customers taking service, especially in residential service.

DSL Market Size: United States

At the end of 1998 there were 39,000 DSL lines. That number grew to 500,000 in 1999 and almost 2,500,000 last year. Almost 4,500,000 are projected by the end of this year, and 13,900,000 by the end of 2004 (see *Figure 2*).

It had been projected that DSL will surpass cable during the next year, but with this year's stumbles in the DSL marketplace, revised projections have cable remaining in the lead for the foreseeable future. The digital loop carrier (DLC) issue needs to be resolved. There is also an expectation that there will be VoDSL and value-added services (VAS) available that drive more adoption of broadband with the cable-modem data over cable service interface specifications (DOCSIS) 2.1 standards. This is going to level the playing field for cable, which might be playing more actively on the business side.

Is the DSL Market Slowing Down?

Deployments in the first quarter of 2001 lagged behind the fourth quarter of 2000. Competitive local-exchange carrier (CLEC) deployments were greatly reduced because of the Northpoint and other failures. ILEC deployments were lower at SBC and Verizon, probably linked to price increases. Interexchange carrier (IXC) deployments were still miniscule in the DSL space, compared to ILEC.AT&T has yet to see any deployment out of the Northpoint acquisition of the equipment and co-location space. And, although Sprint and Worldcom have DSL deployments, they aren't very large. Customers are feeling insecure about buying service from CLECs, and a direct linkage between the service offer and customer needs is still lacking.

Businesses require quality-of-service and performance guarantees. Before businesses jump on the DSL bandwagon, it is really necessary to make it more of a business-class service by offering different qualities, different classes, and different performance guarantees. On the residential side, service providers are starting to move beyond the early-adopter mode for DSL. Residential customers do not understand why they need DSL today; a great deal of education still needs to go on in that marketplace. Most of the service providers still talk about speed when they talk about advertising a DSL server, but content is necessary to drive the bandwidth requirement. Service is faster than dial-up, but the average residential customer does not understand why he or she needs to spend more money to go faster than dial-up.

The DSL Market Is Changing

The ILECs continue to dominate. They had 76 percent of the lines in service during the second quarter of last year and 84 percent this year (Obviously, Northpoint had a big effect on that number). ILECs grew 16 percent in the second quarter, while CLECs grew only 6 percent. Again, Northpoint drove most of that change. Regional ILECs are still doing quite well with advanced services. But the CLEC shakeout is, unfortunately, probably not over. Although Northpoint, Rhythms, and many others are gone, Covad is struggling to exit from its Chapter 11 filing. IXCs are starting to be more aggressive, but there is not a huge deployment in place yet. AT&T still has not acted on the Northpoint acquisition, and Worldcom has just announced the purchase of key Rhythms assets and has some limited DSL assets from UUNET. Other

FIGURE 1

North American Deployment Status

TeleChoice 2Q01 DSL Deployment Summary			
Service Provider	2Q01 Lines in Service	% Residential	% Business
ILECs – US	2,800,160	80%	20%
CLECs – US	508,331	42%	58%
IXCs – US	26,000	12%	88%
Total	***3,334,491***	***74%***	***26%***
Canada	***780,943***	***76%***	***24%***

CLECs and integrated communications providers (ICP)—NewSouth and New Edge, for example—have actually backed away from DSL and are focusing more on virtual private network (VPN) services. Smaller players, like data competitive local-exchange carriers (D–CLEC), are leaving the DSL market.

VoDSL Status

What does all that mean for VoDSL? Although there are deployments, there are still not any major ones, and everyone is waiting for the coming AT&T deployment. But there are many small deployments today; a lot of regional players are doing well offering VAS and VoDSL services. Regional CLECs are doing quite well by offering very tailored packages to the small and medium-sized business market, but they are in very small pockets of the country.

Many people overlook the regional ILECs, the very small incumbent players, but they are really the most progressive in the marketplace. They have VoDSL deployment, and there is a surprising amount of VoDSL deployment for entertainment by small regional ILECs that are serving the customers with very sophisticated services. Granted, though, these are players whose entire market might be 2,000 customers and 2,000 lines.

Among the major players in VoDSL deployment over the last year, Picus, a CLEC provider, has gone out of business; mPower—the leader today as far as VoDSL currently in service—has announced a reduction in the number of central offices (CO) that it is serving; and Trivergent merged into NuVox and is only offering voice over T1 (VoT1).

VoDSL—Why So Slow?

Why is everyone moving so slowly? Small players are doing small deployments. The D–CLECs have not done anything. One thing holding up deployment at players like Covad, Northpoint, and Rhythms was not the technology or the functionality, but the fact that they had to partner with someone else for a voice network and they were struggling with who charged what, how to divvy it up, and how to bill the customer.

The ILECs are all doing lab trials, but none of them have been really aggressive in moving toward deployment. ILECs are very interested in VoDSL for their out-of-region CLEC operations and in areas in region where they have copper exhaustion, but they still are not really thinking about VoDSL as a normal part of their deployment. However, cable telephony is going to become a much more viable competitor for them, and they are realizing that there are 1,000,000 cable-telephony lines in service in the United States. That number is not huge compared to plain old telephone service (POTS), but for voice over cable that is a pretty impressive number, given the number of cable lines in service. They are definitely making a lot of headway there. There are primary-line services and secondary teen-line or business-line services in the mix. People are not only doing a second-line scenario; there are people adopting a primary-line scenario over cable.

Vendor Efforts

What are the vendors doing to move DSL along? For one, they have improved gateways to the point that the ILECs believe that they are truly "carrier class." They are meeting the network-equipment building standards (NEBS) compliance for scalability and redundancy at the level where a large service provider feels comfortable. There have also been a lot of standards bodies put in place, including the open voice-over-broadband (VoB) effort and interoperability labs. Customer-premises equipment (CPE) has improved, and the prices of integrated access devices (IAD) have come down. They are still not low enough for residential use, but they are certainly moving in the downward direction. The Panasonic/Jet Stream announcement that Panasonic is getting into the VoDSL business makes a really strong statement about acceptability in the consumer marketplace. Panasonic is a very strong consumer-oriented brand that people feel comfortable purchasing, and for them to have a VoDSL IAD product is a statement that the technology is ready for primetime in the consumer marketplace.

Panasonic's VoDSL IAD is very consumer friendly. It looks and works just like a normal phone—the bottom is just a little thicker. People will not be put off by having it in their house. The gateway providers are also hedging their bets—no one is really talking about VoDSL anymore. Instead, there is VoB, and there is also a lot of conversation about moving to voice over Internet protocol (VoIP) and partnering with softswitch vendors so that all the bases are covered.

Who Is Going to Make the First Move?

Does VoDSL come out first? Or does VoIP? Or do they come out together? What is coming next?

Most of the potential VoDSL providers are also talking about providing the IAD as part of service, as opposed to selling it today, because of the price point. But to get to a retail model, where customers could buy an IAD at a department store, the price needs to come more in line with the standard subset. Indeed, it could be argued that Sprint ION is VoDSL. It is VoIP over DSL. In fact, if there is not a gateway involved, that is really VoIP technology. It is a proprietary CPE technology, but the connection to the home or the business is over DSL for the consumer market. On the business side, there can be different transport technologies, but on the consumer side it is all DSL.

The ILECs are still moving slowing, though some vendor selections are expected by the end of the year. And even after vendor announcements, long technical and market trials are anticipated.

Or Maybe Nobody?

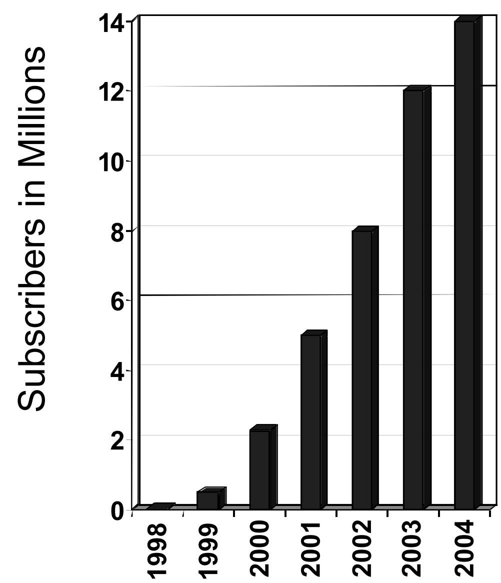
According to most ILECs, the quality is not there for VoIP to be a reality in the near future; it will probably be three to four years before it is a real service offering with the necessary quality of service. Between now and then, there would just be very small pockets of early adopters that would do it, or businesses within their business on a campus.

If VoDSL does not happen soon and VoIP continues to progress, will we have a VoDSL? VoDSL has a limited "shelf life." If deployments do not come before VoIP solutions are equally mature, they may not come at all.

There probably will be a migration. True VoDSL, where there is a gateway and DSL is the transport, would be the

FIGURE 2

DSL Market Size: United States



Source: TeleChoice, Inc. (January, 2001)

first deployment. Then there would be many levels of VoIP, where there would originally be VoIP over DSL, but it still goes through a gateway and actually travels over Class 4 and 5 networks. An entire VoIP infrastructure is really many, many years away. Service providers will start with VoDSL and progress over the long term before truly getting to VoIP. Although some people say that if VoDSL does not happen soon, it may not happen and we will jump right to VoIP, it is not likely that VoIP is going to get through its issues any more quickly than VoDSL.

Of course, this discussion is specific to the United States. Outside the country, there is much more willingness to adopt VoIP–VoDSL type of services. They will probably take off and be adopted much more quickly outside of the United States.

Service providers, for the most part, are still very limited in their focus. ILECs are more likely to pursue gaming, security, video, and other "entertainment" applications first to counter cable companies. For example, Speakeasy.net, an Internet service provider (ISP) in the Seattle area, is residentially focused, but it has packages for specific target markets. It has the gamer package, which has guarantees on latency and number of hops; it has a day-trader package; and it has a system administrator packet—all this and with almost no advertising. It is all word of mouth within these communities, but it has become incredibly well known for having the services to fit these very tacky little cliques within the industry. It is a provider that, from a VAS perspective, can be held up as an example in the residential market.

Small businesses are still underserved, though there are regional CLECs that are really striking out at the small-business market. ILECs are still, for the most part, ignoring the small-business market. They are just starting to realize that this can be a big market for them. There is a lot of opportunity in the small-business market for service providers thinking of going with VoDSL, and there is a huge opportunity in the small and medium-sized enterprise (SME) marketplace. They are currently pretty much ignored by the large providers. They have the low-cost residential services that probably do not have the functionality they need or the larger business services with functionality but with a price point that is way out of their range. So there is not a lot out there today that is targeted for that market.

What Do DSL Providers Need to Do Next?

Right now DSL service providers are focusing on profitability—everyone said that this year was going to be the year of VoDSL. Why didn't it happen? Is there something wrong with VoDSL? No, because last year the service providers were focusing on deployment at all costs. Then, at the end of the year, the market suddenly wanted to know where their profitability was. So this year all of them are focusing on being profitable on the core DSL services and VoDSL. VASs have not been taken off the table; they have just been delayed while providers focused on profitability.

Therefore, profitability is clearly number one. Number two is for the ILECs to really recognize the competition. Among ILECs there has never been a real fear of the CLECs taking away any substantial part of their business, and with a lot of the CLECs crumbling there is even less fear. Cable is serious about voice and is turning into the real threat for the ILEC market. The IXCs are starting to look like the more progressive players for the large players. There is an opportunity for the IXCs to make a serious attempt at bringing voice and data into ILEC territories and really learning from the small guys. There are a lot of smaller players like Speakeasy.net and Telocity that are very successful with targeted packages, creative, value-added packages for smaller audiences. Thus there is an opportunity for the large players to think like small players and really get ahead in the marketplace.

Security Risk Management: Challenges for Today and Tomorrow

Charlie Baggett
Chief Technology Officer
SAFEOperations, Inc.

Abstract

This paper provides a quick overview of the state of information security, taking a fairly critical stance at times. It is helpful to remember, however, that this is a very young field, and most of the disciplines associated with it are immature. This paper focuses on the motivations of information security, reviews the state of the practice, evaluates emerging standards, and offers some solutions. Finally, it considers what the future will look like, with particular emphasis on the necessity for moving beyond signatures to predictive analysis.

Motivation

The biggest cause of concern about information security is reaction to a serious incident. That is not surprising because once users are harmed in some way, they turn their attention to security and become much more interested in the larger issues. What usually follows is concern about the consequences of rapidly expanding connectivity, especially mobile computing (landline and wireless), that, while certainly aiding the growth of business, introduces a new set of problems in itself. High-speed digital subscriber line (DSL) technology in homes (and hotels) facilitates telecommuting, while the wireless world deals with personal digital assistants (PDA), laptops, and cellular phones. Another added layer of complexity is virtual private networks (VPN). Thus, all the problems introduced by those technologies are introduced into the entire network. They lack identification and authentication, with no intrinsic encryption, so users must employ add-ons.

Customer service is another motivating factor behind information security. Businesses want to provide more information and gain more access to their customers, but at the same time they want that information to go only to the customers. Businesses do not want that information going to other people, particularly competitors. Other underlying motivating factors include network and software complexity, the human element, security as "bolt-on" in business and application planning without a systems worldview, and the shortage of security professionals.

State of the Practice

Business Recognition
Businesses must first recognize that senior management must pay sufficient attention to security problems, particularly in their information systems, and then provide the resources to solve those problems. From this recognition flow the policies and procedures to ensure the information security implementation that tracks the goals and objectives of the business. To accomplish all this requires careful attention to staffing and training. However, awareness training is needed for the entire workforce—not for only the security practitioners—because there are a number of weaknesses in any organization.

Technology
The biggest set of technology issues is associated with configurations. Most of the malicious activity today, particularly the scripted schemes, is directed at configuration problems and known software bugs that are not patched. Scaling issues could fill an entire briefing, but one particular issue deserves attention. Private public key infrastructures (PKI) are desired by businesses that want to have public keys that are not accessible to everybody. In other words, they want some privacy, which introduces a registry security issue into the whole set of PKI issues.

One problem that pervades information security involves user authentication—being able to identify who is actually interacting with the system. Current practice is for users to choose passwords and passphrases, but this is a very weak approach to system security. The short development life cycle of security products contributes to system insecurity because enhanced feature sets are rapidly added to already immature security products before existing problems are identified and solved. Therefore, consumers are the problem finders. In other words, the users find the bugs and then report them back, with the expectation that they will be fixed. The industry needs to figure out how to get beyond that through improved operating systems (OS), devices, and applications.

In the misuse and incident detection area, the current products on the market are relatively crude. Most are signature based, and it is simple to demonstrate how easy it is to bypass signatures. Encryption, when used by attackers, can blind many of these products. The telecommunications industry has difficulty defining what "normal" is in networks. It does not know how to do it, but it is learning how. Yet defining "normal" involves a temporal problem because the criteria for "normal" change over time. Products are only beginning to integrate monitoring and management capability. As this trend accelerates, the outputs of those products will help security specialists to gain a better understanding of the problem. Currently, it is difficult to monitor high-speed, large-scale networks; to solve problems when there are attacks against those networks; and to discern what is going on, where attacks are coming from, and how they are composed. Network security today is in a reactive mode. Things happen after the fact, which is very costly because it requires paying for investigations. In addition, the loss of business and reputation associated with any attack can have devastating economic repercussions. Worse, because current security paradigms deal with attacks after they have been identified, the full extent—and success—of an attack might never be known.

Emerging Standards

One of the key emerging standards will be the Internet protocol (IP) version 6. Designed with security in mind, it has a 128-bit address space, authentication, encryption, host interface address switching, and numerous other new features. In the meantime, though, with IP version 4, IP security (IPSec) has been implemented, and that requires the implementation and deployment of some kind of PKI to tighten user identification and authentication. Another area of weakness is in the domain name server (DNS) area, where a requester makes a request and has to believe the response. Unfortunately, it is easy for someone to spoof the rudimentary authentication features. For example, caches are vulnerable to unauthorized access and insertion of incorrect or malicious data. Undetected software deficiencies can subject the network to simple attacks with disastrous consequences. Servers are also subject to attacks, such as denial of service (DoS) and buffer overflow attacks.

Coordination among providers is a growing concern. Most of the attacks that occur now take place across providers and across legal jurisdictions, requiring multiple people to solve the problem. Even if providers agree that they must share information, they still have numerous questions, such as: What do they share? What format do they put it in? How do they find information that needs to be shared in this huge sea of packets? It is not a simple problem. Because attacks cross jurisdictions, law enforcement organizations face a plethora of legal, political, and technical problems. When attacks originate internationally, these issues are magnified, causing problems with attaining and executing court orders. But law enforcement has been pretty slow getting up to speed, both in the technology and in the legal process aspects of this. Law enforcement is complicated by the industry's reluctance to share and expose information on attacks because providers are concerned about what will happen to that information.

Solutions

There are several steps to take to secure an environment, although there are basically no current system-wide solutions available. The first step begins with a risk assessment, a very expensive task performed largely by consultants. The results can be inconsistent, not because of the quality of the work, but because there is no solid baseline against which the assessor can measure. It is hard to make measurements over time and from peer to peer. The next step involves policies and procedures, the road map to information security. Because of the lack of attention by senior management, consultants often find that policies are either incomplete or nonexistent and that the ones in place are usually not enforced. Worst of all, because no policies are in place to track the business, business policies do not drive the selection of technology or the implementation of security solutions.

An in-depth defense is needed. Attacks have occurred at all layers of the protocol stack. At the network level, guarding the information assets includes the use of routers, firewalls, and antivirus software. One of the first things needed in any system is strong authentication that is stronger and easier to implement than the current password system but not as costly and expensive as implementing a comprehensive PKI. Something is certainly needed now to fill this gap.

Products must be centralized so that they can be centrally monitored, which requires more vigorous product development and testing. More proactive monitoring is essential. Information should be consolidated and correlated across various aspects of the OSs, not done piecemeal. Continuous feedback is important, and the monitoring and analysis systems must be updated. A vigilant monitoring system will have a network intrusion detection system (NIDS), a host intrusion detection system (HIDS), and limited application misuse detection. The industry must move away from strict signature identification and should learn how to monitor in high-speed, large-scale environments in real time. Instrumentation of the entire computing environment is needed to attain more complete network security.

Network security involves a very complex set of issues. To tackle the problem, service providers may choose to outsource information security for their networks. The managed service provider should not be somebody who does it as a sideline; instead, experienced security professionals should be hired who have a demonstrated history of providing thorough, timely security services. In addition to the experience of its employees, the service provider should have a robust, secure operations center from which to manage client networks.

Beyond Signatures: Predictive Analysis

Any network-security solution must work at the network, host, and application levels. A coherent solution will address the entire stack simultaneously and will allow the establishment of norms in preventive action so that damage to the network can be limited. Predictive analysis will allow network security to move beyond signatures in the current intrusion detection systems. Processing must go as far forward in the system as possible. Effective instrumentation must be included at all levels of the network. Products are now opening themselves to the capability for monitoring and management. Ideally, this would be done as transparently as possible, without having to place sensors in the networks, and using the minimum necessary bandwidth. The establishment of network-specific behaviors, norms, and patterns will help predict attacks and malicious behavior. Those behaviors, norms, and patterns specific to the traffic flowing over the network can be linked to the geographic locations in which activities are taking place and to the people who participate in the conduct of the business so that security analysts can begin to understand these parameters as a function of time. The data must be timely and reliable. The false-alarm rate must be compatible with the business objectives, and the tools must be able to learn and to keep up with Internet time. Predictive analysis will support the focusing of resources, which will have benefits beyond merely the capabilities to handle security items.

Leveraging Optical Options

Richard Barcus
President and Chief Operating Officer
Tellium

Incredible advances in technology have occurred over the past couple of years. This is especially true in the world of communications, where advances in optical networking have made new and exciting broadband applications possible. While the emerging opportunities show promise for the end user, carriers are struggling to support these applications while remaining profitable. This paper discusses leveraging the optical layer to help carriers introduce new broadband services while remaining profitable.

Carriers were once enthusiastic about reports of bandwidth demand doubling every six months. Incumbent carriers raced to expand their networks, and new carriers built an infrastructure from the ground up. Fierce competition drove the expansion of infrastructure, but it also drove bandwidth prices into the ground. Carriers began to question their ability to respond to the demand while also making a profit. As bandwidth prices plummeted and marginally profitable carriers began closing their doors, a number of reporters and analysts began to cite a bandwidth glut. The idea of a bandwidth glut appears ludicrous, though, given that most carriers continue to struggle to meet demand.

Nevertheless, these carriers do recognize that building and maintaining an infrastructure is expensive. Their current drive to build a robust infrastructure that can handle the emerging applications has their costs rising at a rate that outpaces the corresponding increase in revenue. Consequently, these carriers are now looking for a way to decrease costs, increase revenue, and create a sustainable competitive advantage over the competition.

While the short-term future of the industry remains a challenge, the long-term possibilities remain extremely encouraging. Success will be achieved by those carriers that recognize that the communications landscape has changed. These carriers must plan for the long term; they can no longer forecast and build infrastructure based on the traditional traffic-engineering model using the predictable and steady growth of voice traffic. A number of emerging technologies support a multitude of broadband applications, which could explode and turn a perceived bandwidth glut into a real bandwidth shortage overnight. Remote-office networks, WebMD, instant messaging, Internet gaming, distance learning, webcasts, MP3 audio, streaming video, electronic photo albums, e-libraries, e-movies, and on-line museums are just a few applications currently driving the need for bandwidth. The challenge for carriers is to make these applications available to global consumers at a fair and affordable price while remaining profitable. On-demand access with a pay per use creates a need for a dynamic network. Bottlenecks, which could kill an application, must be eliminated in both the core and edge of the network. Eliminating bottlenecks in the core of the network has been the focus of long-haul carriers for the past couple of years and includes a fairly well-defined solution.

Eliminating the bottleneck in the metro—particularly the first mile where end users request large files or listen to music over the Internet—remains a challenge. A host of companies are using a wide variety of technologies to address the problem. These include cable modems, satellite, private networks, fiber to the home, synchronous optical networks (SONET), new-generation SONET, asynchronous transfer mode (ATM), Internet protocol (IP), metro dense wave division multiplexing (DWDM), or the all-in-one multiservice protocol platform. The lack of a clear, winning solution, though, exasperates the problem. A clear winner would benefit the end user by allowing investment in a technology with longevity. This should, in-turn, support continued bandwidth growth in both the edge and core networks.

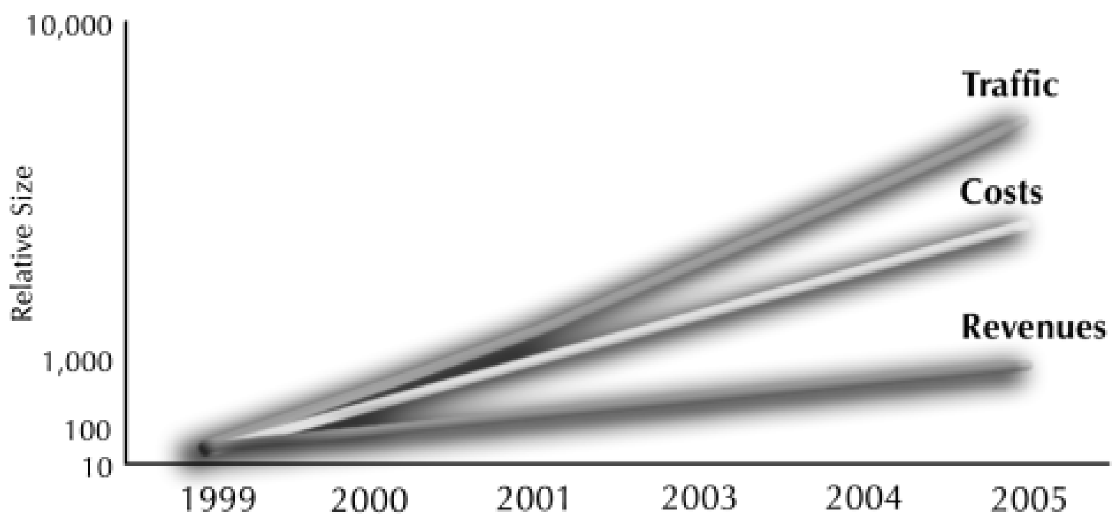
Technology advancements in the core provide carriers with an opportunity to create a network that is more scalable, flexible and dynamic than today's core network. These advancements are based on optical switching technology, which has had an accelerated time of development over the last couple of years and promises further developments over the next decade.

Market Influence

Advancements in technology were aided by the economic well-being of the United States during the late 1990s. The abundance of investment capital funded sophisticated and innovative developments in a number of areas, including optical switching. Small, eager firms with focused research and development organizations were able to commercialize optical technologies that had been in the laboratories for a number of years. Investment funds also flowed freely into communication carriers with aggressive plans to profit from the unprecedented demand for bandwidth. Incumbent carriers saw their territories challenged by new, aggressive upstarts as well as by non-traditional players such as cable companies and utility consortiums. End users finally began to see the competition and, more importantly, the lower

FIGURE 1

Carriers' Dilemma



prices that were alluded to at the time of deregulation. Carriers began forward pricing their services, i.e., cutting prices to attract new customers. The result was more carriers competing for the same pool of customers and cutting their prices to gain a competitive advantage. Carriers had to build out their networks to support the anticipated demands, while dropping prices to attract new customers. This contributed to costs rising at a faster rate than revenues, as indicated in *Figure 1*. Given these circumstances, it is not surprising that some carriers had to shut their doors.

The recent turn of the market is unfortunate, but it should help stabilize pricing by reducing the number of competitors and by concentrating bandwidth demand among a manageable number of suppliers. The key to carrier survival will be to reduce the cost of building out their infrastructure while continuing their evolution toward a network that is more scaleable, flexible and dynamic. These carriers should then be able to offer new optical services, supporting the emerging bandwidth-intensive applications. Their newer, lower cost basis will permit them to price their services aggressively, provide better service, and enjoy higher margins.

Optical Network Elements

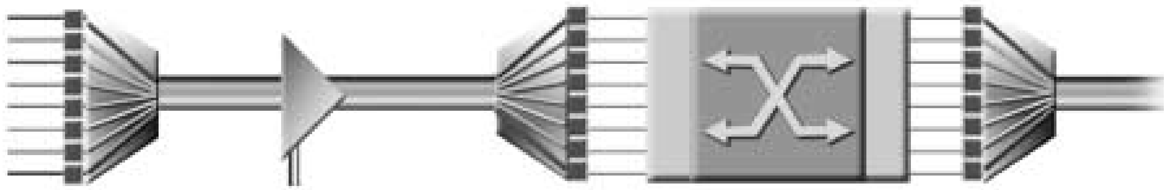
Impressive developments in key optical-networking components have occurred over the last couple of years. It is imperative that the industry builds on this momentum and maximizes the benefits of the resulting optical network elements. Continued advancements on these products are the key to carriers supporting the bandwidth growth that will, in return, encourage new applications. These network elements, as depicted in *Figure 2*, include DWDM, optical add/drop multiplexers (OADM), and intelligent optical switches. Advancements in these areas hold the promise of supporting new bandwidth-intensive applications in medicine, education, law enforcement, banking, and entertainment. Taking a quick look at each of these elements will show how continued development in each supports the evolution of the optical network.

DWDM is probably the key element that defines optical networking today. This device, which quickly established itself in core long-haul networks, solved the bottleneck issue for inter-exchange carriers who were short on fiber and facing challenging right-of-way issues. DWDM created the opportunity to increase the capacity of fiber 100 fold. Continued development of this element promises to add unlimited capacity on a given physical fiber path. DWDM manufacturers are promising to open up new transmission bands, while decreasing channel spacing to offer virtually unlimited capacity on a single fiber. While the prospect of thousands of wavelengths on a single fiber is exciting, it is the process used by DWDM that makes new services possible. DWDM transmits hundreds of discernable light signals as individual light paths. Each of these light signals can carry different bit rates, different technologies, and can be routed to various parts of the network. In essence, it provides the foundation for optical networking. DWDM is well entrenched in the core of the network, and continues to show promise in the metro to allow the extension of end-to-end optical services closer to the user.

As the number of wavelengths increases, the ability to access a subset of them becomes increasingly important. It would be overly expensive to demultiplex all of the wavelengths just to access a small subset, and OADMs have been introduced to address this issue. OADMs will play a major role in the continued evolution of the optical network. These devices are not very mature, however, and are just now emerging as reliable elements that allow access to a subset of wavelengths without converting the optical signal to electrical and back to optical again. OADMs generally use filters, which introduce loss into the network and until recently only allowed access to a very small portion of the

FIGURE 2

Optical Network Elements



wavelengths. There are promising developments that allow access to a growing number of these wavelengths without introducing an unmanageable amount of loss. In addition, developers are working on complementary products to allow carriers to dynamically select the wavelengths they want to add or drop. The continued development and deployment of OADMs will help reduce the cost of optical networks while helping to improve its flexibility.

While DWDM and OADMs create a foundation for optical networking, the true promise of a network that is scalable, flexible, dynamic, and economically viable will not be fulfilled without optical switches. Unlike OADMS, optical switches can manage a large number of wavelengths entering a network node from multiple directions.

Optical switches provide large-scale photonic management of signals between DWDM terminals. These intelligent devices add manageability to the large number of optical signals supported by today's DWDM devices. Optical switches that normally interface with numerous DWDM terminals generally process signals at the transport-network line rate of 2.5 gigabits per second (Gbps) or 10 Gbps. These optical switches empower carriers with the ability to remotely provision these signals, rapidly reroute these signals around failures, or implement new and varied optical services. Because the majority of this bandwidth is carrying an increasing amount of data traffic, it is important to note that core optical switches, grooming at 2.5 Gbps, can perform these functions without adding appreciable network latency.

Intelligent optical switches also allow carriers to use more of their network to generate revenue. Most carriers today use dedicated ring-network architectures that reserve half of their bandwidth for protection. This results in circuits that sit idle most of the time waiting for something to go wrong. Intelligent optical switches support multiple architectures, including mesh, which will allow a greater portion of the network to be used to carry revenue-based traffic. Mesh networks, as shown in *Figure 3*, not only allow working circuits to share restoration routes but also provide optional paths for the unlikely event that the primary restoration route is occupied. The ability to dynamically select various restoration routes makes mesh networks more reliable than rings on a network-wide basis. Optical switches, deployed in mesh architectures, provide carriers with the ability to offer various grades of service. They can continue to offer dedicated restoration paths to those discerning customers who insist on, and are willing to pay for, premium services. Carriers may also offer discounted services to a consortium of users that establishes a dedicated working path but shares restoration routes. Shared restoration can be used for diverse working traffic where it is unlikely that simultaneous failures would occur. This method increases the efficiency of a carrier's network and uses more of it to generate revenue.

Flexible architectures such as mesh, which use intelligent optical switches, ultimately give the end user more control. Optical switch-powered networks also give customers control of their own restoration scenarios, invoking various schemes based on the time and type of traffic they are supporting at any given instance. This type of control can be supported through either the introduction of improved hardware or sophisticated software support. The use of software currently has the most momentum.

Sophisticated software algorithms work together as the central nervous system for the next-generation of optical mesh networks. Improved developments in this area will allow the optical switch to recognize service conditions and match them with service obligations, performance criteria, and maintenance events. The correlation and subsequent reactions will occur for either planned or unplanned events. The software will process all of the information and then take action based on criteria established by either the carrier or customer.

The Case for the All-Optical Switch

The current state of network evolution includes the deployment of intelligent optical switches, which uses an electrical core. These switches are known as optical-electrical-optical

FIGURE 3

Mesh Network

(O–E–O) because they convert an optical signal to electrical and the back to optical. While the conversion supports a number of useful functions, such as grooming and 3R regeneration, some see it as it as introducing unnecessary expense into the network. Proponents of an all-optical switch conclude that the elimination of electrical components will result in a switch that is significantly less expensive than the current generation of O–E–O. While this may be true in some limited applications, the lack of any significant deployment of all-optical technology indicates that the all-optical switch is not yet ready for prime time. Without the electrical components, all-optical switches have no way of passing important performance data. They lack the ability to communicate vital network information used for restoration and dynamic provisioning. So while eliminating the costs of electrical components, all-optical switches also eliminate the intelligence required for a more flexible and dynamic network.

Certainly, the promise of the all-optical switch is well understood. Theoretically it is infinitely scaleable, supporting any bit rate on each of its ports. Thus, the throughput of the switch can be greatly increased simply by increasing the line rate of the subtending transport equipment. A 256 port all-optical switch can support growth from less than 1 to 10 terabits throughput by upgrading the transport equipment from optical carrier (OC)–48 (2.5 Gbps) to OC–768 (40 Gbps). If the switch is truly transparent, this is accomplished with no impact. However, as the number of ports increases, so does the loss through the fabric, the complexity of control, and the difficulty of fiber management.

All-optical networks require a great deal of sophisticated optical engineering to plan for physical impairments that accumulate over an end-to-end path. Such preplanning is, of course, counter-intuitive to the movement toward a more flexible and dynamic network. The introduction of an all-optical switch into an all-optical network may actually cause the total network cost to increase by requiring additional engineering and equipment to accommodate the different optical performances introduced by the appearance of a new optical element to the network. An all-optical network currently has to be engineered for worst-case scenarios, thereby eliminating the savings that one might otherwise expect from optimized network links. In addition, all-optical networking requires the implementation of equipment from a single vendor and could eliminate savings garnered from using best-of-breed for particular areas of the network. Open standards, which support interoperability at the optical level, do not exist and are not expected in the foreseeable future.

All-optical switches, implemented correctly and at the right time, will further the cause of optical networking. The economics of an all-optical switch in a core network doesn't appear to be viable until an appreciable number of high bit-rate signals (40 Gbps and above) are deployed. In addition, these signals will support optical services that do not require grooming at intermediate nodes. Although it looks like wide-scale use of 40 Gbps transmission will be a market driver for all-optical switching, there will be a real need for grooming 2.5-Gbps and 10-Gbps payloads within these large 40-Gbps signals.

Given the state of all-optical switches and carriers' continued need to groom information from data routers operating at 2.5 Gbps and 10 Gbps, O–E–O switches will be the primary mechanism for managing wavelengths for many years to come, and all-optical switches will be introduced into the network to complement the functions of an O–E–O switch. All-optical switches will support high-speed bypass at a network node, while the O–E–O switch will continue to support functions such as performance monitoring, fault isolation, grooming, and restoration. Together, rather than separately, they represent the suite of advantages needed by carriers to build networks that can provide the services, security, and reliability that will lead to profitability. O–E–O and all-optical switches are not competing; rather, their strengths complement one another. As complementary technologies, they provide carriers with a painless way of using either or both based on the application.

Looking Ahead

Carriers can look forward to continued advancements in optical switching technologies. These advancements, coupled with a sound business plan, will return profitability to the communications industry. The deployment of intelligent optical switches, coupling the latest in hardware development with sophisticated software, will allow carriers to offer new optical services while decreasing provisioning times and lowering both capital and operating costs. Optical switches offer a realistic approach to evolving the network to support new services, without disrupting sound operating processes and procedures. Intelligent optical switches help carriers recover valuable floor space, lower power consumption, introduce new services, and offer differentiated restoration services. They take advantage of advancements in electronic components to support continued scaling, while supporting the maintenance functions required of core optical networking. This evolution will consist of the addition of all-optical switches, supporting the dream of bit-rate independence while offering unlimited scalability. All-optical switching will be added to network nodes and work in conjunction with O–E–O switches to maximize the benefits of both bandwidth and optical services; meanwhile, the O–E–O switch will continue the vital role of grooming and providing valuable performance monitoring information. The all-optical switch will efficiently process the bypass traffic, which neither terminates nor requires grooming. Together these switches will provide increased flexibility without sacrificing the carriers' ability to localize a particular fault down to the card level.

Significant progress is expected over the next couple of years to extend the best-of-breed optical switching concept to include the use of a common control mechanism between not only optical switches but also data routers. This will provide the impetus for new applications and a further reduction in provisioning times. In the end, the clients in many cases will be able to turn up, turn down, change, and alter their own capacity when and where they desire. This function will be supported by network management systems that interact with the optical switches to handle billing functions.

Most of these functions, driven by demand and factors of economy, will occur in the core of the network first. However, as technology matures and the direction of the edge market becomes clearer, optical networking will move closer to the end user. Further development at the edge and core, particularly in the area of control, will make true end-to-end opportunities a reality.

Where Communications and Computing Meet

Craig R. Barrett
President and Chief Executive Officer
Intel Corporation

We're going to talk about the digital world. We'll talk about the divergence of communications and computing and try to give you some historical insight on what's gone on in the past, what sort of evolutionary changes there are, and what we need to do.

So we'll talk a little bit about the state of the industry today. We'll talk about the principles of technology evolution, about how you get from one generation to the next, and a little bit about our industries. I want to emphasize "our industries." It's really the computing and communications industries working together to bring solutions to the consumer, whether the consumer is the home consumer or the business, a large business, or a small or medium-sized enterprise.

We've all been impacted by an economic slowdown; that's no secret. There's a dot-com meltdown. There's a carryover from Y2K. Information technology (IT) spending has slowed down dramatically, especially here in the United States. Yet it's still going gangbusters in other geographies around the world. But purchasing of our equipment, some of your equipment, has slowed down. The mobile handset market has slowed down dramatically. It's still growing, but with nowhere near the growth that it had a year or so ago.

If you look more particularly at the communications industry, it is an industry that invests a lot of money. Debts are at record level. You find people who are bidding billions upon billions of dollars on third-generation (3G) spectrum for the next-generation handset wireless capability.

The estimate is that it will take something like $150 billion to buy the spectrum in the various auctions run around the world if those auctions continue to take place. One was canceled in Singapore recently for lack of interest. But $150 billion to buy the spectrum, $150 billion to put the infrastructure in place to deliver that capability, $150 billion to provide the applications to get the consumers to come before you start to see a nickel of return on that investment.

So there's a huge challenge in some of the communications areas for the next-generation capability.

There's also some degree in excess of capacity with dark fiber underground. We've looked at what's happened recently to some of the networking communications suppliers, the original equipment manufacturers (OEMs) in this space. We've seen that it grew like there was no tomorrow and that the business would never slow down. It would grow on at 50 percent compound annual rate going forward.

Well, it turns out that supply-line management wasn't wonderful in that space. As orders fell off, we've seen massive inventory write-offs. The entire supply chain has been impacted to various degrees.

That is the state of the industry today, but it's going to get better tomorrow. If not tomorrow, then next day. And the real reason is that we have a digital world ahead of us. And there's no doubt that this digital world is not going to slow down. If you look at the number of Internet users, the number of computers, the number of personal digital assistants (PDAs), the number of handsets that were sold each year, those numbers continue to go up.

We know that the Internet buildout is going to happen. We know that the Internet is going to be the medium for communication, for entertainment, for access to information, and for conducting business and commerce. We know that that's going to continue.

Every two minutes, there are approximately 50 new subscribers to the i-Mode phone at DoCoMo, which is the always-on packetized capability with handsets in Japan.

There are approximately 400 new users joining the Internet around the world every two minutes.

There are approximately 1,400 new auctions listed on eBay every two minutes. And we're just going to continue scaling this up.

About 1,500 cell phones are sold every two minutes. That translates to roughly 400 to 450 million new cell phones a year.

Amazon.com sells about $11,000 of goods over the Internet every two minutes.

And look at how many searches are completed at Google's high-performance search engine: something like 83,000 searches every two minutes.

And in its heyday, there were something like 100,000 file transfers started every two minutes on Napster.

If you look at how many instant messages are exchanged on America Online (AOL) every two minutes, it's something like 900,000 short messages.

Somewhere between 500,000 pages and one million pages are downloaded from Yahoo! every two minutes. This continues to grow.

And there are about 50 trillion voice bits on the backbone every two minutes. And if you look at data bits on the backbone, there' something on the order of 100 trillion data bits every two minutes.

Every one of these numbers, save Napster, perhaps—but there will be follow-ons to Napster—will continue to increase as we go forward. This is really the future of our two industries: This immense amount of information being communicated over the various backbones and then the computing power to be able to analyze it, manipulate it, deal with it, redirect it, enhance it, and enjoy it.

One of the things that bother me a lot is reading in the press about the United States and how our Internet buildout is complete, mature. The United States has about 5 percent of the world's population. And if you look around the world, you're starting to see immense activity going forward in terms of number of Internet uses, users, and capabilities.

Europe, for example, is projected to have more Internet users than the United States within the next one to two years. They have the highest mobile phone usage in the world: more than 52 percent penetration of mobile phones—higher than that of Japan, higher than that of the United States.

In Asia, Internet usage is growing by a compound annual rate of about 45 percent. They're projected to have 400 million users on the Internet by 2004. Within a couple of years, Asia (excluding Japan) is projected to have 25 percent of the global Internet users.

Meanwhile, although Japan has discovered the latest in cellular phones, packet switch capability, and the i-Mode phone with 20 million users, at the same time they've also grown their Internet usage phenomenally: more than 60 percent compound annual growth rate (CAGR) in the last year or two as the Japanese consumer has discovered the Internet. Furthermore, about 50 percent of the Japanese consumers are, in fact, mobile phone users as well.

The key issue to all of these statistics is that the Internet is growing dramatically and will continue to grow dramatically—and that's what we're all about: using the Internet for communication, information access, entertainment, and conducting commerce. And that's why we collectively need to work together—to make sure that that Internet usage continues to grow and that the world becomes increasingly digital.

So the Internet is our growth engine. And whether we like it or not, we're both—the computing industry and communications industry—tied, together, to that growth engine.

And if that is the growth engine, then it probably makes sense to look a little bit at the principles of that growth. What do we know from the past about how technology moves forward? What can we do about it in the future? What can we expect in the future?

We're really starting off today in the communications space with three separate networks. They're relatively inefficient today as three separate networks, but as we move forward, the inefficiencies have to grow out of the system, and the network has to become much more efficient (see *Figure 1*).

If, in fact, the whole world is going to be tied together by Internet protocol (IP), one network, then, in fact, these three networks—a voice network, a wireless network, and a data network—have to come together in a single network. These inefficient systems have to become more efficient as we go forward.

Today, in fact, they're tied together to some degree by gateways and services. And increasingly, the people are recognizing that you're not going to have a separate data network; you're not going to have a separate wireless network; you won't have a separate voice network. In fact, all of these networks will be linked together seamlessly, running the same protocol, running the same efficiencies, getting the same volume economics that you get when you have a common infrastructure and a common set of standards.

This is what makes our collective industries work and provide great value to the consumer. We've come up with standards; we've come up with volume economics associated with those standards; and we've delivered those volume economics to the end user.

So, these three networks, which are somewhat glued together today, are going to have to be integrally tied together in the future. And that's what we all refer to as the next-generation network.

We're going to evolve, but we won't throw away the old generations instantly. We all know that—just the same way that we know that when the personal computer (PC) came about, we didn't throw away the mainframe computer. We just built around it. We won't throw away all of the elements of the old-generation networks, either. We will build around them. But we'll have the convergence for the universal IP network. It will be a single network for maximum service, maximum applications, and maximum economics to the end user.

We'll have different ways of accessing this network and the content on that network, and we'll have scalable content delivered to the device at hand.

Now, we've had a lot of press in the last year or two, especially coming out of western Europe, which kind of missed out on the computer revolution but is a leading player in the mobile handset. The press out of Europe basically said that the PC is dead—that everything is going to be mobile handset, the mobile Internet, and mobile commerce. Everything is going to be e-mobile.

FIGURE 1

Today's Network: Inefficient Systems Become Efficient

I think that misses the point entirely. There are various ways to access the Internet, but there will be only one Internet. That one Internet will be the place where content resides. If you access that content with your handheld device or your PDA, you'll get scaled content. If you access it via your PC, you'll get the same content at a different scale. It will be essentially the same content, just scaled for delivery.

Just as our computing industry for years has looked at evolutions of technology, we're hoping to see the same thing in the bandwidth area. Look at the line-up of Intel processors going back to the first 8-bit and 16-bit processors that populated the first IBM PC, which is today just 20 years old, and that were running basically a megahertz or less when they were introduced; then look at today's state-of-the-art processors, which run nearly at 2 gigahertz (GHz). You can see at what sort of speed that transition has occurred.

We joke in our industry about Moore's law, which says processing speed doubles every 12 or 18 months, while in the telecommunications industry, bandwidth doubles every century. So the two industries are integrally tied together here. They're just a little bit out of step.

When it was first introduced, the Internet speed was, in fact, 300 baud; so we have come up a little bit from that. But there is a decided shortage of high-bandwidth content capability to the users, especially to small/medium enterprises and the home consumer in the United States today. Those consumers want more bandwidth. The computers that they have can handle a lot more bandwidth. And if you want rich content going into the home, whether that content is information, entertainment, or commerce-related content, they need more bandwidth to achieve that.

And not just the United States, clearly. You need that content around the world. Some countries are a little more progressive in this space than we are. Korea, for example, I think has the highest density of high-bandwidth capability to the home of any country in the world. And that's a result of the government fostering that installation plus strong competition between digital subscriber line (DSL) and cable in Korea.

We have yet to really establish that strong competitive spirit here in the United States to achieve that same sort of penetration that Korea or Singapore or other countries have. It's estimated that in the United States, only about half of the people who really want high-bandwidth capability to their home will get it this year. Two million or so DSL users and a similar number or so of cable users are faced with increased difficulty to get that content, increased difficulty in servicing that content, and most recently, the realization that the providers are, perhaps, more interested in profit margins associated with delivering that than they are with expending the capital outlay and expanding the service to their users. So they're starting to raise prices.

If you want to look at what volume economics can bring, though, by a single-standard capability, the transistor world is a good example. *Figure 2* shows the number of transistors that are produced each year by our industry worldwide: something like 200 quintillion transistors per year. That is roughly equal to every printed character, letter, or number that has been recorded in the history of mankind. So each year we make the same number of transistors as every character that man has written down in man's lifetime.

You can see that this number continues to grow at a logarithmic rate in terms of the increase and that the average price per transistor continues to decrease the logarithmic rate. That's why you get the anti-inflationary nature of our industry in terms of bringing more capability for the same cost, year upon year upon year.

Metcalf's law really drives the networking industry, and it basically says that if you double the number of intersections

FIGURE 2

Transistors Shipped versus Average Transistor Price

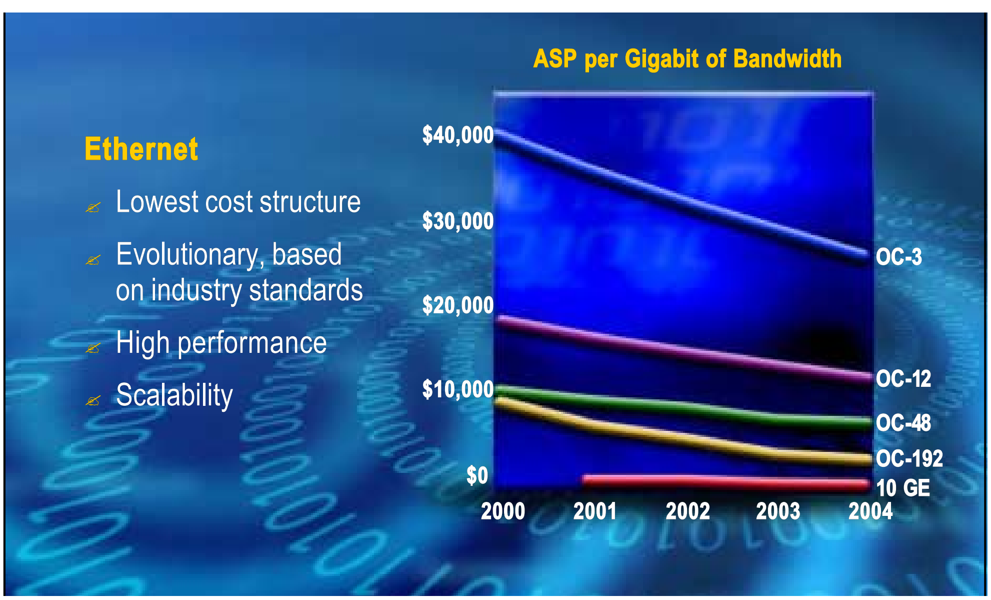
to a network or network and patch points, then the network becomes more valuable. And if you have more and more contact points, have interoperability between networks, and have competition, then you start to get the same thing in the network space that we've had in the transistor space for the last 30 years.

Figure 3 shows the cost per unit of bandwidth for different styles of bandwidth, different communications protocols. There's optical carrier (OC)–3 on up to OC–192, and then at the bottom there's 10 Gigabit Ethernet. And 10 Gigabit Ethernet happens to be a longstanding standard protocol that's been used in local-area networks (LANs) for years and is available almost for free in terms of bandwidth capability in the LAN.

It seems pretty clear that the LAN standard and the long-haul or metro network standard are going to merge, probably in OC–192 and 10 Gigabit Ethernet. They're both at the same bandwidth. There's no reason to have two separate

FIGURE 3

ASP per Gigabit of Bandwidth



protocols, per se. If you had one, then you can do without a lot of the intermediate switching, redirection, and gateway gear. It's directly traveled.

But the issue here is that open standards beget volume economics, beget value to the end user. Very, very low cost, similar to the economics of transistors. And "open standards" here means that the point of origin and the point of destination adhere to the same protocols. And whether we're talking about the application stacks, the transport stacks, the networking capability, the data links, or the physical interface devices, once we get to common standards, then, in fact, we can start to get volume economics.

And the real beauty of this sort of open-standard capability is it really opens up the arena of competition—most specifically for applications. We can sit and talk about the merits and technical details of Ethernet versus OC–192, and the end consumer just really doesn't care. The end consumer is interested in the solution, the capability: What do you bring me? What can I do with it? What enjoyment do I get? What's the user interface look like? As soon as you start to have open standards, you open up the entire industry to people who can bring applications and port those applications from machine to machine, locale to locale. Then, in fact, you start to increase the rate of innovation and bring the end consumer more value.

So this open interface concept, fostering competition, fostering the rate of technology moving forward is very, very key to the whole message today. This is what's happening with the convergence of computing and communications.

Industries that historically were built up with rather stovepipe proprietary standards are being opened up and are allowing the whole industry to innovate around them, rather than just one company innovating around a particular proprietary standard.

So I think that this next-generation network—this collision bringing the best computing standards together with the best communications standards, and then allowing the whole industry to innovate around those standards—will keep technology moving forward very rapidly.

This paper was excerpted from the author's keynote speech at Networld + Interop in Las Vegas, May 2001.

Optical Networking: Recent Advances, Trends, and Issues

Naveen Bisht

Nayna Networks, Inc.

Abstract

This paper summarizes the latest optical telecom networking market developments. Issues that are being debated hotly in the networking community are presented. This includes the issue of traffic glut versus growth, optical versus electrical switching, Ethernet versus synchronous optical network (SONET), and mesh versus ring. We then also explain the trend toward optical cross-connects.

Introduction

The telecommunications industry experienced a rapid downturn in 2001. As a number of industry gurus attempted to "call the bottom," some of the most generally accepted beliefs turned into mirages. Take a look at the metro market. It was believed that the metro market was poised for strong growth. Institutional money flowed into this sector and created dozens of start-up competitors in every segment, each claiming its own position and striving to provide cheaper, faster, and smaller products. However, the demand turned out to be smaller than was anticipated. On top of that, with the obvious price competition that results in such a situation, a seemingly great opportunity now looks significantly gloomier. The question, which comes to the mind of every telco professional, is "have we hit the bottom yet?" Perhaps not. There are a few factors that will have a large impact in 2002 and ahead:

1. Capital expenditures budgets for carriers are still declining by about 24 percent in 2002.
2. Carrier spending is transitioning from large network build-outs to incremental bandwidth expansion based on immediate revenue-generation models and through the extraction of more efficiency out of the deployed capacity.
3. Oversupply of optical components caused by consolidation and bankruptcies of some of the carriers are expected to last through at least the first half of 2002.
4. Spending disruptions due to carrier consolidation, management changes, and reorganizations, etc.
5. Pricing pressures at all levels of the food chain from systems and components to services.

A silver lining, however, exists among this gloom. Optical systems based on new technologies are going to offer new services opportunistically at a reasonable cost by incorporating new functionalities. Much of the innovation is required to enable carriers to offer new, higher-margin services and to reduce their capital and operational expenditures and network costs. These will be accomplished by the innovation at the component level, at the systems level by adding these innovative components with intelligent software, and at the architectural level by leveraging new architectures that result in cost savings and higher margins.

Ultimately, the end-user customer, whether it's business or residential, will drive growth in our industry. The days of "get to market fast, build it, and customers will come with open arms" are gone, and the mantra going forward is success-based, revenue-based, and incremental investment in the network. On the business side, lambda services are gaining traction with the carriers, and these services aim to provide line functionality at high speeds and competitive costs. Although 2002 may still not look very good for us in the industry, the foundation for innovation in the optical networking industry has been set. This innovation offers a compelling value proposition for the carriers to use as they start planning their next phase of network upgrade, build-out, and the maximizing of the efficiency of their networks.

In spite of the economic downturn, it is important to note that the number of Internet users has grown consistently during the past five to six years. In the late 1990s, UUNET traffic was almost doubling every 90 days. While the current rate of growth may not be as high as during those times, it is still growing at a rapid pace. This growth will provide opportunity for the system vendors and component vendors to be able to leverage their innovative products to build into systems for the carrier infrastructure upgrade that they will have to do in order to remain competitive in the market place.

Each technology follows an S-shaped curve, as shown in *Figure 1(a)*. If we were to plot the number of problems solved as a function of time required to solve them using a given technology, the curve would have an S shape. In the beginning, when a technology is just evolving, it takes quite a bit of time to solve very few problems. In financial terms, it means that the technology developers require substantial funds but that the resulting commercial value may be little. This phase of the technology is called the "research" phase and is funded by governmental research-funding organizations such as the National Science Foundation (NSF) or the Defense Advanced Research Project Agency (DARPA) in the United States. After the fundamental problems have been solved, the technology growth curve takes an upturn, and it takes very little time to solve many problems. In other words, it takes very little money to produce quite a bit of money using that technology. The technology is then taken over by the commercial sector. Finally, after all easy problems have been solved, the technology growth curve takes another turn. Now only hard problems are left and it takes quite a bit of time to solve very few problems. In other words, the technology is no longer cost-effective. At this point, the researchers and the commercial world move on to some newer technology.

Computer networking has also followed an S-shaped curve. If we were to plot either the number of hosts on the Internet or the total number of Internet users, we would find that the curve is S shaped.

The technology started with the concept of packet switching in 1968 and the initial implementation of four-node ARPAnet in 1969. The knee of the networking growth curve occurred in 1995 with the popularity of the World Wide Web (WWW). The peak growth rate (the center point of the S curve) happened sometime in late 1999 or early 2000. At this point, we are slightly beyond the center point as shown in *Figure 1(b)*. This is true for the electronic networks. Conversely, optical networking is still near the knee. There is quite a bit of research activity going on and the commercialization of the optical networking technologies is just starting to take place. We should soon see an exponential growth in optical networking.

There are four issues that are being hotly debated this year at networking conferences. These are as follows:

1. Bandwidth Glut versus Traffic Growth
2. O–O–O versus O–E–O
3. Ethernet versus SONET
4. Mesh versus Ring

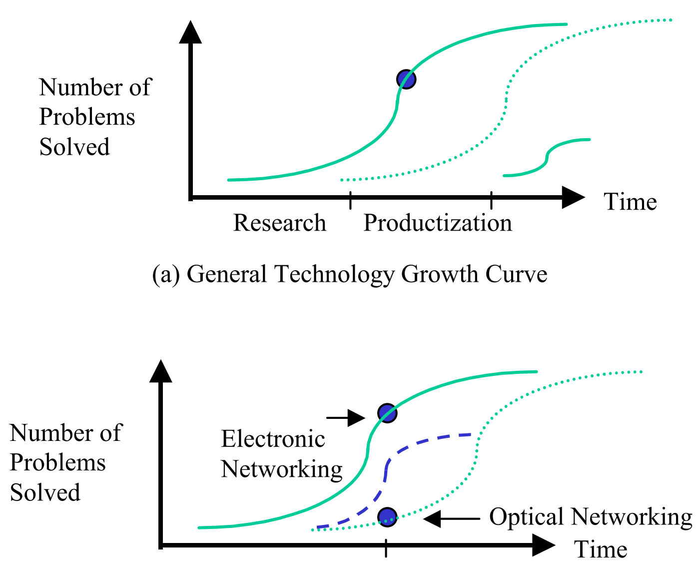
We explain both sides of these debates next in this paper and also explain the trend toward optical cross-connects.

1. Bandwidth Glut versus Traffic Growth

One of the fundamental issues that are being debated is whether network traffic growth has stopped. The starting point of this debate was a forecast by McKinsey & Co and J.P. Morgan in May 2001 that Internet traffic growth will slow down from 200 to 300 percent per year to 60 percent by 2005. Soon after that, *The Wall Street Journal*, *The New York Times*, *Forbes*, and other popular media papers and magazines reported the finding that 98 percent of the fiber is unlit. Nortel Networks blamed the loss of its revenue on the falling Internet protocol (IP) traffic. Michael Ching, a Merrill Lynch analyst, reported that carriers are using only average 2.7 percent of their total lit fiber capacity.

All of these gloomy statements and forecasts accentuated the fall of the telecom market. However, when one analyzes

FIGURE 1



(a) General Technology Growth Curve

(b) Electronic versus Optical Networking Growth these statements, one finds that while these statements might be true, they should not be a cause for alarm. Of the three aforementioned statements, the first one is a forecast while the other two are based on current usage. While the forecast may or may not be true, the current usage needs to be explored further. Installed fiber alone does not constitute the telecom infrastructure. Actually, fiber installation costs are high compared to the costs of the fiber itself, and so it is quite common for carriers to install cables with hundreds of fibers when they need just a few fibers. Having unlit fiber is quite common and should not be considered alarming. Similarly, the average usage of networking facilities is generally very low. For example, most of the computers today are equipped with 100 megabits per second (Mbps) Ethernet ports. The average usage of these ports is very low—generally less than 1 percent. Nevertheless, networking links are often the bottlenecks, and we find ourselves waiting for the information to arrive over the network. At those peak usage times, we need all 100 Mbps and more. Thus, the network capacity is planned for peak usage and not the average.

Telechoice, a market research company, conducted a usage study for Williams Communications. They studied the 22 most used routes in the United States and found that the utilization on 14 of these routes exceeded 70 percent. This high utilization would necessitate upgrading these routes and the networking equipment. Larry Roberts, one of the early founders of the Internet, himself conducted a measurement study of traffic on 19 of the largest Internet service providers (ISPs) in the United States. He obtained data on 95-percentile usage at each of these ISPs at six months intervals between April 2000 and April 2001. A plot of this data is shown in *Figure 2*. The figure also shows 95-percentile of the total traffic on the measurement dates. Roberts concluded that the traffic growth factor was 390 percent per year during the April 2000 to October 2000 and that it was 400 percent during the next six months. This study has been very helpful in calming down the bandwidth glut debate—at least for the time being.

2. O–O–O versus O–E–O

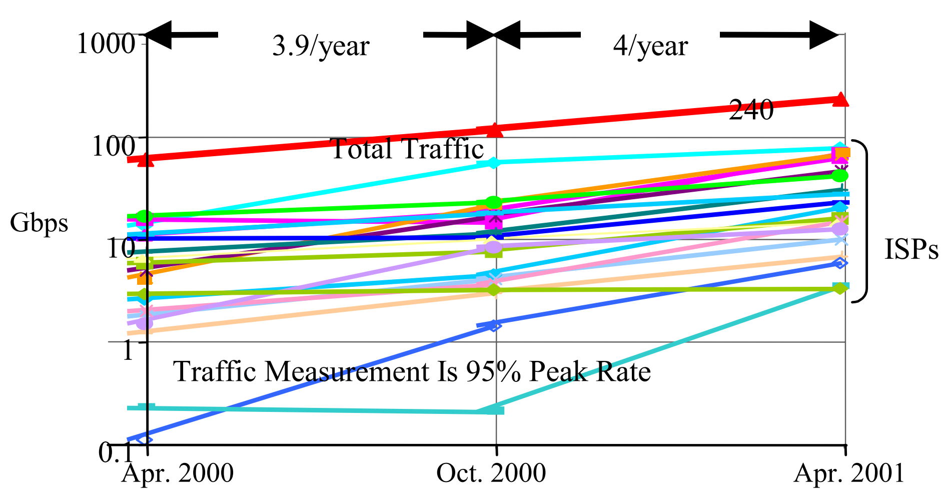
Gordon Moore, one of the founders of Intel, observed that the number of transistors in integrated circuits doubles every 18 months. This observation has been found to be true over the last two decades and is often interpreted to mean that the speed of electronic circuits is doubling every 18 months. Even this high rate of growth is slow when compared to the growth of network traffic. *Figure 3* shows the growth of network traffic and the speed of electronic circuits as a function of time. The traffic growth has been assumed to be 400 percent per year using the aforementioned Roberts study. Note that within a few years, the network traffic growth is expected to be several orders of magnitude greater than what can be handled by electronic circuits without parallelism. This is an argument in favor of optical switching.

In current switches, even though the signal comes in optically on a fiber and goes out optically on a fiber, it must be converted to electronic form for switching. This is called optical-to-electrical-to-optical (O–E–O) switching. In optical-to-optical-to-optical (O–O–O) switches, the signal is switched optically. There are several methods for optical switching, the most common being the use of micro mirrors using a micro-electrical machines (MEMs). Based on the switching instructions, the mirrors can be rearranged quickly to make the light coming on one fiber go to another fiber as desired.

O–O–O switches are data-format independent in the sense that the data being switched could have any data link format, such as SONET or Ethernet or synchronous digital hierarchy (SDH) or optical transport network (OTN) (based on ITU G.709). The same O–O–O hardware can support all data link formats. An O–E–O switch, on the other hand, will require a different circuit or software to support each of these formats.

The O–O–O switches are also relatively rate independent. The same hardware can switch a 2.5 gigabits per second

FIGURE 2



(Gbps) signal or 10 Gbps signal. Of course, the noise tolerances are tighter for 10 Gbps than 2.5 Gbps, and so the component quality has to be better for 10 Gbps equipment than those designed for 2.5 Gbps. O–E–O switches, on the other hand, are highly rate dependent. An integrated circuit designed for 2.5 Gbps cannot handle 10 Gbps. In the simplest approach, four 2.5 Gbps circuits will be required to handle a 10 Gbps signal, and so the cost of O–E–O switches grows proportionally to the data rate. The same argument applies for space and power. This is the prime reason in favor of O–O–O switching at high data rates. The conventional wisdom at this time is that, at 10 Gbps and higher rates, the per-port cost of O–O–O switches is less than that of O–E–O switches.

The rate independence of O–O–O switches also reflects in their upgradability. Upgrading a 2.5 Gbps O–O–O switch to 10 Gbps may require fewer changes than those in an O–E–O switch. As mentioned earlier, for an O–O–O switch, the same basic design can be upgraded with higher quality components to support the higher rates. Upgrading an O–E–O switch, on the other hand, will require a complete change of design.

The next two issues are related to the ability to handle part of a wavelength or multiple wavelengths. An O–E–O switch can easily separate out a part of a signal, and so adding or dropping a part of the wavelength is easily accomplished. In an O–O–O switch, this can be done only if the different parts of the signal are different in some optical characteristics, such as time (slots), frequency, phase, or polarization. On the other hand, an O–O–O switch can switch a multiwavelength signal as easily as a single wavelength, provided that the optical components are properly designed. O–E–O switches will require separate circuits to handle each of the wavelengths and would be very costly for the large number of wavelengths that can be accommodated in a fiber.

In terms of performance monitoring, O–O–O switches are bit-rate– and format-independent and so cannot easily see bit errors (which are basically rate or format errors). O–O–O switches monitor optical defects such as wavelength shifts, optical signal-to-noise ratios, or power levels. These defects also result in bit errors, but not all bit errors are visible to optical monitors. To monitor electrical signals, O–O–O switches provide optional electrical monitoring. In O–E–O switches, the cost of monitoring is already built in, since they have to verify the data rate and format before they can switch the signal.

If two or more signals need to be sent on a single fiber, they should have different optical characteristics (wavelength or polarization). Therefore, it may sometimes be necessary to convert these optical characteristics (primarily the wavelength) at switching points. Optical approaches for wavelength conversion are a few years away. Several companies have announced products in this space, but none is shipping at this point. Therefore, O–O–O switches offer optional O–E–O–based wavelength conversion on selected channels as needed. Often, this is not needed, since the dense wavelength division multiplexing (DWDM) equipment, which is used with both O–E–O and O–O–O switches, already has transponders that change wavelengths as required.

A comparison of O–E–O and O–O–O switches is summarized in *Table 1*.

In summary, O–O–O switches are the direction for the future as we transition into higher speeds and larger switch capacities.

3. Ethernet versus SONET

It is now well established that the traffic on most carrier networks is predominantly data traffic. SONET/SDH technology is designed for voice traffic and is very expensive compared to Ethernet, which is designed for data. It is clear that using Ethernet switches in place of SONET add/drop multiplexers (ADMs) will reduce the cost considerably. However, there are several obstacles to the adoption of the Ethernet technology, the primary ones being the reliability and availability.

FIGURE 3

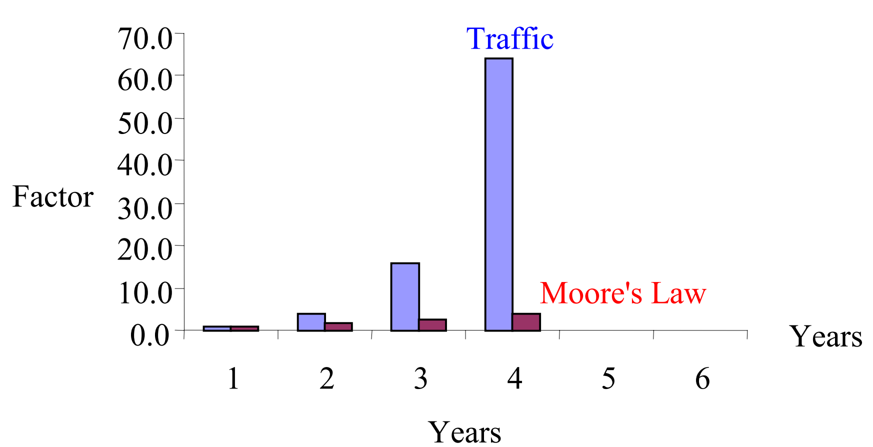


TABLE 1

O–E–O versus O–O–O

Feature	*O–E–O*	*O–O–O*
Data Format Dependence	Yes	No
Cost/Space/Power Independent of Rate	No	Yes
Upgradability to Higher Rate	No	Yes
Sub-Wavelength Switching	Yes	Future
Waveband Switching	No	Yes
Performance Monitoring	Bit-Error Rate	Optical Signal Degradation
Wavelength Conversion	Built-In	Currently Electronic

SONET technology was designed primarily for carrier networks and has very robust reliability and availability mechanisms built in. In particular, SONET networks are designed to provide 99.999 percent (five nines) availability, which is equivalent to a down time of five minutes per year. This is achieved by a high-level of redundancy inside and outside the equipment. Ethernet technology, on the other hand, was designed primarily for enterprise networks, where availability requirements are not that high.

Carriers' recent interest in Ethernet is visible from the activities in the 10-Gbps standardization efforts. 10-Gigabit Ethernet is designed for two data rates: 10 Gbps for local-area network (LAN) applications and 9.5 Gbps for wide-area network (WAN or telecom) applications. The WAN version uses SONET framing. It is compatible with SONET equipment except for the clock jitter requirements. SONET requires a clock jitter of 4.6 to 20 parts per million (ppm) while 10-Gigabit Ethernet requires only 100 ppm. This decision was highly debated in the Institute of Electrical and Electronics Engineers (IEEE) standards committee and may have resulted in the delay of the standard; however, requiring tighter tolerances would have increased the cost of the equipment significantly. As a result of this, a 10-Gigabit Ethernet signal cannot be sent directly to a legacy SONET ADM. Ethernet line-termination equipment (ELTE) is required to buffer the incoming signal and send out the well-conditioned signal to the SONET equipment. In this way, the extra cost of clock-jitter conditioning is not incurred if the entire WAN is based on 10-Gigabit Ethernet technology. This is the future plan of many carriers, particularly those that are primarily data carriers.

SONET networks are traditionally organized in dual-ring topologies that allow for a very fast recovery from node and link failures. Ethernet equipment is traditionally organized as mesh networks. Ethernet switches use a spanning tree algorithm to automatically convert the mesh topology to a spanning tree topology for forwarding. The spanning tree takes a few minutes to converge, and so the restoration times may be large. The IEEE has started an effort to design a fast spanning tree algorithm.

To provide fast recovery time for Ethernet traffic, the IEEE has also started a resilient packet ring (RPR) project that will allow Ethernet traffic to be sent on dual-ring networks. This will provide fast recovery times matching those of SONET, while at the same time being more efficient in terms of redundancy by allowing both rings to be used when there is no failure.

A comparison of SONET versus Ethernet is summarized in *Table 2*.

Now that the 10-Gigabit Ethernet standards are nearing completion, IEEE has started discussing the next steps. In particular, a survey of IEEE 802.3ae members has indicated that 70 percent of the members would like the next version of the Ethernet to be 40 Gbps rather than 100 Gbps. This will allow the optical carrier (OC)–768 technology being developed for SONET to be reused for Ethernet.

4. Ring versus Mesh

Telecommunications networks are currently organized in ring-based topologies while the data networks use the mesh-based topologies. This has started the debate on the merits of ring and mesh topologies. This debate is similar to that between Ethernet and token rings back in the initial days of IEEE 802 standardization.

As shown in *Figure 4*, on a ring, all links have to have the same data rate. If any one link is upgraded—for example, from 2.5 Gbps to 10 Gbps—all links and nodes have to be upgraded to that rate. Therefore, rings are more suitable for networks where the traffic among the nodes is homogeneous. Rings are not generally used in long-haul networks where the traffic is highly non-homogeneous. The mesh networks, on the other hand, allow incremental upgrades. Any link can be upgraded to a higher rate while the others can remain at a lower rate. Similar arguments apply in the case of DWDM networks, where the number of wavelengths must be the same on all nodes of a ring.

Mesh networks typically require 50 percent less protection and 50 percent less working capacity than rings. This is because of the inherent spatial reuse feature of mesh networks whereby the links not being used by one flow can be used by other flows. The savings from mesh networks increase as the degree of connectivity increases and as the non-homogeneity of the traffic increases.

TABLE 2

Feature	*SONET*	*Ethernet*
Bit Rate (bps)	155M, 622M, 2.5G, 10G, 40G,…	1M, 10M, 100M, 1G, 10G,…
Timing	Isochronous (Periodic 125µs)	Plesio-Isochronous
Multiplexing	Bit	Packet
Clocks	Common	Independent
Clock Jitter	4.6 to 20 ppm	100 ppm (May Change)
Usage	Telecom	Enterprise
Volume	Millions	100s of Millions
Price (10 Gbps)	>10k	<1k
Recovery	50 ms	Few Minutes
Topology	Rings	Mesh

Currently, there are two parallel efforts in the telecom networking community. On one side, they are trying to develop mesh-based protection and restoration mechanisms and protocols, while on the other side they are also trying to develop ring-based mechanisms and protocols suitable for data traffic. This second effort is reflected in the RPR work going on in the IEEE. RPR uses a dual counter rotating ring topology similar to that used in SONET and fiber distributed data interface (FDDI) networks.

5. Optical Cross-Connects

As the network traffic increases, the capacity of cross-connects and switches must also increase. There are two ways to increase the capacity: higher port count or higher speed per port. For example, 80 Gbps traffic can be handled with eight 10G ports or two 40G ports. Increasing the port speed increases the number of multiplexing and demultiplexing (grooming) points and increases the number of hops. This has lead to a trend toward a larger number of ports per switch. A similar argument applies toward the number of wavelengths and the data rate per wavelength as well.

A single cross-connect with a large number of ports is more cost-effective than an interconnection of several smaller cross-connects. To illustrate this, consider the two alternatives shown in *Figure 5* for a 24x24 cross-connect. Alternative A consists of using 24 4x4 switches with a total of 192 ports. Alternative B consists of a single 24x24 switch with a total port count of 48. Since most of the cost of the cross-connect is in the port cost, alternative A is almost four times more expensive than alternative B. In general, larger cross-connects are more cost-effective than multiple smaller ones. This has lead to a trend toward large cross-connects that can be more economically realized with optical technology than electrical.

FIGURE 4

Ring versus Mesh

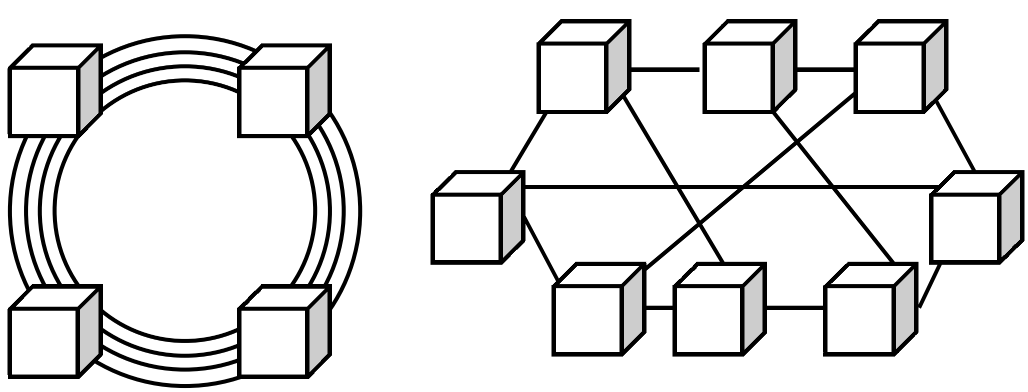

FIGURE 5

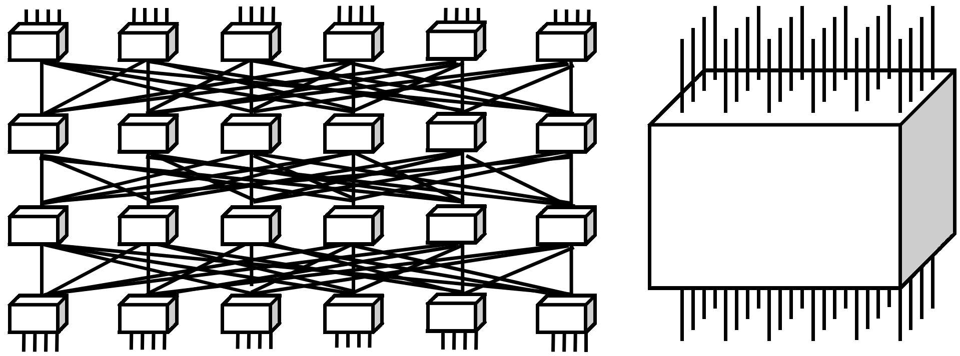
SONET versus Ethernet



(a) Using Several 4×4 Cross-Connects (b) One Cross-Connect

Summary

The optical networking industry has been affected by the economic slowdown. However, we believe that the slowdown is temporary. Internet traffic is still growing. Carriers need to find ways to increase their revenues from this increasing traffic and to reduce their capital and operating expenditures. Optical cross-connects, larger number of ports, mesh topologies, and Ethernet-based networks seem to be more economical than their counterparts.

Free Space Optics and the Last 500 Meters

Chief Technical Officer
AirFiber Inc.

Introduction

There are several key factors that are bringing free space optical technology (FSOT) into the carrier space as a means for broadband access. The first is growing and seemingly insatiable bandwidth demand in the marketplace. FSOT technology provides fiber-like speeds without significant initial capital expenditures for scarce resources such as spectrum. While fiber rings are becoming ubiquitous, getting the bandwidth from the rings to customers remains challenging. While FSOT infrastructure sounds inviting, there are many near-term hurdles for FSOT products. The primary customer concern for FSOT products is availability. This needs to be statistically demonstrated with real FSOT systems in the field before there is widespread customer acceptance of this technology. Other concerns are compatibility with existing local-exchange carrier (LEC) networks and premises networks, cost, carrier-class hardware, ease of installation, and network management.

The physics of the atmosphere dictate some very specific performance limitations on free-space systems that can be derived very generally to put an upper bound on carrier-grade range expectations and claims by many vendors in the industry.

Free Space Optics Subsystems

Figure 1 illustrates the major subsystems in a complete carrier-grade free space optics communications system. The optical apertures on a free space system can have an almost infinite variety of forms and some variety of function. They can be refractive, reflective, diffractive, or combinations of these. In the figure, the transmit, receive, and tracking telescopes are illustrated as separate optical apertures; there are several other configurations possible where, for example, a single optic performs all three functions thereby saving cost, weight, and size. The important aspects of the optical system on the transmit side are the size, which determines the maximum eye-safe laser flux permitted out of the aperture and may also prevent blockages due to birds, as well as the quality of the system, which, along with the f-number and wavelength, will determine the minimum divergence obtainable with the system. On the receive side, the most important aspects are the aperture size, which determines the amount of light collected on the receiver, and the f-number, which determines the detector's field of view. The tracking system optics must have a wide enough field of view to acquire and maintain link integrity for a given detector and tracking control system.

Diode lasers are driven with a DC bias current to put the devices above threshold and are then modulated with an AC current on top of that to provide, for example, on-off keying (OOK) for data transmission. For lasers with output powers below about 50 mW, off-the-shelf current bias and drive chips are available; for higher power lasers, custom circuits or radio frequency (RF) amplifiers are generally used.

The receive detector is coupled to the receive aperture through either free space or a fiber. Depending on the data rate and optical design alignment tolerances can be extremely restrictive. For example, for data rates to 1.25 gigabits per second (Gbps), detectors with relatively large active areas (500 microns diameter) can be used, making alignment to the receive aperture fairly straightforward. For fiber coupling into multimode fibers, the core size is about 63 microns in diameter, and this makes alignment much tougher. The use of special materials or controls is required, however, coupling is more modular.

Detectors are generally either photo intrinsic diodes (PINs) or avalanche photodiodes (APDs). For carrier-class free space optics systems, an APD is always advantageous, since atmospheric-induced losses can reduce received signals to very low levels where electronics noise dominates the signal-to-noise ratio (SNR). Of course the APD has to be capable of meeting the bandwidth of the system. Usually, a trans-impedance amplifier is used after the detector, and in most cases they provide the highest gain at the fastest speed.

Tracking detectors are relatively large-area devices if they are CCD, CMOS, or quad cell detectors and are therefore easy to align to the tracking optics, although care must be taken in manufacture to co-align these optics with the transmit and receive optical axes. For building-mounted free space optical systems, the tracking bandwidth can be very low, sub hertz, since the bulk of building motion is due to uneven thermal loading of the building. These effects occur on time scales of hours. For systems that are to be mounted on towers or tall poles, the tracking bandwidth should be higher, most likely on the order of several hertz at least, to remove wind-induced vibrations.

Acquisition systems can be as crude as aligning a gun-sight to very sophisticated global positioning systems (GPS)–based, high-accuracy, fully automated systems. The choice of this subsystem really depends on the application and number of devices to be put into a network.

The Free Space Optic Link Equation

The link equation for a free space optical system is actually very simple at a high level (leaving out optical efficiencies, detector noises, etc.). The equation is illustrated in *Figure 2*. The amount of received power is proportional to the amount of power transmitted and the area of the collection aperture. It is inversely proportional to the square of the beam divergence and the square of link range. It is also inversely proportional to the exponential of the product of the atmospheric attenuation coefficient (in units of 1/distance) times the link range.

Looking at this equation, the variables that can be controlled are the transmit power, the receive aperture size, the beam divergence, and the range of the link. The atmospheric attenuation coefficient is uncontrollable in an outdoor environment and is roughly independent of wavelength in heavy attenuation conditions. Unfortunately, the received power is exponentially dependent on the product of the atmospheric attenuation coefficient and the range, in real atmospheric situations, for carrier-class products (i.e., availabilities at 99.9 percent or better). This term overwhelms everything else in the equation. This means that a system designer can choose to use huge transmit laser powers, design large apertures, and employ very tight beam divergences, and the amount of received power will remain essentially unchanged. *Figure 3* graphically illustrates this point. Except for clear air, the atmospheric loss component of the link equation dominates by many orders of magnitude, essentially washing out any system design choices that could affect availability. For free space systems that are designed to be carrier-class, this fact needs to be accepted and the system design produced with this in mind. Basically, the only other variable under the designer's control is link range, which must be kept short enough such that the atmospheric attenuation is not the dominant term in the link equation. As will be discussed in a later section, this implies that the link range *must* be kept at less than 500 meters. If this is realized, then efficient designs can be produced that permit economical, reliable operation under this constraint.

Figure 4 shows a tabular link budget for the top five free space optical system manufacturers. Most of the system parameters are freely available from manufacturers data sheets; where a parameter has been assumed, it is noted. One of the vendors (highlighted) has a product at 155 megabits per second (Mbps) and really should not be compared with the others at 1.25 Gbps but has been included for informational purposes. The atmospheric attenuation condition is 200 decibels (dB)/km. The link ranges were adjusted for each system such that the margin came out to approximately zero. It is interesting to note the wide variety of aperture sizes, wavelengths, transmit divergences, and transmit powers (all of the adjustable system parameters) that have been employed in these systems, yet as previously discussed, the maximum link ranges are all about the same (+/– 30 meters or so), again illustrating the point that there is not a lot that system designers can do to increase link

range in realistic carrier-grade atmospheric conditions. Given that all manufacturers have about the same performance in high attenuation conditions, *Figure 5* plots the maximum range versus atmospheric attenuation (dB/km) for one of the vendors, which is about the same for all of the vendors. It is interesting to note that at longer ranges (about 1 km or so) the maximum attenuation allowable is about 30–40 dB/km. It turns out that heavy rain can produce this range of attenuation values, and therefore the long link range issue is going to be widespread throughout the world, and not limited to just foggy coastal areas.

The key issue for carriers in deploying free space optical systems is the system availability. The system availability has many factors to it, including equipment reliability and network design (redundancy for example), but these are well known and fairly quantifiable. The biggest unknown is the statistics of atmospheric attenuation. While almost all major airports around the world keep visibility statistics (which can be converted to attenuation coefficients), the spatial scale of visibility measurements is rough (generally 100 meters or so), and the temporal scale is infrequent (hourly in most cases). With the spatial and temporal scales being crude, estimates of availability for carrier grade equipment (99.9 percent or better) are going to be limited to 99.9 percent or worse. These huge databases are therefore not useful except for estimating the lowest acceptable carrier grade of service. To permit carriers to write reasonable service-level agreements (SLAs), better data must be taken. At AirFiber, we have had instruments capable of acquiring this data running continuously for roughly the last couple of years. These instruments, which include a nephelometer and an in-house designed and built weather benchmark system, provide data at the correct spatial and temporal resolution for accurate estimates of availability versus link range.

Figure 6 shows a plot of this data for two cities, Tokyo and San Diego. The one line shows the cumulative probability

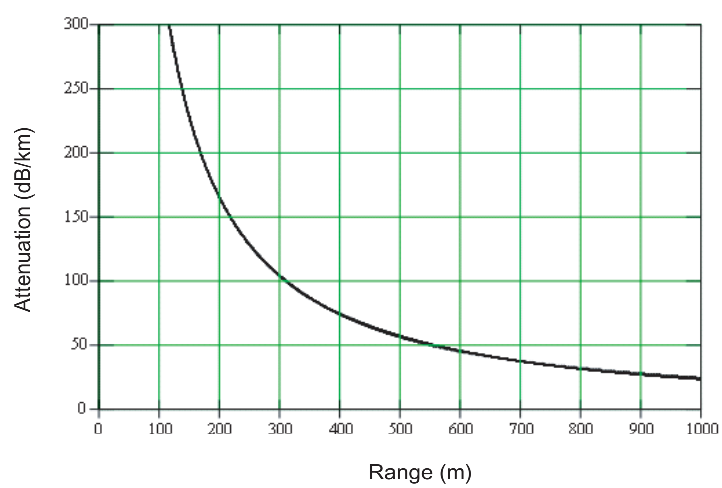
density function for San Diego and another line shows the same for Tokyo. Also plotted is the link budget equation for an AirFiber product; other vendors' products will have about the same link margins. The left vertical axis shows the percentage of time that the attenuation is greater than or equal to a given value. The horizontal axis is attenuation in dB/km, and the right vertical axis is the maximum link range at zero link margin. To use the chart, one must choose an availability, say 99.9 percent (as shown by the dotted line), move horizontally to the desired city (say Tokyo in this example), move vertically to the link budget equation, and finally move horizontally to the maximum link range, (in the case of Tokyo is about 350 meters). It is interesting to note that Tokyo is qualitatively in the top 10 percent of cities for clarity of the atmosphere and that San Diego is in the bottom 10 percent. Therefore, for most deployments, the maximum range will fall somewhere in between these two cities, certainly less than 500 meters in most cases.

FIGURE 5

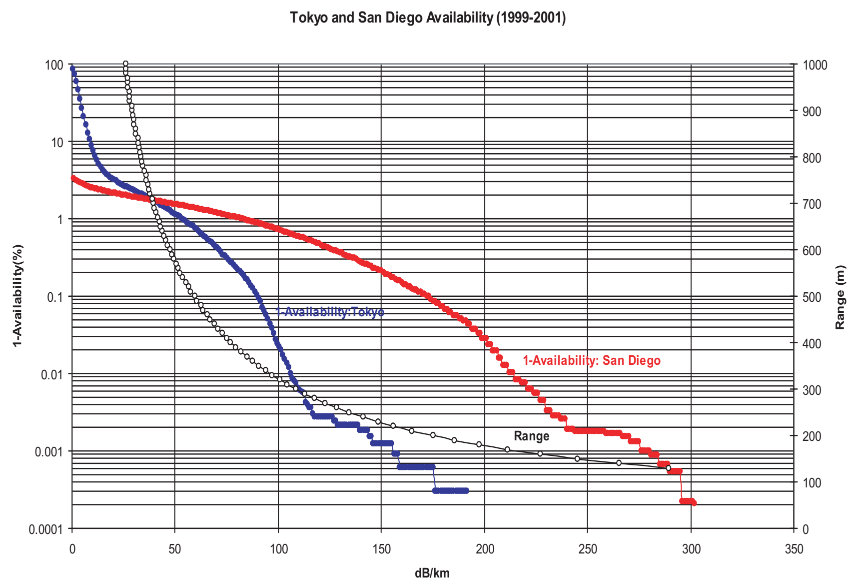
Link Range versus Attenuation for a Typical FSO Vendor



Theoretical preliminary link budget at 1.25 Gbit/s, 10^{-12} BER

FIGURE 6

FSO Availability to 99.999 Percent Resolution for Tokyo and San Diego



As a final statement about the performance of free space optical systems in realistic weather conditions, we perform some calculations of maximum link ranges for a straw man theoretically "perfect" but as yet unobtainable—the free space optical system. *Figure 7* illustrates the assumptions and results of this calculation. Under the assumptions, it is worthy to note that the detector, electronics, and background noise were set to zero and that the collection aperture was assumed to receive *all* transmitted photons—that is, beam divergence was set at zero. In addition, a very large transmit aperture was chosen so that 80 watts of transmit power could be used and still maintain eye safety. Running through the numbers for 200 dB/km and 10^{-12} bit-error rate (BER) at 1 Gbps data rate, we arrive at a maximum range of about 500 meters. So, even in an "unobtainium" system, the maximum range in realistic atmospheric attenuation situations is about 500 meters.

Another topic that frequently comes up concerning the performance of free space optical systems is the issue of atmospheric propagation and wavelength. One generally held belief is that systems operating at longer wavelengths have better range performance than systems at shorter wavelengths. *Figure 8* shows several calculations performed using MODTRAN for a 1 km path length for which the x-axis is wavelength. The conditions were a visibility range of 200 meters, typical of an advection fog. The y-axis in the top panel is transmission from a minimum of 0 to a maximum of 1. The top panel shows the amount of absorption due to water only in the atmosphere. Here, there are many wavelengths that propagate very poorly due to absorption by water vapor, particularly near 1.3–1.4 microns. The next panel down shows absorption due to oxygen and carbon dioxide, which are relatively narrow lines and are easily avoided.

FIGURE 7

Straw-Man Range Calculation for a "Perfect" FSO Link

Assumptions

– Eye-safe laser
– No detector/electronics or background noise
– **No geometrical loss**
– 1 Gbit/s
– 25.4 cm aperture
– 80 W transmit power
– 200 dB/km Attenuation
– Need SNR=14 for 10^{-12} BER

Results

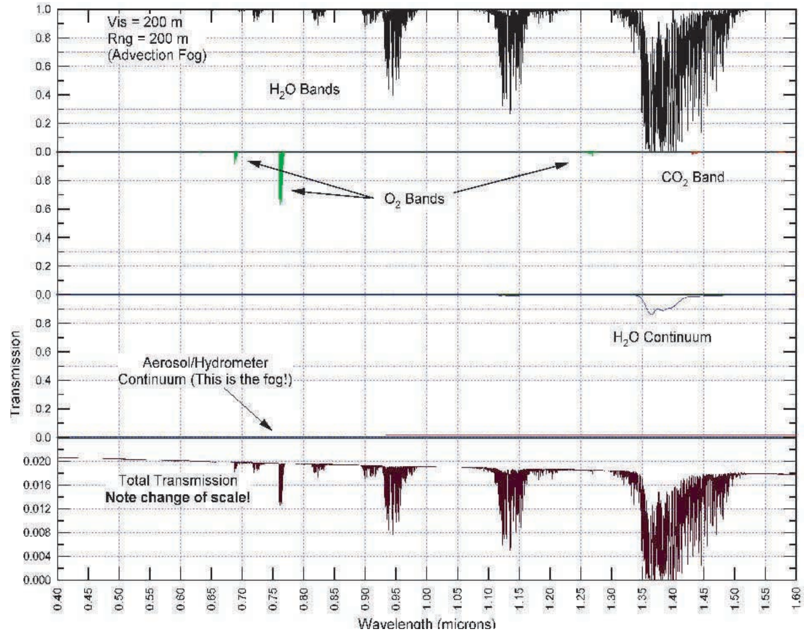
$$SNR = \frac{1}{2}\,\frac{\eta\, P_{signal}}{h\nu B}$$

$$80W\;10^{-\frac{200\,Range}{10}} = 8.9nW$$

Range = 497 meters

FIGURE 8

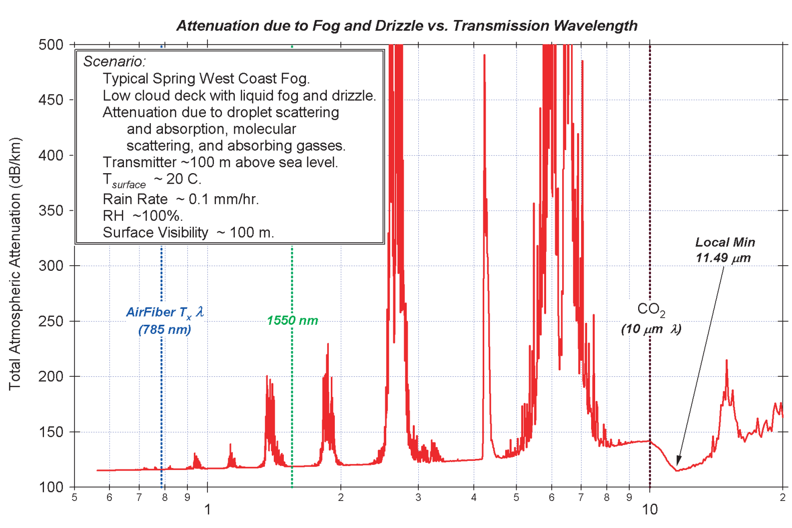
MODTRAN Calculation of 785 nm versus 1550 nm Propagation



The third panel down shows the effects of Mie scattering by water droplets in the fog. Clearly, this is the dominant loss mechanism under these conditions and is basically independent of wavelength (it is actually a little *worse* at 1.5 microns than at 785 nm, for example). Finally, the bottom panel shows the combined effects of all three loss mechanisms. Again, the result is basically independent of wavelength. There is no advantage in propagation range by using longer wavelengths. Taking this one step further, the calculations were performed at even longer wavelengths, as illustrated in *Figure 9*. Here, the x-axis is again wavelength, the y-axis is the combined loss over a 1 km path. In these illustrations, the vertical axis is attenuation in dB/km. For all wavelengths up to about 12 microns, the result is the same: there are no "spectral holes" in which it is very advantageous to propagate—the attenuation is basically flat over these wavelengths. Finally, the same calculations were carried out all the way to millimeter waves,

FIGURE 9

MODTRAN Calculation out to 10 Microns



as illustrated in *Figure 10*. This was done for completeness and to make sure the attenuation reduced at RF frequencies to generally accepted values. Not until the wavelength gets to sub-millimeter size (RF) does the attenuation get markedly reduced.

In summary, we can clearly state that for the majority of cities around the world, the carrier-class distance (as defined by 99.9 percent availability or better) is less than 500 meters. In addition, despite numerous claims, all free space optics vendors have about the same range performance in carrier-grade conditions (99.9 percent or better) due to complete domination of the link budget equation by the atmospheric attenuation factor in high attenuation situations. Finally, wavelength has absolutely no effect on propagation range under carrier-grade conditions for wavelengths from visible all the way up to millimeter wave (RF) scales.

Free Space Optics Systems Enhancements

One issue that is debated among free space optics vendors is the necessity of having a tracking system. That is, does the hardware need to compensate for small amplitude, low frequency, and building motion, usually thermally induced, in order to maintain link integrity, or is it sufficient to spread the divergence of the transmitter beam large enough to encompass all foreseeable building movement amplitudes? Going back to the link equation, it is easy to see that spreading the beam divergence impacts the link margin by the inverse square of the spread. In other words, every doubling of the beam divergence negatively impacts the link margin by 6 dB. In addition, even if the beam is spread broadly enough to accommodate building motion, the overall system link margin will fluctuate negatively and/or degrade, since precise alignment of the free space optical systems, by design, will not always be achieved over time and temperature.

Figure 11 illustrates this effect with actual data from a fielded system (distance of 500 meters) running live customer traffic in Phoenix, Arizona. The upper graph shows the change in azimuthal position as a function of time. The x-axis units are arbitrary, however, the pattern of peaks and valleys is due to diurnal thermal changes at the site. The same is true of the bottom graph but for the elevation axis. One tick on either vertical axis corresponds to about 100 microradians of motion, so the maximum azimuthal variation (building twist) was about 1.5 milliradians, and the maximum elevation variation was about 2.5 milliradians. In fact, we have observed elevation variations of 8 milliradians on this same link under different thermal conditions. Another interesting point to note is that a competitor's non-tracking units were removed from this link because they consistently lost link with diurnal thermal cycles. A calculation of the lost link margin for non-tracking units due to building motion is now in order. If the $1/e^2$ beam divergence is 2 milliradians and the links are perfectly aligned at installation, then a motion of 1 milliradian would incur a loss of link margin of about 8.6 dB. Even if the link stayed up during this excursion, the system performance would be degraded by 8.6 dB from the initially specified margin. For a typical carrier-grade link of 200 meters, this means that not having tracking means the system can withstand about 43 dB/km *less* atmospheric attenuation than the initial design. For calibration, heavy rain can induce about 17–40 dB/km of attenuation, so a system that might be designed to handle heavy rain could now be down in a severe storm.

Atmospheric scintillation, as used in this document, can be thought of as changing light intensities in time and space at the plane of the receiver detecting the signal from a transmitter at a distance. The received signal level at the detector fluctuates due to thermally induced changes in the index of refraction of the air along the transmit path. The index changes cause the atmosphere to act like a collection of

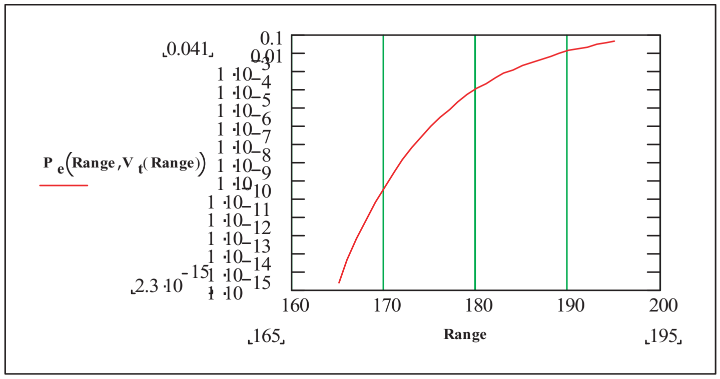
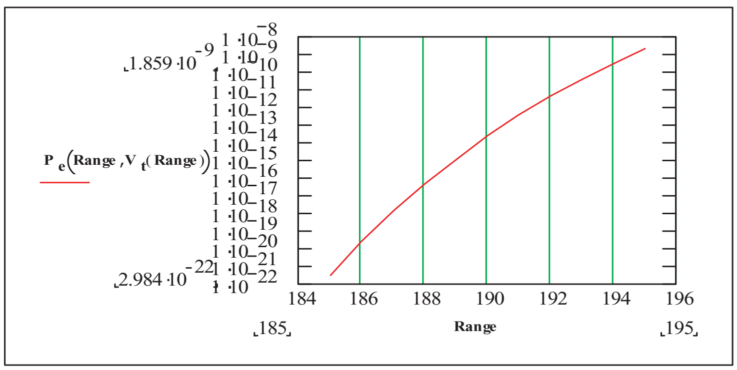
Tracking Data—Live Customer Network in Phoenix, AZ



Decreasing the data rate from 1.25 Gbit/s to 100 Mbit/s increases the range for 10^{-12} BER by only about 30 meters in 200 dB/km attentuation



small prisms and lenses that deflect the light beam in to and out of the transmit path. The time scale of these fluctuations is about the time it takes a volume of air the size of the beam to move across the path and therefore is related to the wind speed. There are many theoretical papers written on this effect, primarily for ground to space applications, and, in general, are very complicated. It has been observed that for weak fluctuations, the distribution of received intensities is close to a log normal distribution. In the case of free space optics, which implies horizontal path propagation and therefore stronger scintillation, the distribution tends to be more exponential.

One parameter that is often used as a measure of the scintillation strength is the atmospheric structure parameter or C_n^2. This parameter roughly measures how turbulent the atmosphere is and is directly related to wind speed. *Figure 12* illustrates some measurements of this parameter taken at our facility in San Diego, California. The most interesting feature of the data is the fact that the parameter changes by more than an order of magnitude over the course of a day, being the worst or most scintillated during midday when the temperature is the greatest. The variation in C_n^2 is interesting because C_n^2 can be used to predict the variance in intensity fluctuations at the receiver through the formula displayed at the top of *Figure 13*. The variance is linearly proportional to C_n^2, nearly linearly proportional to 1/wavelength, and nearly proportional to the square of the link distance. Two interesting facts can be inferred from this. First, longer wavelength systems have proportionately larger variance in the scintillation intensity. For example, a system operating at 1550 nm has about twice the variance as a system operating at 780 nm. Second, the effect increases severely with range. At twice the range, the variance is four times greater. The graphs represent the variance as a function of range for the minimum, median, and maximum values of C_n^2 measured in *Figure 12*. The effects of scintillation are graphically illustrated in *Figure 14*. The figure depicts a receiver aperture with dark and light “”speckles” distributed randomly over the aperture. The size of these speckles scales like $(\mu R)^{1/2}$. Again, there are two interesting features to note about this scaling. First, the longer the wavelength, the larger the speckle. This is not good for system performance, because a smaller number of speckles at the receiver aperture means that less aperture averaging over the various intensities of each speckle can occur. If the receive aperture is only collecting one speckle, for example, then the required increase in system transmit power to make sure the BER is maintained even for a “dark” speckle is very large. Second, the size scales like the square root of the link distance; longer links imply larger speckles, which impacts system performance as previously described.

FIGURE 12

Scintillation and Measured Cn2 in San Diego, CA

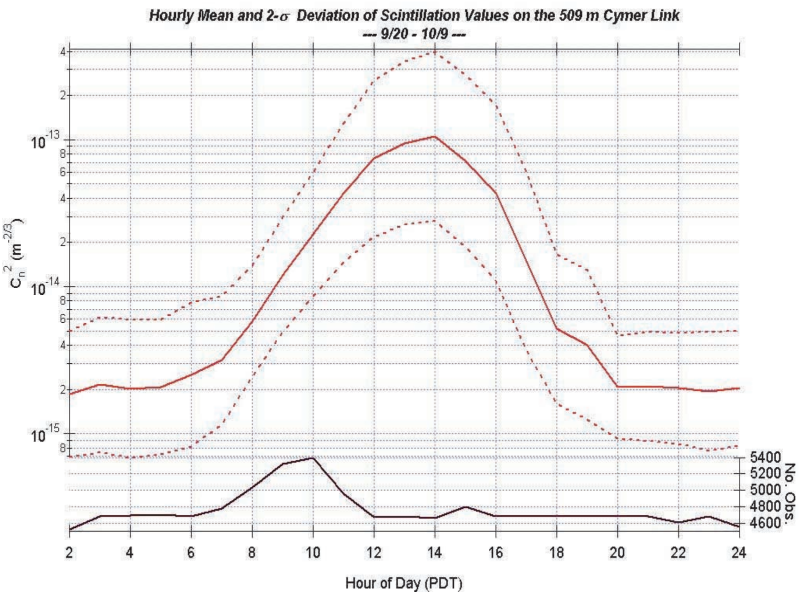


Figure 15 shows the effects of aperture averaging on the required link margin for a three-inch aperture. The plots are for a 100-meter link and a 1,000-meter link. The 100 meter link shows a received intensity distribution that is nearly Gaussian, centered about the mean transmit intensity of 1. Here, scintillation plays no role. In fact, for nearly *all* carrier-grade links (ranges of less than 500 meters), scintillation effects are a few dB at most. At 1 km, the intensity distribution is more skewed and requires about 13 dB more power for the same BER as the 100-meter link (to overcome scintillation, not geometrical effects). The point of this is that for *carrier-grade* links, scintillation is not an issue and therefore does not need to be addressed in the system design. For long links, there are system design choices that can be made—for exam-

FIGURE 13

Intensity Variance Derived from Cn2

$$\sigma_\chi^2\left(C_{nsq},k,L\right) := 0.31\cdot C_{nsq}\cdot k^{\frac{7}{6}}\cdot L^{\frac{11}{6}}$$

Variance in intensity fluctuation is derived from atmospheric structure constant

Scintillation effects scale (become worse) like Range^2

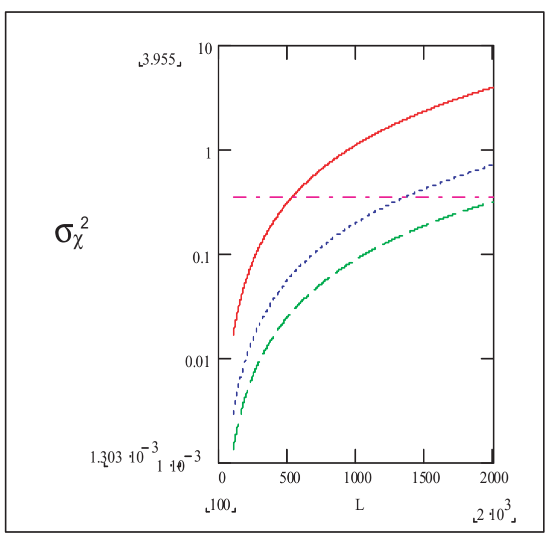

FIGURE 14

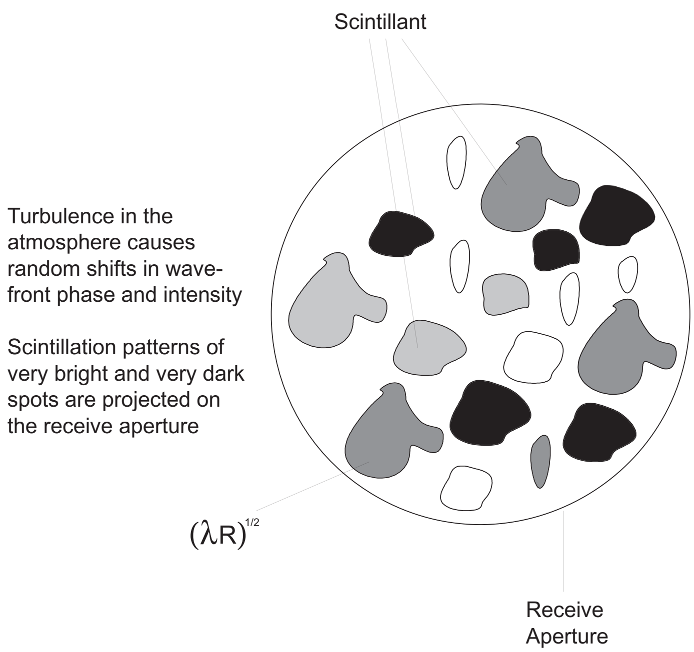
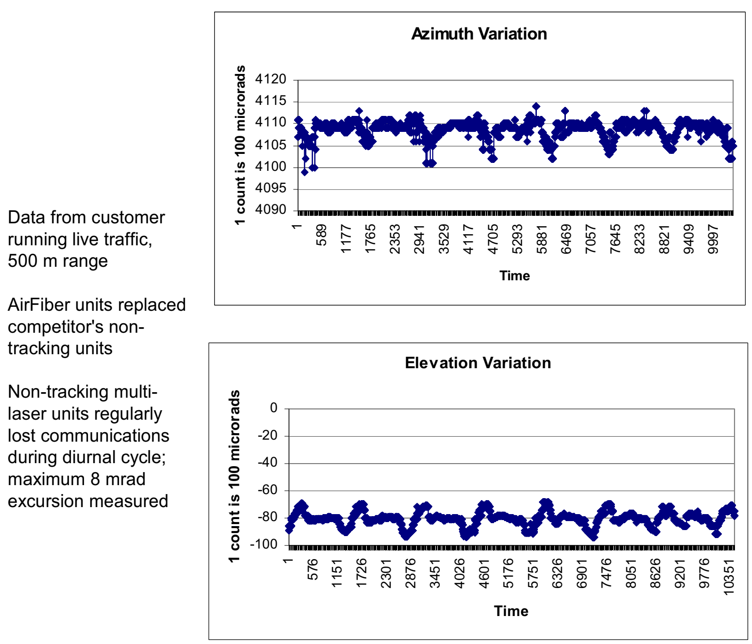
Scintillation Spots and Aperture Averaging



ple, using multiple laser transmitters—that substantially reduce scintillation effects, but again this is not necessary on a carrier-grade system, since the link ranges are generally less than 500 meters. Additionally, for carrier-grade systems, the link margins are engineered to take care of severe attenuation conditions, such as fog, and therefore already have enough margin to take care of any scintillation conditions, since the air is always clear when it is highly scintillated.

FIGURE 15

Theoretical Aperture Averaging Gain



Laser reliability is an issue for carrier-grade free space optical systems that need to have an MTBF of eight years or more. There are basically two factors that influence the lifetime of a semiconductor diode laser: the average operating temperature of the case of the diode and the average operating output optical power of the diode. For AlGaAs diode lasers, the activation energy is about 0.65 eV, which implies that the lifetime of the diodes increases by about a factor of two for every 10 C decrease in the average operating temperature of the diode case. This is illustrated in the upper graph of *Figure 16*. Here, the lifetime increase as a function of case temperature is shown. For outdoor equipment, a general rule of thumb for most places in the world is that an average temperature of 25–30 C can be used to predict thermal effects on lifetime. More important than thermal effects is the average output power of the laser. In this case, the lifetime scales inversely with the cube of the power, as illustrated in the lower graph of *Figure 16*. This means that significant lifetime increases can be obtained in systems that employ automatic power control (by this we mean reduction in output laser power, not attenuation of power using a filter, for example) in their operation, since most of the time the air on a given link is clear and the output power can be reduced substantially. Systems that do not employ power control will probably have very difficult time meeting MTBF expectations of carriers.

Eye safety is also a concern among large service providers. There are basically two classes of eye safety to which free space vendors build: Class 1 and Class 1M. Basically, Class 1 means the beam can be viewed under any condition without causing damage to the eye. Class 1M means the beam can be viewed under any condition with the *exception* of an aided viewing device—for example, a binocular or other optical instrument. In terms of wavelength, the IEC60825 rulings permit 1550 nm devices to output about 50 times the flux level of near IR devices, such as 780 nm lasers. While this can be an advantage, the detectors at 1550 nm are noisier, and therefore, on a system level, there is a slight advantage for link margin, usually at a *substantial* increase in cost, especially for carrier-grade systems where the atmosphere is the limiting variable in the link equation, as previously discussed.

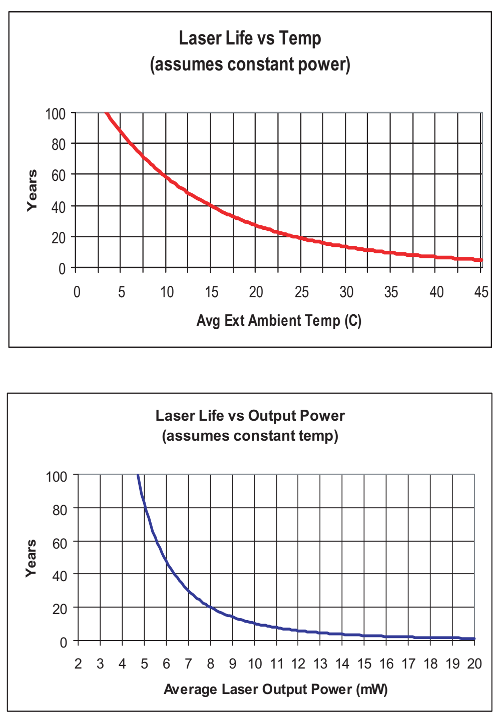
In summary, free space optical systems can be enhanced to carrier-grade (99.9 percent or better). This requires several simple design rules to follow for the vast majority of cities on the planet.

Notes

1. Atmospheric physics *fundamentally* limits range to less than 500 meters. *Accept* and *design* the hardware to meet this limit.
2. The equipment must be hardened to withstand the rigors of an outdoor environment; it *must* meet Telcordia GR-63, GR-487, and NEBS Level 3 product integrity standards.
3. Carrier-grade systems *must* have tracking. This is the *only* way to guarantee link margin.
4. Carrier-grade systems *must* have a carrier-class EMS.
5. Carrier-grade systems *must* meet Class 1M or Class 1 laser eye-safety standards as defined in IEC 60825 rulings.
6. Carrier-grade systems *should* have an optical management channel. This permits the carrier to avoid building an overlay network to manage the free space optical units.

FIGURE 16

Laser Lifetime versus Temperature and Power



Laser lifetime approximately doubles for every 10°C decrease in case temperature (activation energy 0.65 eV)

Laser lifetime scales approximately as $1/P^3$. For example, a diode rated at 40 mW maximum output power gets a lifetime boost of 64x if run at 10 mW

Enhanced Services in the New Converged Telecom Environment

Peter Briscoe
President, Founder, and Chief Executive Officer
Convedia

Introduction

Telephony service is converging with Internet protocol (IP) and the Internet. This evolution will involve 15 years of transition in which services will undergo changes that will open up service design to a greater pool of creative talent. At present, the world is just starting on the long road to convergence (see *Figure 1*), and all players agree that it is not if but rather when this will happen.

In the past, telephony services were defined by committee, developed by large companies, deployed by big service providers, and hampered by a poor human interface.

The Internet is an open system, with end users and service providers able to create, share, and sell their products over the Internet as fast as technology development allows. The Internet has always been asynchronous with best-effort delivery.

The challenge looking forward is to ensure that the result of the convergence is the best of both worlds. The best of both worlds would see a reliable system with an open architecture that enables flexible service deployment options and regulations that encourage new business models for approaching telephony services and applications.

The intent is to unlock the telephony industry by empowering the end user (business or home) to rapidly create and deploy services—opening up telephony to the massive talent available in the world to find and develop new ideas for services and applications, resulting in increased wealth creation.

Enhanced Services

This discussion will focus on enhanced services and the issues involved with evolving to the new converged world. Enhanced services are defined as services that require technology assistance and typically use special software and/or hardware to interact with the users to provide the service. Enhanced services may be provided by terminal equipment, by enterprise-based equipment, or by network service provider (NSP)–based equipment (see *Figure 2*). Enhanced services are provided in the network when there are advantages due to centralization, such as processing power requirements, sharing of the resource to bring down cost, bandwidth restrictions, or cost of bandwidth. Enhanced services move to the edge when the technology is a commodity and the cost is minimal.

A good example of this is voice messaging, which started off as a terminal device application but is now available on many home phones, through the private branch exchange (PBX) or from the traditional telephony service provider. Conferencing is another feature that is available today through a residential service offered by the traditional service provider, through the PBX or through third-party conferencing service companies.

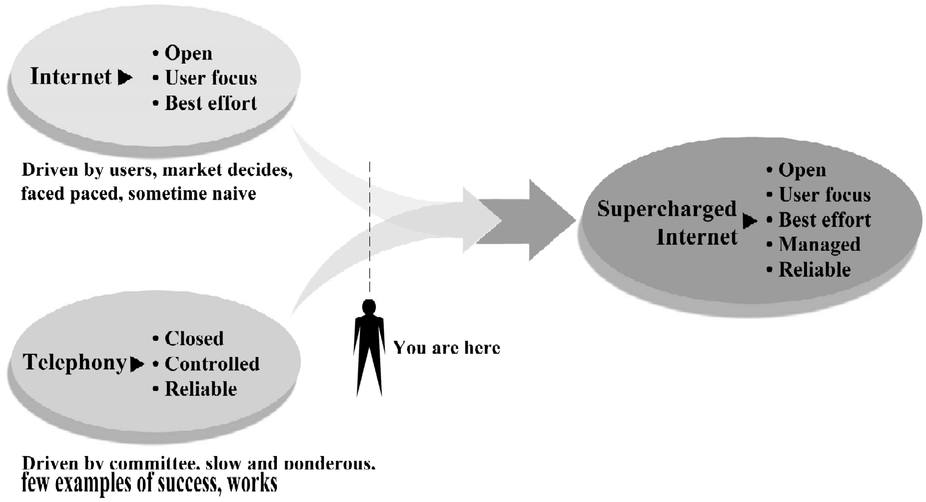
The present structure of enhanced services is shown in *Figure 3*. The terminal is simple with rudimentary signaling capability through dual-tone multifrequency (DTMF). The enhanced services platform consists of software service control logic and hardware processing of the audio streams.

Today, a separate hardware/software platform is used for each service and is called a feature server. Some common services that are provided by feature servers today are voice-mail, voice messaging, interactive voice response (IVR) services, conferencing services, unified communications services, and voice portal services

The evolution to a converged network and services, with the combination of the highly graphical interface of the Web and telephony capability, will result in new, exciting enhanced services and changes in how they are created, deployed, and used. The focus of this discussion is the enhanced service structure and how it changes as telephony and IP converge. This raises some fundamental questions:

- Which enhanced services are successful today and why?
- How should enhanced services be deployed in the converged network?
- Who will provide enhanced services in the converged environment?

FIGURE 1
Convergence



- Do service-creation environments make sense in a Web and rich media model?

This paper discusses these issues.

What Enhanced Services Are Successful Today and Why?

The following are the top successful enhanced services. Overall service revenues for these are in the billions-of-dollars range, with a 30 percent to 40 percent annual growth rate and projected revenue of tens of billions of dollars by 2005. Profitability is very high for these services.

- IVR systems (e.g., touch banking, touch reservations) provide convenience and save time by allowing people to access information and undertake activities from any phone without having to go to the institution where the service is provided. IVR systems also save businesses money in operator costs and lost revenue.
- Calling-card services save time and frustration by allowing access to phones without having cash on hand.
- Voice messaging and voice-mail saves time by allowing people to accomplish a task without having to be in touch with the other party. At this point in time, it is tightly coupled to the local access service provider.

FIGURE 2
Today's Enhanced Services

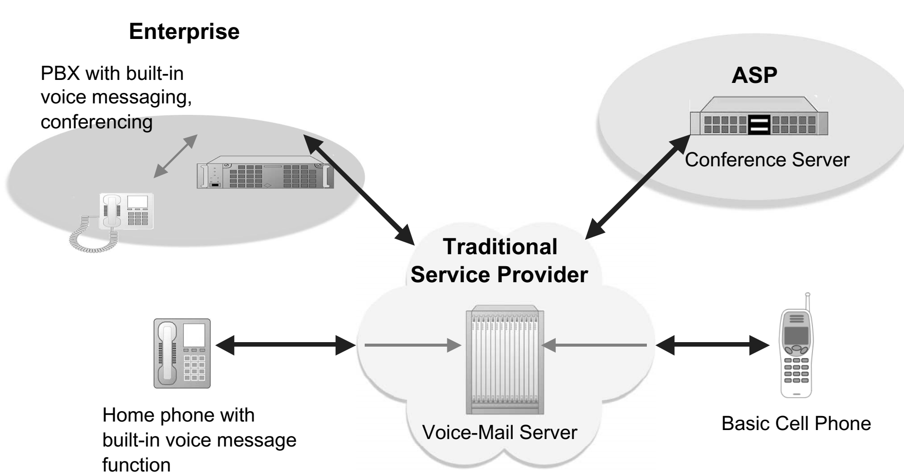


FIGURE 3

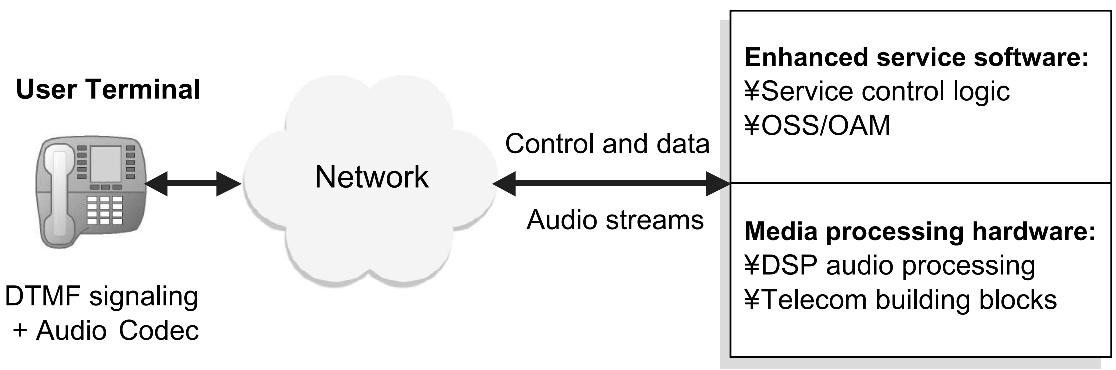
Enhanced Service Components



- Conferencing saves people time and money by allowing them to have meetings without traveling to a central location.
- Call centers give people access to assistance while lowering the cost to the business that must provide this.
- Videoconferencing is still in its infancy but has seen growth after the September 11th disaster.

The aforementioned services are the first targets of convergence due to their proven attraction and resulting revenue potential. The following services are new to the market and have not yet started to grow in any perceptible way in the marketplace.

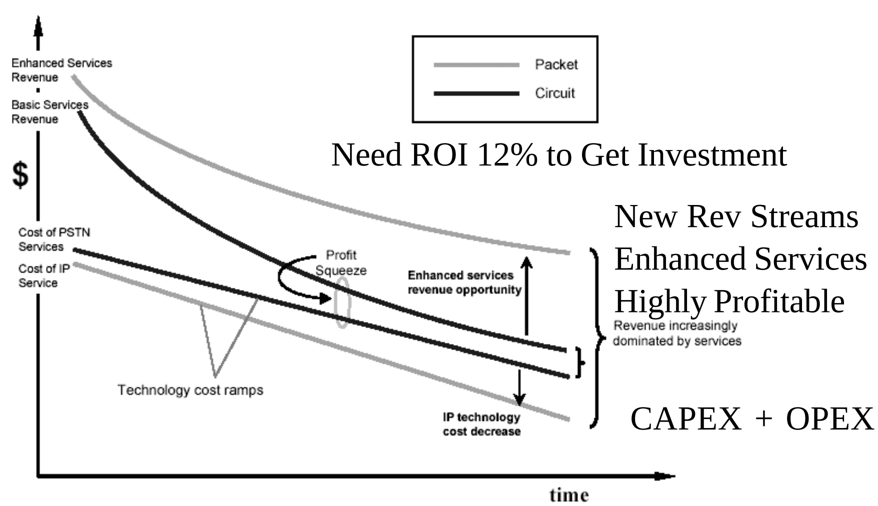
Voice portals are slowing gaining popularity but have been trying to gain success for a few years now. This is a good example of how long it takes to bring a new service to market. Unified communications promises to be a valuable service, but it has not yet shown to be successful.

Enhanced services are extremely important to service providers. The movement to open competition and deregulation has put traditional service providers under a profit squeeze due to increased competition, causing basic voice service to become a commodity. This is shown by the two middle lines in *Figure 4*. These service providers must create a 12 percent return on invested capital to attract new capital infusions to continue evolution. With profit squeeze, this is becoming more and more difficult.

Service providers expect IP technology to provide as much as 40 percent savings over time division multiplexing (TDM) technology, as shown by the bottom curve in *Figure 4*. But it is enhanced services that hold the promise to large profits as shown in the upper curve. Some service providers already get up to 40 percent of their profits from enhanced service revenues. It is the enhanced services that are keeping service-provider profits at acceptable levels, and this is expected to become more significant in the future.

FIGURE 4

Profitability



Source: Convedia, CIBC World Markets

The roll out of services will follow a fairly standards business model. The initial opportunities will be to replace the existing proven public switched telephone network (PSTN) services with IP–based services. This is the lowest risk and fastest return on investment (ROI), which is very important in the present investment climate. These services may get enhanced along the way with Web capabilities. As of yet, there has been no truly successful converged enhanced service where the power of the graphical Web interface is married to the quality and reliability of telephony.

How Should Enhanced Services Be Deployed?

It is nearly impossible to predict the next successful service. It is therefore important to create the right environment that will allow new services and applications to be explored so that the successful ones can become reality. The right environment includes an open architecture and access to new technologies, along with regulations that encourage people from industry and academia, as well as individuals, to apply their creative thinking and business acumen to new ideas for services and applications and then let the markets to dictate winners.

The softswitch architecture (SSA) provides a mechanism to ensure a seamless transition to the world of new media services (see *Figure 5*). The architecture has been formulated to take into account the business and technical realities of the world today and provide a flexible evolution path to get to the goal of a converged network and services.

There are many important attributes to this architecture, which provides the open environment required to stimulate new ideas, business models, and ultimately services. The SSA breaks down the telecoms service system into four distinct functional parts. These functions can be combined into products in many different ways that will allow different business requirements to be met and to explore entirely new business models.

One important change that the SSA has accomplished is to take the feature server of today and break it down into its software service logic and hardware media processing functional components called the application server and the media server. This step allows the software control logic for a service to be contained in a variety of devices leading to the very flexible deployment options that we seek for convergence. The complex, expensive hardware digital signal processor (DSP) equipment is reusable by multiple software services and applications among many users to bring the service CAPEX and OPEX down.

The DSP–audio processing building blocks located in the media server (bridging, tone detection and generation, announcement playing, recording and playback, speech recognition, and text to speech) are now basic telecom building blocks that can be accessed and controlled by any service software anywhere in the network through session initiation protocol (SIP) and voice extensible markup language (Voice XML), either directly or through a SIP proxy server (see *Figure 6*). This has the potential to unleash many new services if the service providers allow access to these blocks with suitable safeguards.

One obvious benefit is that the telecom building block control for services can be accessed through SIP, allowing telephony services to be more tightly integrated into computers and the Web and making telephony an integral part of computer applications for business and home.

There are a number of ways that enhanced services can be deployed:

1. Service platform
2. Enterprise server
3. End-user terminal

1. The service platform (see *Figure 7*) is a platform with all of the traditional telecom pieces: operations sup-

FIGURE 5

Softswitch Architecture

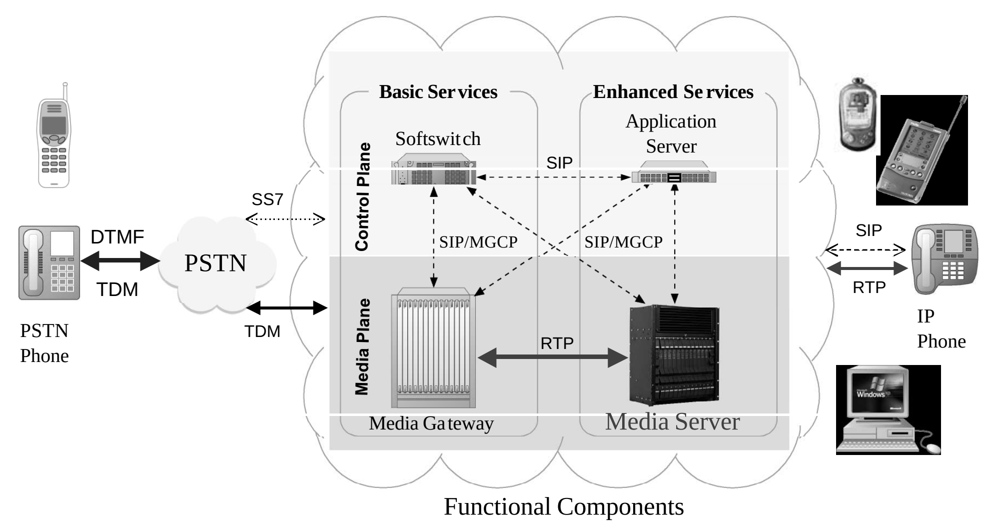


FIGURE 6

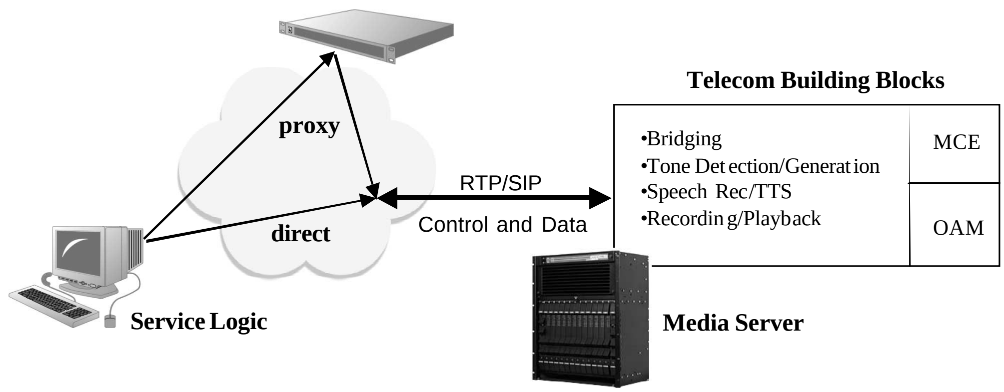
Media Server Building Blocks



port systems (OSSs), billing, policy, application plug-ins, media server control, and a service-creation environment (SCE). This is an expensive product but very flexible and complete.

Service platforms are offered in various levels of complexity and sophistication. Some include all of the functions shown in *Figure 7* and allow other vendors to plug their service modules into the platform. Some service platforms have imbedded predeveloped services and do not contain the OSS/business support system (BSS) capabilities in-board but pass information to other existing systems. These tend to be much cheaper than the full platforms but lack the sophistication. .

2. Enterprise PBXs can have service control built into their applications in order to permit the automated control of services by the enterprise equipment to provide services to the enterprise users in conjunction with the service provider's services and network. In this scenario, the enterprise device contains the application server functionality and controls the network service on behalf of its enterprise terminals. This may be used to provide new services to old PBX terminals or to translate PBX feature-rich services into simpler network-based services.

   This approach allows the enterprise to retain control of its service design and still use the services and reach of the large service provider.

3. The Internet model has different characteristics than the TDM model. Peer-to-peer capability in IP allows basic calling without a "call control" being required (see *Figure 9*). The only issue in crossing network boundaries is to maintain network quality of service

FIGURE 7

Services Platform

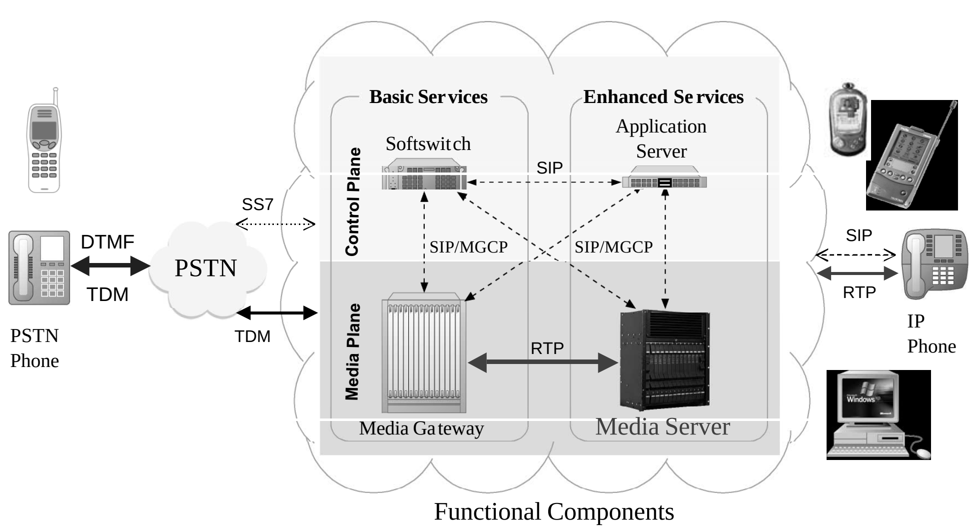


FIGURE 8
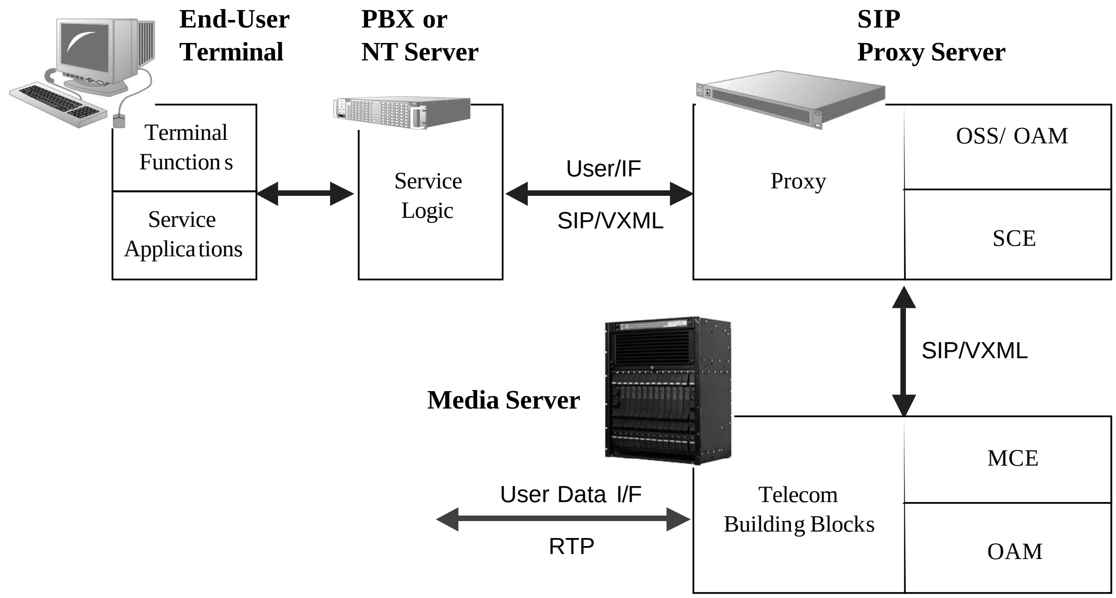
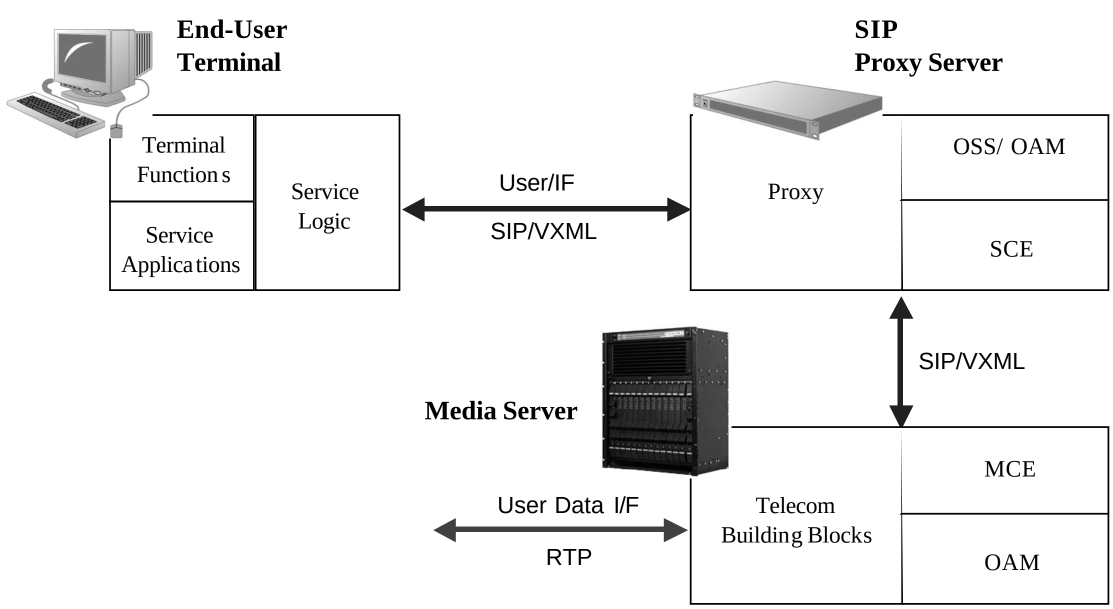
Enterprise Server



(QoS) throughout the network. The opening up of the service control interface also allows service providers to offer the telecom service building blocks to end users to create their own services or imbed services into their own computer applications.

SIP, along with service control languages such as Voice XML, allow a user to do more than request services; the user can activate and control services from the terminal equipment. End-user terminal devices, such as personal digital assistants (PDAs) and SIP phones, can have service applications built into them and allow the end user to program and control their own services. This puts service creation and control into the hands of the end users and application developers, similar to what happened with the PC and with the Internet. When the creativity of tens of thousands of programmers is let loose on telephony services and the promise of great wealth to the successful ones, there will be many exciting new services created and huge traffic generated.

FIGURE 9
End-User Terminal



Undoubtedly, systems 2 and 3 are a clear departure from the normal service environment of the present telephony system and will require a number of changes. Security and authentication is critical before giving an end user access to the service building blocks. Billing for this style of service can be monthly or by the session and service type. Predefined and tested Voice XML scripts will have to be published to users to enable specific services until the development community obtains widespread knowledge. But, of all of the methods, this unleashes the most creativity, albeit with the most change as well.

Who Will Provide the Services?

Working from the core of the network outward, we see that there are multiple players that have built viable businesses at natural interface points of the network. From experience, it is likely that most, if not all, of the existing business models will continue to grow and flourish even as new players enter the market. Service providers all over the world understand the strategic importance and cost benefits of moving forward quickly with convergence.

In this section, we explore the deployment of voice over IP (VoIP) by various services providers, shown in *Figure 10*, including local providers (ILEC, wireless, and cable multiple-system operators [MSOs]), long-distance providers (IXCs and next gens), and enterprises.

Long-Distance Service Providers

Long-distance (LD) service providers have already started to adopt VoIP for LD arbitrage and LD Class-4 replacement. Many of these providers have built massive IP backbone networks, making them ideally positioned to provide VoIP services. These service providers wish to take advantage of their central position in the network to offer services that span geographic areas. They have the benefit of shorter backhauling of traffic to a central point and access to a high percentage of cross-country traffic.

Local Service Providers

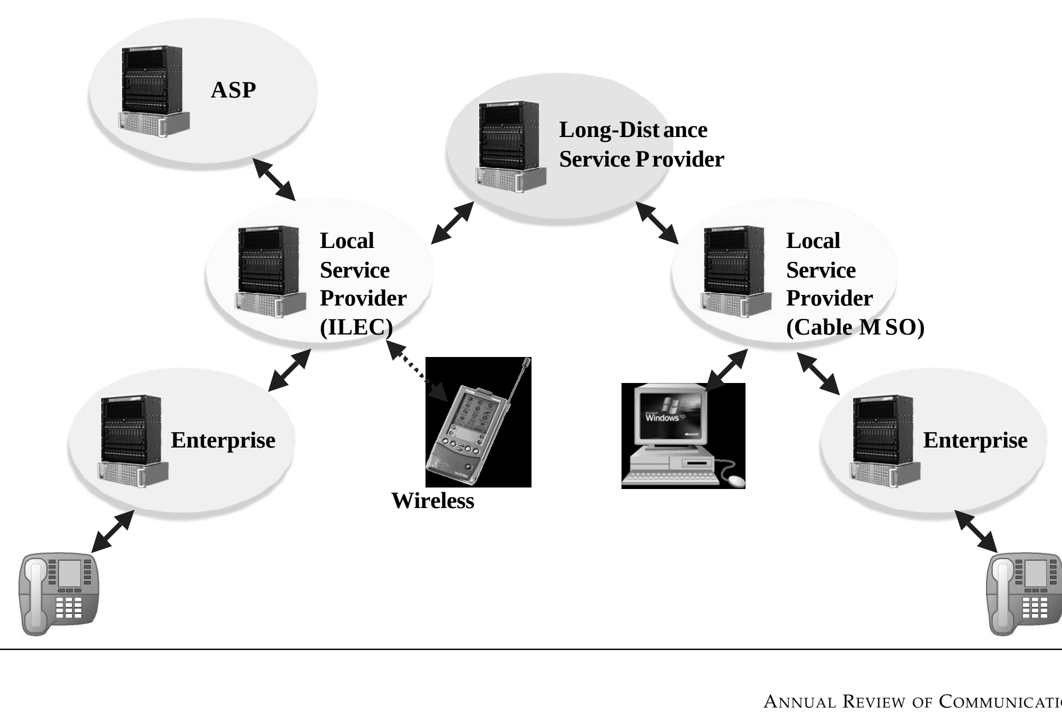
There is a battle underway for ownership of the access for home and business services. Presently, the ILEC or the Post Telephone and Telegraph Administration (PTT), have control of telephony services. But challenges to this dominance can occur from the cable-television (CATV) players and the wireless players. Traditional local service providers wish to add more services and increase their revenues and profits. In some service providers, enhanced services, such as voice-mail and card services, provide as much as 50 percent of the company profits. These players can not cannibalize their existing services or disrupt their amortization scheduled for their installed base of equipment, but they can use the converged services to attack market areas where they are weak or where they have little sunk investment. Rather than wait for this while VoIP starts without them, they are busy exploring areas that are good candidates for new revenue streams.

IP Centrex

Enterprise organizations are outsourcing everything that is not core to their business. This provides an opportunity for incumbent players to gain back enterprise customers that they lost to PBX vendors in the 1980s. Hosted business services such as IP Centrex give the incumbent service providers a powerful story that is separate from their core residential

FIGURE 10

Service Options



telephony business, allowing them to deploy VoIP, learn the technology, and position for convergence.

IP VPNs

Large players have deployed IP VPNs to service their largest customers. Today, those mainly carry data traffic, although many of them contain VoIP traffic hidden in the data. The service provider is ideally positioned to put an enhanced services platform on this core network and to add telephony services on these IP VPNs. This protects the enterprise customer from newcomers with VoIP, and it does not require a complete change over of the service provider's residential TDM equipment.

Enhanced Services Offload

ILECs can use enhanced service offload to consolidate enhanced services onto a single technology. This technique requires a mini softswitch package of products that connect into the TDM network at a logical trunking point. This package consolidates all of the traditional TDM feature server products into a single flexible, scalable product that is IP–enabled. This provides cost savings in both CAPEX and OPEX over TDM–based solutions while capping purchases of dead-end TDM equipment and positioning for VoIP. The service provider can even offer Web-based enhanced services off the same platform to explore these new, exciting services.

Cable MSOs

The CATV industry is poised to provide new, exciting services, being the only other player with substantial bandwidth capability to the home. The new entrants into local access are looking to replicate the Class-5 features at a lower cost than the incumbents in order to offering new lower-cost service that will help them to capture customers away from the incumbent players. Wireless players are hungry for new, exciting services to differentiate themselves, and with a wave of intelligent wireless handsets on the way, they will have the graphical user interface (GUI) to do this.

Application Service Providers (ASPs)

ASPs are relatively new service-provider business models. These players rent a connection to the service provider's network and sell services across the network to the consumers or small business. In some cases, they supply the local or LD service provider with services, and sometimes they compete with the local and LD service providers and rely on their ability to provide richer service features, faster time to market, and better customer support than the larger service providers.

Enterprise

Enterprises may wish to control and manage their services locally. This can be done by a PBX or by a PC running Windows XP. They can look inward and outward to provide enterprise-wide services that are hosted by the enterprise server or through a combination of enterprise services and carrier-hosted services.

End Users

Consumers and small businesses may wish to control basic services directly from their PCs or intelligent terminal devices. They may imbed the application server functionality in the intelligent terminal device to allow service control and management to be built into the terminal application. In this scenario, the terminal device may access complex media server processing functionality in the network and pay on a monthly basis or as required.

Summary

Telephony service will be converging with the Internet during the next 15 years. Enhanced services are one of the keys to profitable business in telephony. Enhanced services can be provided through service platforms to end users. Service providers are already starting to deploy enhanced services where economics show there is a benefit, such as for Class 4, IP Centrex, enhanced services offload, and IP VPNs. In the near future, enhanced services building blocks can be provided by the network for any user to use through SIP and Voice XML.

The Battery and the Digital Load

Isidor Buchmann
Founder and Chief Executive Officer
Cadex Electronics, Inc.

With the move from analog to digital devices, new demands are being placed on the battery. Unlike analog equipment that draws a predictable and steady current, digital devices load the battery with short, high current bursts.

One of the urgent requirements of a battery for digital applications is low internal resistance. Measured in milliohms (mΩ), the internal resistance is the gatekeeper that, to a large extent, determines the runtime. The lower the resistance, the less restriction the battery encounters in delivering the needed power bursts. A high mW reading can trigger an early "low battery" indication on a seemingly good battery because the available energy cannot be fully delivered.

In this article, we examine the current requirements of analog and digital communications devices. *Figure 1* provides typical examples of peak current of the analog two-way and digital Tetra radio, as well as the AMP, Global Systems for Mobile Communications (GSM), time division multiple access (TDMA), and code division multiple access (CDMA) mobile phones.

Why Do Seemingly Good Batteries Fail on Digital Equipment?

Service technicians have been puzzled by the seemingly unpredictable battery behavior when powering digital equipment. With the switch from analog to digital wireless communications devices, particularly mobile communications equipment, a battery that performs well on an analog system may show irrational behavior when used on a digital unit. Testing these batteries with a battery analyzer produces good capacity readings. Why then do some batteries fail on digital devices but not on analog?

The overall energy requirement of a digital mobile phone is less than that of the analog equivalent, however, the battery must be capable of delivering high current pulses that are often several times that of the battery's rating. Let's look at the battery rating as expressed in C rates.

A 1C discharge of a battery rated at 500 mAh is 500 mA. In comparison, a 2C discharge of the same battery is 1,000 mA. A GSM phone powered by a 500 mA battery that draws 1.5A pulses loads the battery with a whopping 3C discharge.

A 3C rate discharge is acceptable for a battery with very low internal resistance. However, aging batteries, especially Li-ion and NiMH chemistries, pose a challenge because the mΩ readings increase with use. Improved performance can be achieved by using a larger battery, also known as an extended pack. Somewhat bulkier and heavier, an extended pack offers a typical rating of about 1,000 mAh or roughly double that of the slim-line. In terms of C rate, the 3C discharge is reduced to 1.5C when using a 1,000 mAh instead of a 500 mAh battery.

As part of ongoing research to find the best battery system for wireless devices, Cadex has performed life-cycle tests on various battery systems. In *Figure 2* through *Figure 4*, we examine NiCd, NiMH, and Li-ion batteries, each of which generate a good capacity reading when tested with a battery analyzer but produce stunning differences on a pulsed discharge of 1C, 2C, and 3C. These pulses simulate a GSM phone.

A closer look reveals vast discrepancies in the mΩ measurements of the test batteries. In fact, these readings are typical of batteries that have been in use for a while. The NiCd shows 155 mΩ, the NiMH shows 778 mΩ, and the Li-ion shows 320 mΩ, although the capacities checked in at 113 percent, 107 percent, and 94 percent, respectively, when tested with the DC load of a battery analyzer. It should be noted that the internal resistance of a new battery reads between 75 mΩ and 150 mΩ.

From these charts, we observe that the talk time is in close relationship with the battery's internal resistance. The NiCd produces a long talk time at all C rates. In comparison, the NiMH only works at a lower C rate. The Li-ion performs better but is marginally at a 3C discharge.

How Is the Internal Battery Resistance Measured?

A number of techniques are available to measure the internal battery resistance. One common method is the direct current (DC) load test, which applies a discharge current to the battery while measuring the voltage drop. Voltage over current provides the internal resistance.

The alternating current (AC) method, also known as the conductivity test, measures the electrochemical characteristics of a battery. This technique applies either a fixed frequency or a frequency range from 10 Hz to 1,000 Hz to the battery terminals. The impedance level affects the phase shift between voltage and current, which reveals the condition of the battery.

FIGURE 1

Peak Power Requirements of Popular Global Mobile Phone Systems

	Two-Way Radio	Tetra Radio	AMP Mobile Phone	GSM Mobile Phone	TDMA Mobile Phone	CDMA Mobile Phone
Type	Analog	Digital	Analog	Digital	Digital	Digital
Peak Power	2–4 Watts	1 or 3 Watts	0.6 Watts	1–2 Watts	0.6–1 Watts	0.2 Watts
Peak current	1.5A at 4W	1 or 3A	0.3A DC	1–2.5A	0.8–1.5A	0.7A
In service since	1962	1997	1985	1986	1992	1995

Moving from analog to digital equipment reduces the overall energy need but increases the peak current during load pulses. The wattage varies with signal strength.

Some AC resistance meters evaluate only the load factor and disregard the phase-shift information.

Cadex uses the discreet DC method to measure internal battery resistance. Added to the Cadex 7000 Series battery analyzers, a number of charge and discharge pulses are applied, which are scaled to the mAh rating of the battery tested. Based on the voltage deflections, the battery's internal resistance is calculated. Known as *Ohmtest*™, the mΩ reading is obtained in five seconds.

None of the three methods is dead accurate. The discrepancies are reasonably small on a good battery, but the readings get more diverse on weaker packs. *Figure 5* compares the accuracy obtained using the three methods.

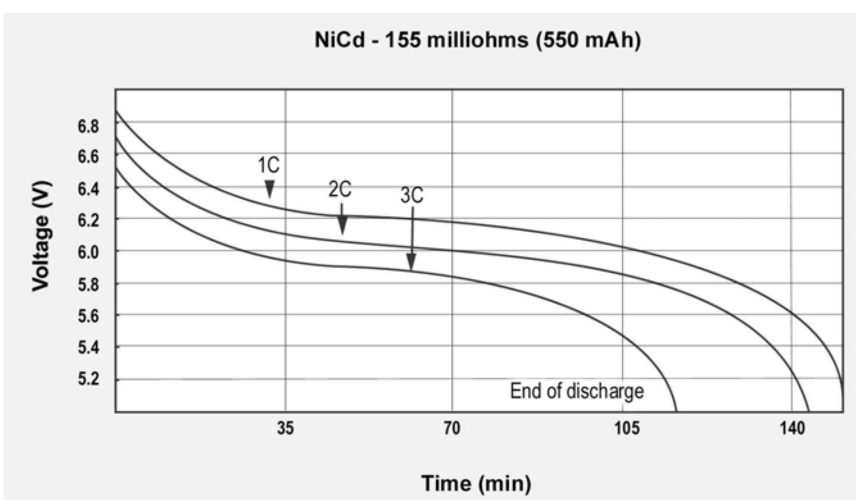
Resistance measurements alone do not provide a reliable indication on the battery's performance. The mΩ readings may vary widely depending on battery chemistry, cell size (mAh rating), type of cell, number of cells connected in series, wiring, and contact type.

When using the impedance method, a battery with a known performance should be measured and its readings used as a reference. For best results, a reference reading should be on hand for each battery type. *Figure 6* provides a guideline for digital mobile phone batteries based on impedance readings.

The milliohm readings are related to the battery voltage. Higher voltage batteries allow higher internal resistance before the system fails, because less current is required to

FIGURE 2

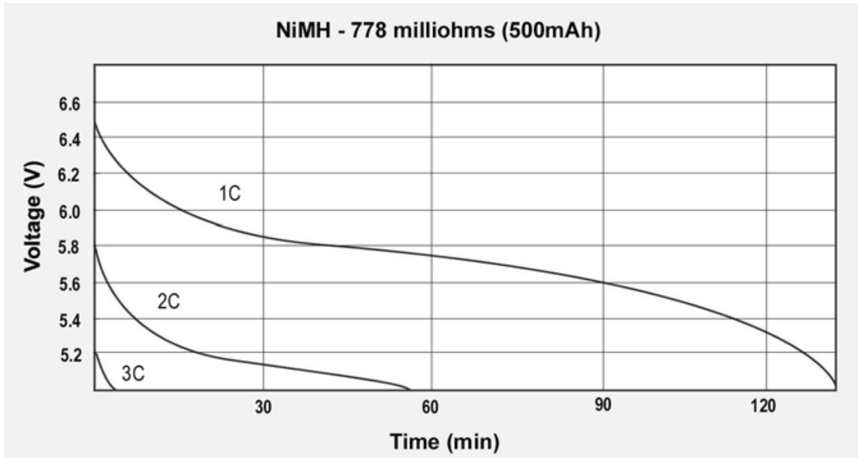
Talk Time of a NiCd Battery under the GSM Load Schedule



This battery has 113 percent capacity and 155mΩ internal resistance.

FIGURE 3

Talk Time of a NiMH Battery under the GSM Load Schedule



This battery has 107 percent capacity and 778mΩ internal resistance.

deliver the same power. The ratio between voltage and milliohm is not totally linear. There are certain housekeeping components that are always present whether the battery has one or several cells. These are wiring, contacts, and protection circuits.

Temperature also affects the internal resistance of a battery. The internal resistance of a naked Li-ion cell measures 50 mΩ at 25° C (77° F). If the temperature increases, the internal resistance decreases. At 40° C (104° F), the internal resistance drops to about 43 mΩ and at 60° C (140° F) to 40 mΩ. While the battery performs better when exposed to heat, prolonged exposure to elevated temperatures is harmful. Most batteries deliver a momentary performance boost when heated.

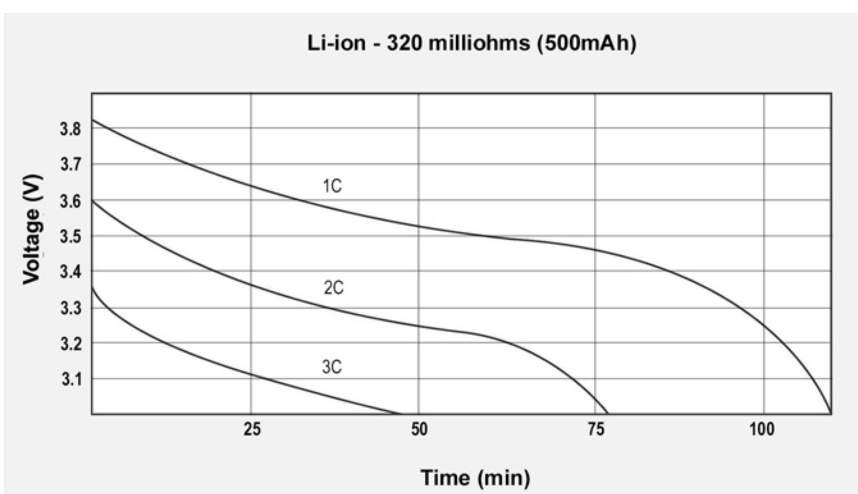
Cold temperatures have a drastic effect on all batteries. At 0º C (32º F), the internal resistance of the same Li-ion cell drops to 70 mΩ. The resistance increases to 80 mW at –10º C (14º F) and 100 mΩ at –20º C (–4º F).

The internal resistance readings work best with Li-ion batteries because the degradation follows a linear pattern with cell oxidation. The performance of NiMH batteries can also be measured with the internal resistance method, but the readings are less dependable. There are instances when a poorly performing NiMH battery can also exhibit a low mΩ reading.

Testing a NiCd on resistance alone is unpredictable. A low resistance reading does not automatically constitute a

FIGURE 4

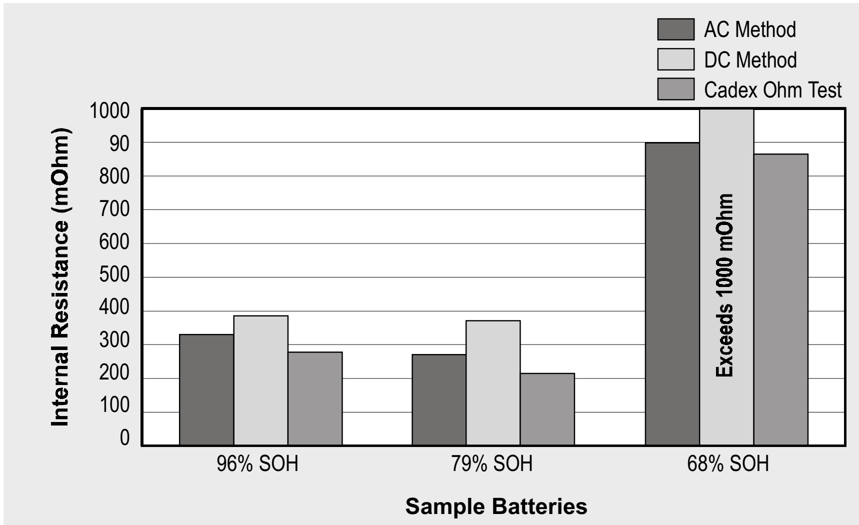
Talk Time of a Li-ion Battery under the GSM Load Schedule



This battery has 94 percent capacity and 320mΩ internal resistance.

FIGURE 5

Comparison of the AC, DC, and Cadex Ohmtest™ Methods



State-of-health readings were obtained using the Cadex 7000 Series battery analyzer by applying a full charge/discharge/charge cycle.

good battery. Elevated impedance readings are often caused by memory, a phenomenon that is reversible. Of course, high internal resistance can have sources other than memory alone.

Summary

Customer demand has compelled manufacturers to equip portable devices with batteries that provide a long talk time, are small, and are light in weight. By packing more energy into a pack, other qualities may be neglected, one of which is internal resistance and longevity.

Predictable low mΩ reading sand long service life is found in the NiCd family. This chemistry has been replaced with higher-energy dense batteries for many wireless applications. In addition, negative publicity about the memory phenomenon and concerns of toxic metals have caused a shift toward alternative choices.

For many applications—including biomedical devices, power tools, and most notably the Tetra system—the NiCd may be the only battery that has the endurance of delivering high pulse current under continuous usage. Other chemistries are simply too fragile. The resistance on a NiMH rises after a few hundred charge/discharge cycles. In comparison, a properly maintained NiCd provides over 1,000 cycles.

For many portable devices, the battery is one of the most expensive components. It is also the only part that repeatedly fails during the life of a product. It is therefore prudent that manufacturers not only focus on high energy density, but also address the issue of longevity. The longer a battery lasts, the fewer batteries are discarded—a win-win situation for business and the environment.

This article contains excerpts from the second edition of Batteries in a Portable World – A Handbook on Rechargeable Batteries for Non-Engineers.

FIGURE 6

State-of-Health on Mobile Phone Batteries Based on Internal Resistance

Milliohms	Battery Voltage	Ranking
75–150 mΩ	3.6V	Excellent
150–250 mΩ	3.6V	Good
250–350 mΩ	3.6V	Marginal
350–500 mΩ	3.6V	Poor
Above 500 mΩ	3.6V	Fail

The milliohm readings relate to the battery voltage; higher voltage allows higher milliohm readings.

Data on MMS: An Introduction to Mobile Multimedia Messaging

Simon Buckingham
Chief Executive Officer
Mobile Streams

1. Evolution from Text to Multimedia

Over time, the nature and form of mobile communication is getting less textual and more visual. Mobile messaging is evolving beyond text by taking a development path from short message service (SMS) to enhanced messaging service (EMS) to multimedia messaging service (MMS). Mobile Streams already publishes its renowned SMS reports called "SMS Express" and "SMS Tech," and its EMS report "Yes 2 Enhanced Messaging."

The transition that we will see from SMS to MMS is akin to the revolution from DOS to Windows in the computing world. It was this change that took computing from the early adopter innovator category into the early majority and onwards into the late majority mainstream status. When you compare a text message or an operator logo with a multimedia message or screensaver, the difference is an order of magnitude. The main features of this transformation from text to multimedia are shown in *Table 1*.

The SMS is the ability to send and receive text messages to and from mobile telephones. The text can comprise of words or numbers or an alphanumeric combination. SMS was created when it was incorporated into the Global System for Mobile Communications (GSM) digital mobile phone standard. The first short message was sent in December 1992 from a personal computer (PC) to a mobile phone on the Vodafone GSM network in the United Kingdom. Two-way SMS is supported on GSM, code division multiple access (CMDA), and time division multiple access (TDMA) networks.

The EMS is the ability to send ringtones, logos, and pictures to mobile phones and also to send and receive a combination of simple media such as melodies, pictures, sounds, animations, modified text, and standard text as an integrated message for display on an EMS compliant handset. There are many different potential combinations of these media. For example, when an exclamation mark appears in the enhanced message, a melody could be played. A simple black and white image could be displayed along with some text and this sound effect. EMS is an enhancement to SMS but is very similar to SMS in terms of using the store-and-forward SMS centers, the signaling channel, and the like to realize EMS. There are no network modifications needed to support EMS. Only new phones supporting EMS are needed. The first EMS compliant handsets became available in mid 2001. EMS is a GSM and CDMA standard.

The MMS is, as its name suggests, the ability to send and receive rich media messages comprising a combination of text, sounds, images, and video to and from MMS–capable handsets. The MMS confers the ability to send still images such as mobile postcards, mobile pictures, mobile screensavers, mobile greeting cards, mobile maps, and business cards. Additionally, moving images, cartoons, and interactive video will also be supported by multimedia messaging. New mobile network infrastructure is needed for multimedia messaging—in addition to implementing the new bearer services such as general packet radio service (GPRS) and third generation (3G), new network elements such as multimedia messaging relays and stores will be needed. MMS is a service that will run over Internet protocol (IP)–based mobile networks—initially GPRS networks—and will later be ported to enhanced data rates for GSM evolution (EDGE) and 3G networks.

2. Comparison between SMS and MMS

The SMS is a very popular mobile messaging service, with tens of billions of SMS messages sent and received each month globally. MMS will want to tap into and replace some of the SMS traffic over time. It is therefore useful to compare SMS and MMS. SMS and MMS share some similarities and have some discontinuities, as detailed in *Table 2*.

Both SMS and MMS are non–real-time services—this means that there is an intermediate platform such as the SMS center (SMSC) or the MMS relay through which the short or multimedia messages pass. Another characteristic that SMS and MMS hold in common is that both include confirmation of message delivery—the sender of the message can find out whether or not the message they sent was successfully delivered.

Media Supported
The SMS supports text and binary as media, allowing, for example, rudimentary images to be sent and received. The

TABLE 1

Type	Characteristics	Content Reformatting for Mobile Necessary?	Applications	Support	Time Frame for Availability
SMS/Text Messaging	100–200 characters	Yes	Simple person-to-person messaging	All phones	1990s
Nokia Smart Messaging	Simple rudimentary images	Yes	Simple person-to-person messaging with a visual feel	Some networks and Nokia phones only	1999 onwards
Enhanced Messaging (EMS)	Text messages plus simple media formats, e.g., sound, animation, picture, text formatting enhancements	Yes	Simple person-to-person messaging with a visual feel	EMS standards expected to be widely adopted	2001 onwards
Multimedia Messaging (MMS)	Messages in multiple rich media formats, e.g., video, audio plus text	Sometimes	Sharing still images between phones and PCs and later simple person to person messaging with a visual feel	MMS standards expected to be widely adopted	2002 onwards
Source: Mobile Streams					

overwhelming majority of all SMS messages are pure and plain text, however. Multimedia messages, on the other hand, can be coded in various media from text to images to sounds to video clips to a combination of these. As such, the MMS is a much more complicated and powerful service that supports far more media and rich media. For this reason, SMS is to mobile phones what DOS was to PCs, whereas MMS is to mobile phones what Windows was to the PC. This is a revolutionary step, requiring EMS in the middle to steer an evolutionary migration path in mobile messaging. It also mandates terminal negotiation between network and phone to assess capabilities. SMS is the lowest common denominator that all phones support; MMS is a complex service where different phones will have varying media support. Whereas SMS is integrated into every mobile phone (whether that phone also supports EMS, wireless application protocol [WAP], or MMS), MMS clearly requires new terminals.

Delivery Mechanism

All short messages are sent and received over the signaling channel, a channel that is an additional transport mechanism on GSM networks over and above the radio channels themselves. The signaling channel is a little like the hard

TABLE 2

Feature	SMS	MMS
Store and Forward (Non–Real-Time)	Yes	Yes
Confirmation of Message Delivery	Yes	Yes
Communications Type	Person to Person	Application to Person Person to Person
Media Supported	Text plus Binary	Multiple: Text, images, video
Delivery Mechanism	Signalling Channel	Data Traffic Channel
Protocols	SMS Specific, e.g., SMPP	WAP and General Internet, e.g., MIME, HTTP, SMTP
Configuration	Simple Telephone Number	Diverse Parameters
Platforms	SMS Center	MMS Relay plus Others
Principle Applications	Simple Person to Person	Still images, person to person, server-based MMS services, e.g. video news
User Behavior	Discreet	Indiscrete
Source: Mobile Streams		

shoulder or on-ramp on a motorway/expressway—it runs parallel to the traffic lanes themselves. SMS can be transmitted concurrently to other data types—text messages can be sent and received while the user is also on a voice, circuit-switched data or fax call.

Multimedia messages, on the other hand, will be transmitted over the traffic channels themselves, where other data types from voice to data will also be transported. The high capacity of 3G networks will mean that all of these different traffic types can share the same radio resource without the likelihood of congestion. Using the traffic channel helps to overcome the capacity limitations of the signaling system 7 (SS7) signaling channel (see www.mobileSS7.net for more information).

In the GPRS world, therefore, multimedia messages will share limited network capacity with voice and other calls. This will have an important implication for quality of service (QoS), since multimedia-message delivery reliability will be affected if networks are congested for any and all types of mobile services.

Protocols

When SMS was standardized in the early to mid-1990s, the Internet was an obscure academic communications medium. The original European Telecommunications Standards Instititute (ETSI) specifications for SMS closely mandated some areas of SMS and left others open to competition. As a result, proprietary protocols were developed—every SMS–center vendor developed its own interface such that application developers needed to implement different interfaces when porting their applications and services to network operators that had different SMSCs. Short message peer-to-peer protocol (SMPP) has recently become the de facto SMSC interface protocol and is also likely to be used for certain MMS interfaces. Furthermore, an outdated protocol—X.25—remains a popular access mechanism for connecting applications to SMSCs.

MMS, on the other hand, came of age in the Internet world where open systems and standard protocols reign and a wide range of these protocols exist. There is therefore no need to reinvent the wheel—existing standard protocols can be used—and MMS needs to tap into the vibrancy and innovativeness of the Internet companies if it is to maximize its full potential. MMS uses standard Internet protocols such as multipurpose Internet mail extensions (MIME) and simple mail transfer protocol (SMTP) for access to the multimedia messaging service environment (MMSE). MMS is basically a presentation layer for basic e-mail protocols.

While the first MMS implementations will be based on enhanced WAP protocols (WAP MMS encapsulation), later MMS versions will also support non–WAP, standard Internet protocols for communication between terminal and MMS relay, such as hypertext transfer protocol (HTTP) over transmission control protocol (TCP)/IP.

Configuration

SMS is a completely simple service to use. There are no special numbers to remember—the same number that you use to call is the one you use to text, and no additional parameters need to be set by the end user to successfully send the text message. MMS, however, is a very complex service with device negotiation and capability recognition, and different classes of devices with different media support. In the initial implementation of MMS using WAP, WAP Push is used such that concatenated SMS messages are used to transport the notification data (sender, size, retrieval universal resource locator [URL], etc.) encapsulated in a WAP Push data unit. The third-generation partnership project (3GPP) IP–based implementation proposal for MMS does not include SMS notification—it assumes a pure HTTP payload between the terminal and the relay. The 3GPP has defined a frame that allows for different implementations but assumes that the IP address used is fixed. This means that a lot of IP addresses will be needed for MMS, which will be possible using only IPv6 and not the current IPv4.

This difference in the complexity of notifications between MMS and SMS is yet another crucial one that does not favor MMS.

Platforms

In SMS, the SMSC is the heart of the service, with all short messages of any type passing through an SMSC to and from mobile phones. As such, there is one platform type that dominates SMS. Network operators have between one and 50 such SMS centers, but there is only one platform type. Networks also tend to have other platforms such as value-added services platforms.

With MMS, on the other hand, there are several key platforms within the MMSE, including the MMS relay, the MMS message store, the MMS user database, and other platforms, including the existing platforms such as the SMSC, voice-mail platforms, and the like. There may be several of these, and they may be distributed as components in an open environment or integrated together in a single physical place.

The MMS infrastructure vendors have integrated the MMS server and relay into a single platform that they are calling the MMS center (MMSC).

Applications

In SMS, the vast majority of the total SMS traffic volume is accounted for by one application alone—simple person-to-person messaging in which people send messages such as "I'm bored" and "I'll be 5 mins late" from phone to phone. In the MMS world, however, Mobile Streams is predicting that initial applications will be application-to-phone, such as those sent from Internet sites and based on still images—for example, screen savers, mobile pictures, photos, postcards, and the like. In other words, the notion that MMS will be like SMS in that person-to-person messaging is the key application is naïve, because for the first couple of years before MMS reaches critical mass, most MMS messaging will involve a PC to either initiate or terminate the multimedia message.

User Behavior

One of the great advantages of SMS is that it is a very discreet communications medium that can be used "under the table" in meetings and at school, for example. MMS is almost the opposite of this in terms of user behavior insofar as people using a built-in or attached camera in many scenarios will draw attention to themselves. On the other hand, SMS–based enhanced messaging applications such as ringtones are also a means to draw attention to yourself, so perhaps the gulf in user behavior is not quite so great. This difference in user behavior is critical in educating users about MMS and is another factor that needs to be taken into account when it comes to MMS adoption rates.

Summary
MMS takes a lot of the winning features of SMS but improves and extends those capabilities with richer media. The MMS standards have been designed in a very elegant way to take the best of text and improve the rest. However, it is also very clear that SMS and MMS are very different in the way the services are set up, with MMS being far more complex, and also in the types of applications and devices used and the user behavior. Mobile Streams' is predicting that these differences will have an adverse effect on the rate of take up of MMS, as people will continue to use text in many communication scenarios.

3. Timescales

When a new service is introduced, there are a number of stages before it becomes established. Service developments for the MMS will include standardization, infrastructure development, network trials, contracts placed, network rollout, availability of terminals, application development, and so on. These stages for the MMS are shown in *Table 3*.

4. Milestones

Mobile Streams has developed a framework called "messaging milestones" to explain what steps are needed before multimedia messaging can become a success and how to maximize MMS volumes and revenues. The dates given in the parentheses are the approximate timelines for these milestones.

GPRS Networks Rolled Out (2001)
MMS is a 3GPP standard that can be run over GPRS or 3G network bearers. As such, this investment in underlying network technology is a critical one before MMS can be rolled out as a service using that bearer.

GPRS and MMS Billing Tariffs Sorted (2002)
It is important at this stage to start thinking about and investing in billing systems that can cope with MMS style services, including subscription services, service rather than volume-based billing, revenue-sharing arrangements with third parties, and the like, so that the new MMS–based services can be monetized.

First-Generation MMS Center Trials (2001, 2002)
Network operators purchase or trial the first-generation MMSC. As we have seen from the contracts awarded so far, there are a number of MMSC trials being implemented by network operators, mainly in continental Europe. Obviously, messaging infrastructure to manage MMS is crucial, since without it, MMS cannot be offered.

Business Partners Programme (2001)
It is important that network operators start at this stage to think about partners for MMS services. Consumer services will use the MMS synchronized multimedia intergrated language (SMIL) format, so a content creator with that capability would help. Corporate-oriented applications extending unified messaging or caller ID would constitute useful applications at this time too. A partner with a media bank for content and postcard and screen saver content could help here.

Initial MMS Terminals (2001, 2002)
New phones are needed before MMS can be used. As the initial MMS terminals become available, the first multime-

TABLE 3

Date	Milestone
2000/2001	Continuing GPRS, 3G, and MMS standardization with network architectures, terminal requirements, and detailed standards.
Early 2000	First MMS terminals were announced (Ericsson T68).
2000/2001	3G licenses for Phase 1 spectrum were awarded by governments around Europe and Asia.
2001/2002	GPRS networks are rolled out commercially around the world.
Mid-2001	Release 4 of 3GPP MMS specs frozen. WAP–MMS specs (based on pre-Rel-4 3GPP specs) frozen in WAP 2.0 suite. First MMS infrastructure contracts are awarded, and is it shipped for MMS trials and commercial services.
Late Q1 2002	First MMS terminal (Ericsson T68) is commercially available.
March 2002	Release 5 of 3GPP MMS specs frozen.
Mid-2002	M-Services Stage 2 devices, of which MMS is a compulsory part, start shipping.
2002	MMS infrastructure trials and contracts are placed in Europe, North America, Asia, etc.
Late 2002	Commercial volumes of MMS terminals begin shipping.
2003/2004	MMS will have reached critical mass in terms of the installed base of MMS capable terminals.

Source: Mobile Streams

dia messages are sent. The very first MMS terminals, technically speaking, are personal digital assistant (PDA)–type devices with GPRS equipment attached. The first MMS–capable devices, such as the Ericsson T68, will become available. At this stage, the network, software partners, and terminals are in place and services can start to be used, albeit on a small scale initially.

GPRS Roaming and MMSC Interworking for Inter-Network Message Termination (2002)

The addition of interworking between network operators that are competing in the same geographical market gives customers to all networks the opportunity to use MMS in the same way as they do voice. Just as they can make a voice call to each other's phones, so too can they send multimedia messages to each other. Enabling this capability can rapidly increase the number of available messaging destinations, thereby increasing the value and use of MMS.

MMS Terminals and Service for Prepay

The next increase in MMS traffic volumes will be caused by the introduction of MMS terminals on prepay packages. Network operators face an issue in that they want to subsidize MMS terminals to attract usage but do not know what return on that subsidy they will get on a prepay tariff with no fixed contractual length. The youth market was the early adopter of SMS and is likely to be interested in MMS, yet the terminals are likely to be relatively sophisticated, and therefore expensive.

Range of Interoperable Terminals (2002, 2003)

Obviously, it is important that a choice of different terminals is available to potential MMS users from a range of terminal manufacturers. All of these terminals must closely conform to the 3GPP and WAP–MMS specifications and interwork with handsets and MMS infrastructure from a range of different vendors.

End-User Awareness and Education

Obviously, user awareness and education are important, although MMS is expected to grow very quickly in this regard, since it is instantly clear from using an MMS–capable device that the messaging richness is dramatically improved compared to SMS and text messaging.

As such, there are various steps that mobile network operators can and should take to spur the initial development of MMS usage. Each of these steps is complementary and useful in making MMS a success. All of the stages are crucial to the overall success of MMS. It is not until these steps are in place that MMS can start to really succeed. These are the initial factors—networks, services, terminals, billing—before the MMS traffic can really start to take off.

5. Technical Features

The enablers for multimedia messaging have their roots in the changes that are taking place at all levels within the mobile Internet. Enabling bearers such as GPRS, EDGE, and 3G are becoming available. Enabling technologies such as Bluetooth, WAP, MexE, and SyncML are all initiatives that support this new direction toward the mobile Internet. We are also seeing new categories of multifunctional devices, such as MP3 phones, being implemented.

The 3GPP has been studying the limitations of SMS, and the MMS is the answer to the new messaging market requirements. Infrastructure vendors see multimedia messaging as an evolution in mobile messaging as the user moves from SMS to EMS to MMS. The MMS is, according to the 3GPP standards, "a new service which has no direct equivalent in the previous ETSI/GSM world or in the fixed network world." Let's introduce the features of this innovative new service:

1. MMS is a presentation layer for e-mail such that it uses underlying standard e-mail protocols but presents that e-mail in a compelling design.
2. MMS will enable messages to be sent and received using lots of different media formats and types, including text, images, audio, and video.
3. As new more advanced media become available, more content-rich applications and services can be offered using the MMS service environment.
4. The MMS introduces new messaging platforms to mobile networks to enable MMS. These new platforms have been designed to interact with legacy mobile platforms such as SMSCs. The new platforms include MMS relay(s) and MMS user databases.
5. MMS is like SMS—a non–real-time service. A relay platform routes multimedia messages to MMS servers.
6. The MMS is designed to be future-proof. As mobile networks evolve and new media become available, the aim is to make the standards as backward- and forward-compatible as possible.
7. Access to MMS services should be independent of access point—multimedia messages should be accessible through 3G and 2G mobile networks, fixed networks, the Internet, etc. This is where common message stores will be an important enabling technology. To facilitate interoperability and universal messaging access, MMS will comply with the virtual home environment (VHE). VHE is a 3G concept that simply lets customers have seamless access with a common look and feel to their services from home, office, or on the move and in any city as if they were at home. The VHE permits the user to manage his or her services (including non–real-time multimedia messaging handling) via a generic user profile, permitting, for example, all different types of messaging to be presented to the user in a unified and consistent manner. (See www.mobileVHE.com from Mobile Streams for more information.)
8. The concept of a user profile has been included in the MMS standards. This user profile is stored in the mobile network and is user defined and managed via the Internet, and determines which multimedia messages are downloaded immediately to the user and which are left on the server for later collection. The user may also choose to receive notifications of certain multimedia message types.

   User profiles are important for several reasons, including the fact that different MMS devices will support different levels of capability. The user profile will also allow the user to control access and accessibility for multimedia messages that will be mobile originated and mobile terminated. The user profile will include filtering rules and routing tables for unsolicited or undesirable messages.

9. Although MMS is being standardized by the 3GPP, in fact MMS services can be offered on any IP–based air interface, such as GPRS (so-called 2.5G) or EDGE networks. The MMS is a service environment that interworks with and allows multimedia messages to be transmitted across IP–based mobile networks. (See www.mobileGPRS.com, www.mobilEnhanced Data.com, and www.mobile3G.com and the "Success 4 GPRS" and "Yes 2 3G" reports for more information on these bearer networks.)
10. Content scaling (e.g., downscaling of images) and content transformation (e.g., conversion of one audio format into another) have been considered in the MMS standardization process.

In summary, the MMS provides an intelligent environment for multimedia mobile messaging.

6. Architecture Elements

This next section gives an overview into the technical implementation of MMS. It quotes heavily from the 3GPP specifications, in particular 3G TS 23.140, a functional description of MMS.

The multimedia messaging architecture has a number of key elements that have been defined and incorporated into a MMSE. The concept of the "service environment" has been used in the past, for example in intelligent network (IN) solutions with the CAMEL service environment (CSE).

The MMS architecture contains several key platforms that interwork with each other to provide the MMS service. The key elements defined by the 3GPP are as follows:

- MMS relay
- MMS server (or servers)
- MMS message store (or stores)
- MMS user agent
- MMS user databases

It is important to note that MMS infrastructure vendors are integrating MMS platforms, such as an MMS relay and MMS server, and labelling them as an MMSC.

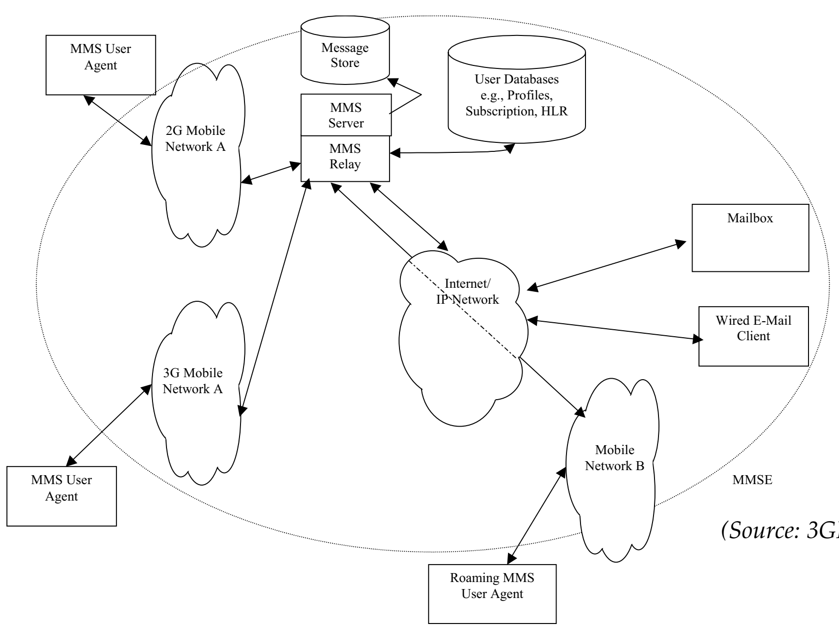
To understand these platforms, think about the internal organs of human beings. The MMS relay is like the heart of the service, which pumps content around the body. The MMS server(s) is like the other organs that perform other related functions. The MMS message store(s) store related fluids that get passed around. The MMS user databases contain the profiles that decide how the multimedia messages are transmitted and displayed. The MMS user agent is a like the eyes—it is the external place through which the processed information is displayed and viewed.

This architecture allows multimedia access to all types of different information with a range of servers providing access to new and legacy services. This allows operators to consolidate access to multiple applications from a single architecture.

Figure 1 shows that multimedia messaging (MMS) may encompass many different network types that can be connected by standard IP messaging formats such as SMTP, MIME, etc. This approach enables messaging in 2G and 3G mobile networks to be compatible with Internet messaging systems.

Having discussed the criteria for selecting an MMS vendor, the MMS infrastructure vendors will now be reviewed. The profiled companies are ADC Enhanced Services, CMG, Comverse, Ericsson, Logica, Materna, Motorola, Nokia, Openwave Systems, SchlumbergerSema, Siemens, Tecnomen, and Unisys (see *Table 4*).

FIGURE 1



(Source: 3GPP)

7. MMS Applications

Mobile Streams believes that the key services and applications based on MMS will be related to mobile entertainment and still images in a person-to-person environment.

MMS Success = Entertainment + Still Images + Person to Person

Let's look at this in more detail:

Mobile Entertainment

Mobile entertainment services are key for MMS. They account for the majority of i-Mode traffic, for example, on the NTT DoCoMo network and are a more popular application than mobile messaging as a category of non-voice services. There are also likely to be substantial revenue premiums attached to mobile entertainment services—it is possible to charge a substantial premium for ring tones and picture messages in the EMS world, and this trend should be and is likely to be enhanced and maintained in the MMS world.

Person to Person

About 90 percent of SMS traffic volumes are still accounted for by simple person-to-person messaging—people picking up their mobile phones and sending each other messages such as "Hello how are you?" and "I'll be 5 mins late." In such an environment, SMS is a medium and the end users self-create most of the content themselves.

In MMS, once an installed base of MMS users have been built up, person-to-person communications will also be the majority of the traffic volumes, although mobile phone users are likely to depict their feelings in visual rather than textual format. With MMS, they may compose a picture that they created themselves on the MMS terminal or a photograph that they took of themselves or something else or one they found on a Internet site and sent to their friend after adding text to the picture. One to one communications from one person to another are likely to still be the overwhelming application usage in the MMS world, with the added visual element.

While simple person-to-person messaging will start off slowly before MMS is widely available in the mass market, we still believe that sharing the moment will be a popular service for MMS.

Still Images

Still images such as screensavers, photographs, pictures, letters, postcards, greeting cards, presentations, and static Internet pages can be sent and received over mobile networks just as they are across fixed telephone networks.

Two variables affect the usability of such applications—bandwidth and time—and they are inversely related. The faster the bandwidth, the less time is needed to transmit images, and vice versa. This is the reason why the transmission of image-based rather than textual information has not been a popular non-voice mobile application until now—it takes too long given the slow data transmission speeds that were available prior to the introduction of GPRS mobile packet data.

Once captured, images can then be sent directly to Internet sites, allowing near–real-time desktop publishing. The size

TABLE 4

MMS Vendor	End to End	Vision/ Strategy	Key Platform	SMS	WAP	Voice	UM	IP	Contract	Partners

Note: A rating of "High" denotes a better ranking than "Med." and so on.

of the file for a picture depends on the resolution and type of compression. Typically, each picture is between 50K and 100K in the Joint Photographic Experts Group (JPEG) format. This can be transmitted quickly using mobile packet data networks, especially 3G networks.

Still image transmission is a much-touted application for lower packet data services such as GPRS and beyond. Many people see still images as a killer application for GPRS and 3G.

While moving images, video, and the like represent a service that is compelling for sports replays, news clips, and the like, it is thought that it will be a relatively small market size for MMS compared to the potential for transmitting still images.

8. MMS Phones

Ericsson T68

The Ericsson T68 will be the industry's first phone to support multimedia messaging (MMS) standards. The Ericsson T68 will also be the first mobile phone from Ericsson with MMS, a color display, digital imaging, and audio capabilities. It is a radical phone in other ways too, as this review will show. The T68 has been developed for GSM 900/1800/1900 and GPRS networks and will be shipping in volume in late Q1 2002.

The first impression of the T68 is that it is very small—fitting easily into the palm of your hand. It is immediately noticeable too that the T68 is also very light. The T68 measures 101x48x19 mm and weighs 85 grams. The T68 has a large eight-row, 256-color display that is very clear and easy to read. The backlit screen is very bright when the phone is in use, but to conserve battery life, the standby mode turns the phone into an almost monochrome status.

The next thing—after the size, weight, and screen—that the user notices is the joystick navigation. A small joystick is centered below the phone screen and is pressed to issue a command or moved up and down to scroll between menu options. There is also a scroll button like a "jog bar" on the side of the phone that can be used, for example, to find out the phone status (battery life and the like). The advanced state of the physical design of the T68 continues to impress with an integrated antenna and even the back of the phone is curvaceous and well thought out without being overdesigned like some of Nokia's newest contrivances.

When you press the joystick, you get a visual menu with icons for different things, such as messages appearing on the screen. The software man/machine interface (MMI) is as surprisingly intuitive as the hardware design. Ericsson has finally and belatedly realized (along with the likes of Motorola and Siemens) that intuitive menus are essential for the usability of the device.

For example, the Messages menu lists Voice-Mail, SMS, EMS, MMS, E-Mail, Chat, Area Information, and Options, and the Fun & Games menu features Themes, My Pictures, Draw Pictures, My Sounds, Composer, Sound Recorder, Games, and Plug-In Camera. The phone supports all kinds of messaging (SMS, EMS, MMS) and even supports (unofficially) picture messages based on the Nokia Smart Messaging format! These cool features mean that you can personalize the phone with an entire theme (such as Microsoft Plus! on PCs) with wallpapers, sounds, ring tones, and the like. I alternated between the psychedelic and penguin modes depending on the time of the day! The sound-recorder feature works as its name suggests—for example, I recorded the sound our credit-card machine makes!

The T68 does not have an integrated camera but can support an add-on; however, this is not an inhibitor, because the phone can use many services that do not rely on taking pictures with a camera. For example, the T68 supports downloading 60x80 color images (MMS pictures). You can also "Add Page" for sequences of multimedia pictures and control page timing—the rate at which the pictures refresh as a multimedia presentation is played. These "screen shows" and wallpaper backgrounds give more personalization options for the phone user.

Within the MMS sub-menu, you can get a feel for the similarities between SMS and MMS. The options are Validity Period, Read Reply, Delivery Report, Auto Delete, Auto Download, Service Center, and WAP Profile. Many of these features, such as delivery confirmation, will be familiar to SMS users. When you write a new MMS message, you select a picture from the on-board pictures (which can be topped up over the air), and then add text to the picture and send it to a mobile number or e-mail address.

The T68 is a close to perfect execution of how an MMS phone should be. It is incredibly difficult to fault any aspect of the phone. The only thing you can really say is that the price of the phone is not yet clear, although it is expected to be priced aggressively. The only other thing I could come up with as a criticism was that the metallic gold finish on the device appeared very flimsy and a little tacky up close, although no-one can mistake this phone for anything other than a very, very serious piece of cool kit. The MMS device supports a picture plus text, and not animated messages or other MMS features, although with slide shows and those features, most users will not know or care about this.

Ericsson is working to ensure that the T68 is interoperable with various MMSCs from Nokia, Comverse, and CMG, as well as Ericsson, of course. Ericsson is not working with Logica for terminal interoperability at this stage, which is a surprise. Ericsson has shipped the T68 for trials with Europolitan-Vodafone in Sweden, for example.

Ericsson has set the bar very, very high with this mature implementation of the first MMS phone. Picking up the phone is really one of those pivotal moments in your life, such as when you browsed the Internet for the first time, when you realize just how great the difference between messaging now and tomorrow will soon be. Because this revelation comes as a gadget in a phone package, it has an even stronger impact. The T68 really brings MMS to life.

Ericsson has found what seems to be the perfect form factor for MMS—a large enough screen size, but not too large, with great hardware and software navigation. Because Nokia and now Ericsson have developed intuitive user interfaces for MMS, this is not likely to be as big an issue as it was in the SMS world before predictive text input was introduced. It is perhaps no surprise that "T68" rhymes with "great," because the Ericsson T68 multimedia phone really is very, very great!

The product I tested is a software upgrade version, which Ericsson will introduce during Q1 of 2002. The launch date was delayed because, according to Ericsson, "MMS development has not been as rapid as we expected which means we haven't been able to test the product as thoroughly against the various server vendors. Therefore, we cannot introduce MMS just yet." Ericsson will ship T68 without MMS during 2001 and introduce MMS in a later release toward the end of Q1. It will be possible to load MMS the first version of T68.

9. MMS Statistics

Global MMS Market Forecasts 2002–2008

Mobile Streams is predicting that MMS will start to grow in 2002 but will not really take off until 2004. We expect MMS to continue growing in volume for many years to come beyond 2003, until at least 2009 (see *Table 5*).

TABLE 5

End of Year (December Figures)	Monthly Total Global MMS Market Size	Monthly Total Global SMS Market Size
2002	$25 Million	$62.4 Billion
2003	$350 Million	$80 Billion
2004	$2.5 Billion	$82.1 Billion
2005	$10 Billion	$79 Billion
2006	$20 Billion	$59 Billion
2007	$50 Billion	$40 Billion
2008	$65 Billion	$26 Billion

Source: Mobile Streams

These figures denote the monthly figure for December of that year, *exclude* all other message types (such as SMS and EMS) and show only MMS, are approximate, and exclude Japan.

The Evolution of Softswitch Architecture

Walter Buga

Co-Founder, Chief Executive Officer, and Chief Technology Officer

IP APPS

Director, Technical Advisory Committee

International Softswitch Consortium

Introduction

The key issues discussed in this paper are softswitch architecture evolution, visions and realities, and challenges and benefits. The paper considers these challenges from a greenfield service-provider perspective.

Softswitch Architecture Evolution

The traditional public switched telephone network (PSTN) is based upon circuit-switching technology, while the new softswitch-based networks will leverage packet-switching technologies. This new architecture will simplify service creation and will integrate today's voice and data networks into one converged one that can provide both services. However, this change will not occur overnight, as there is more than $350 billion of legacy equipment installed in the PSTN today. Thus, this transformation will be evolutionary rather than revolutionary. In the section below, the stages of such an evolution are described.

PSTN Model

In the most basic and simplified view, the PSTN is composed of three layers:

- **Switching fabric:** connected to the transport layer via lines to end users and trunks to networks
- **Signaling and control:** provides call-control functionalities, including call establishment and teardown
- **Applications and services:** available to the end user, such as Class-5 features (call waiting, call forwarding, etc.) and advanced services (toll free, calling cards)

Typically, these three functionalities were implemented in "one box" as a Class-5 or Class-4 switch (see *Figure 1*).

Early Softswitches

The trend toward more open and programmable switches existed for a number of years, but their market penetration was very limited. Early adopters attempted to separate switching fabric from other functionalities via an open (but proprietary) interface/application programming interface (API) (see *Figure 2*). These so-called programmable switches were used for niche applications, such as callbacks, calling cards, etc.

Distributed Switching Fabric

Using packet-based networks—Internet protocol (IP) and asynchronous transfer mode (ATM)—to transport voice traffic, instead of the traditional time division multiplex (TDM) technologies used in the PSTN, allowed for switching fabric distribution. In these new networks, packetization of voice starts at a user device (IP telephony [IPTel], integrated access device [IAD], etc.), and then packetized voice is transported/switched to the "end" of the packet network. Finally, it is converted back to the TDM format before exiting to the PSTN. *Figure 3* depicts this architecture.

Open Architecture

The trend to break the old paradigm, in which a single vendor supplied everything—software, hardware, and applications—in one proprietary box, was gaining more traction because customers did not want to be locked in to their vendor with no room for innovation.

In mid-1999 the International Softswitch Consortium (ISC) (a nonprofit organization) was formed to promote an open architecture and multivendor interoperability for next-generation voice/video/data solutions. In less than two years, its membership grew to more than 180 system suppliers and service providers. This reflects the industry momentum toward this new architecture.

Open standards enable innovation and reduce costs, and customers are free to choose best-in-class products to build their network. Much work needs to be done before that vision can be realized, as many interfaces still need to defined and standardized.

Figure 4 depicts the target open architecture to be realized. This is only a functional view, and some vendors may elect to include various elements of this architecture in one box,

FIGURE 1

PSTN Model Switch

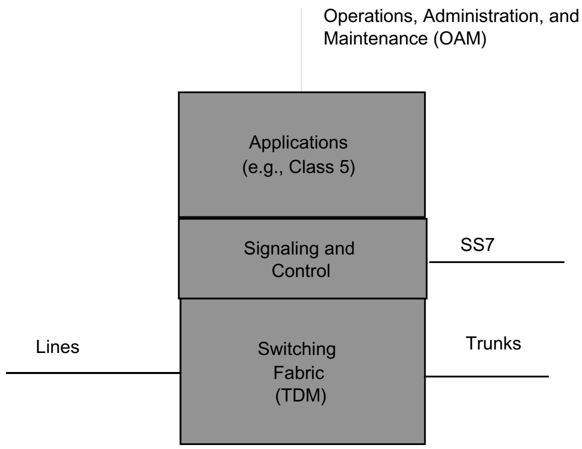

FIGURE 2

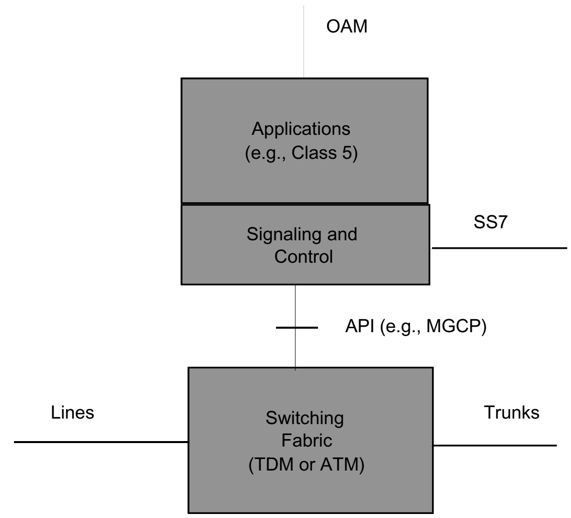
Early "Softswitch" Architecture



while others may wish to focus on a very specific element(s) of this architecture.

The Next-Generation Converged Network

Some next-generation service providers want to build voice services on a softswitch platform that can be deployed on a fully converged broadband and IP–centric network with quality of service (QoS)–managed virtual pipes using multiprotocol label switching (MPLS). This arrangement allows for an easy deployment/add-on of new advanced services and integration with the advanced service-creation platform. In this arrangement, voice applications can be considered one of many application service provider (ASP)–type offerings.

The architecture for such a network is a packetized network built upon a switching fabric that could be either IP or ATM. Everything else in the network is built on top of this switching fabric and integrated through open/standard APIs.

Thus, the greenfield service provider could start with a basic packetized network—no legacy elements are included if they can be avoided. To add a new customer, an IP–based phone or IAD would need to be added on the front-edge customer-premises equipment (CPE) of the network to convert voice to packetized form (including compression). This packetized voice traffic could be terminated "on-net" on another IP phone or IAD. However, for the "off-net" calls (the ones that need to exit to the PSTN), a media gateway (MG) would need to be deployed to convert this packetized traffic back to TDM format. Providers that do not have signaling system 7 (SS7) networks of their own would to be able to connect to providers of SS7 networks to provide call-control and signaling functions for voice traffic to/from the PSTN.

FIGURE 3

Packet-Based Network Architecture

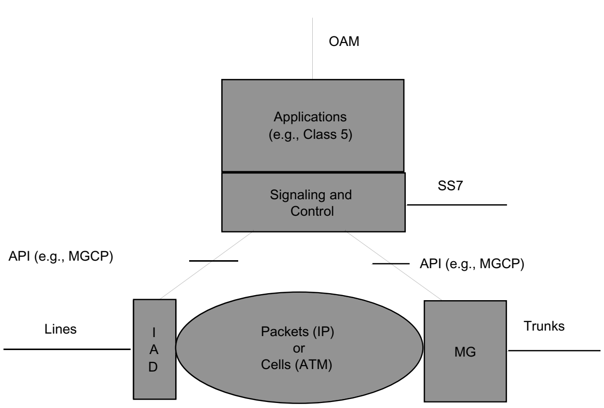


FIGURE 4

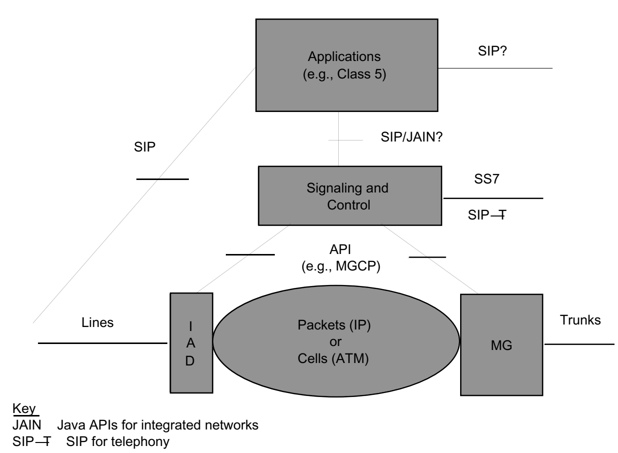
Open Architecture



An MG control protocol (MGCP), or MG control (MEGACO) (when available) could be used to control MGs (including IADs). Access to applications could be provided via a session initiation protocol (SIP). Once this IP network is in place, other applications and content, such as video and audio, can be easily added using a standard IP suite or other standard interfaces.

Figure 5 depicts an example of such a converged network.

The Vision

Unmanaged and Free to All?

It can be assumed that, in the future, all devices and applications will be IP enabled and connected to the ubiquitous IP network. Users and/or applications will communicate/interact via virtual, secure, and QoS–controlled/managed IP channels. Broadband access to the core IP network will be provided via a variety of economically justifiable physical media, including, wire, wireless, cable, optical, etc.

The IP network is location agnostic, as it is concerned with only the IP address, the bandwidth, and the QoS available for a specific connection(s). Assume that a telco has a data center, applications, and content connected to this IP network, while a residential customer has a phone and a browser connected to the same IP network. The difference between the telco and the residential customer is that the telco has a bigger pipe. In both cases, all the applications reside on the edges of the network, including users, telcos, ASPs, access devices, and applications (see *Figure 6*).

The number of users, devices, and applications connected to the Internet is constantly growing, enabling more and more choices. A user must have access to a small set of applications available on the Net. In the early years of the Internet, search engines helped to navigate the Net. Later, vertical portals, such as Pet.com, and horizontal portals, such as Yahoo (evolved from the most popular search engines), helped to navigate the Net. Such issues as QoS and network security were ignored or left to the end user to deal with.

Service-Provider Vision

What must the service provider do to implement the vision of a manageable and secure Internet?

The first necessity is content and applications, which someone must produce. Another requirement is service creation. The provider should be able to customize and provide an application, or a set of applications, for its customers. The provider may wish to create its own applications or to have access to others that are creating applications for the Internet. Then the provider must deliver and manage the service by provisioning, configuring, maintaining, and charging for it. Because voice applications are part of the service portfolio, control and management of QoS is a must.

The service-provider vision must go beyond the typical Internet, where every user can access everything out there. To realize that vision, service providers must implement middleware functions—such as security, directories, policies, etc.—and back-office systems to provide the necessary support.

The Challenge

Realizing this vision requires surmounting some obstacles.

One obstacle is product maturity, particularly in a voice/softswitch space. Until recently, a provider could choose

FIGURE 5

Converged Architecture

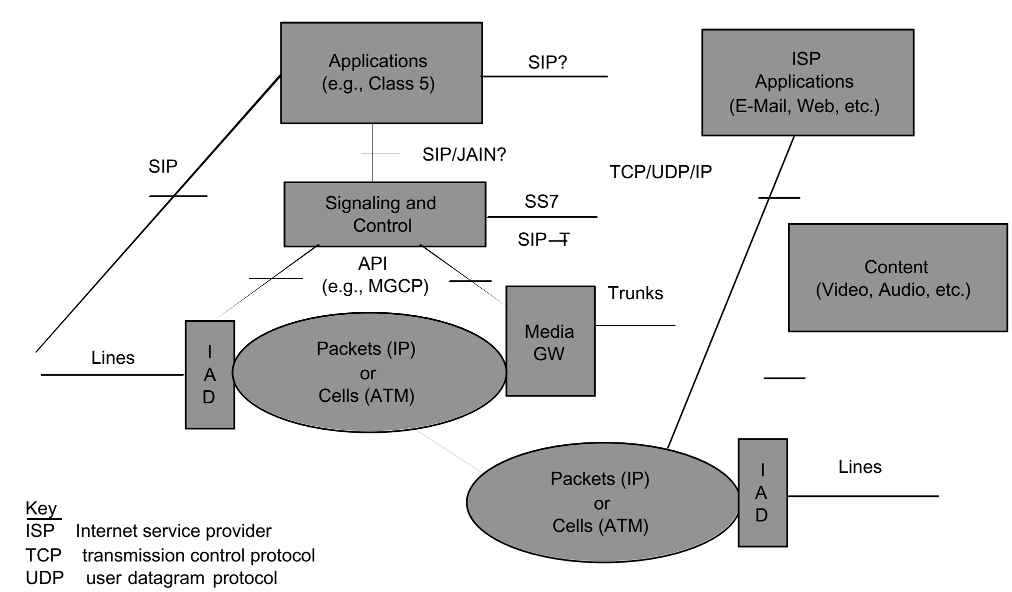


FIGURE 6

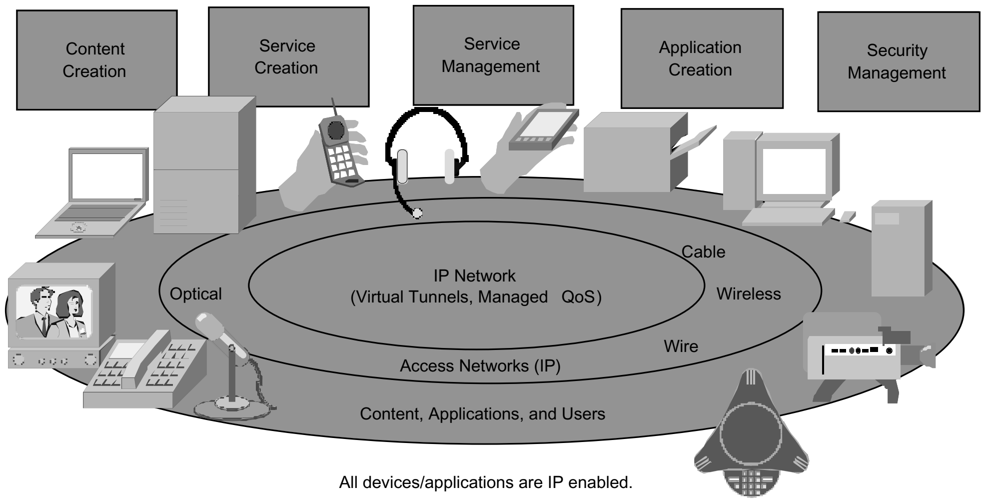
Vision



from only a few products. This picture is improving, however, and new vendors are bringing appropriate products to market. Product-release dates and schedule delays are other concerns. They create numerous problems as providers try to design a network that will implement the vision and meet target schedules, all while dealing with multiple vendors. Price is a key obstacle. Even if the provider offers SIP, customers will not accept the offering unless the price is right. But the provider must generate revenue in accordance with the business plan to survive in today's market.

Deployment

What is the solution? Deploying the best available solution and evolving it as soon as possible is the only way to overcome these obstacles. This approach will accomplish the vision.

Deployment of new technologies to existing networks carries some risks, but deployment of cutting-edge technologies and services in greenfield networks involves a very high risk—from scheduling problems and interoperability to the actual operations.

As an example: The greenfield voice service provider must be concerned with at least the following:

- Getting all common language location identifier (CLLI) codes in place
- Getting numbering plan area (NPA)–NXX numbers (pooling, lotteries, time limits, cumbersome processes, etc.)
- Getting SS7 connectivity
- Getting 411 services
- Obtaining Communications Assistance for Law Enforcement Act (CALEA) compliance or waiver
- Bridging a "culture" gap between the PSTN and the Internet

It is difficult to address the above because the process is cumbersome, random (e.g., lotteries), and not well defined, and the solution must then be implemented within a specific time frame or the process will need to be restarted. And perhaps, overcoming the cultural gap between the PSTN and the Internet is the biggest challenge.

However, the advantages are clear:

- Capital costs of a softswitch are dramatically lower than with a traditional circuit switch.
- Softswitch technology scales better, making it possible to employ a "pay as you grow" approach.
- IP switching also enables extremely efficient use of bandwidth
- The softswitch fits well in an IP network and enables an easy transition to IP services.

Conclusions

This discussion has presented a vision of an IP converged network that can offer a portfolio of new IP–based services and applications, including softswitch-based voice.

Obstacles to implementing the vision include product maturity, scheduling problems, operational challenges, price, and interoperability. Deploying the best available solution and evolving the network as new possibilities emerge can overcome those obstacles and lead the provider toward the goal: the fully realized vision of a fully converged and manageable network and services.

The Past and Future of Wireless

Martin Cooper
Chairman and Chief Executive Officer
ArrayComm

Business people in the United States are transfixed on the war on terrorism, the recession we've just entered, and the inevitable but elusive recovery. But the telecom industry has been in recession for some time. In fact, the telecom industry is in meltdown. Just look at the continuing layoffs, shrinking valuations, once respectable companies in a cash crunch, and some companies in deep trouble, and the only discussion, once again, is not "will there be a recovery this year," but rather, "will there be a recovery, at all, in 2003."

I respectfully suggest that there will not be recovery for most of the industry. Rather, in the long term, we will see a rebirth—a new telecom industry rising above the residue of the meltdown. Our industry has finally, after 120 years (yes, that's how long ago Alexander Graham Bell invented the telephone), started to grow up—started to escape from the burden of its monopoly heritage.

Things *will* get better, of course, but, in the short term, we will only encounter an illusion of recovery. The real recovery, the rebirth, will involve fundamental changes in our industry. Our industry will change because it has to change

The wireless segment is in just as much trouble as rest of the industry, but that trouble is largely masked by the continuing growth of subscriber usage. Wireless—cellular—is, today, an unfulfilled vision. Performance is marginal-to-poor everywhere. Infrastructure deployment is not keeping up with traffic growth, but it's difficult to find the capital to deploy more infrastructure when revenues grow only upon the addition of *new* subscribers. We are in recession, and there are just not a lot of new subscribers.

How will carriers get revenues going up again? The carriers have figured out that voice is just one data application and that the solution to the growth need is data applications. Data is now the Holy Grail—the brass ring.

But there's a serious obstacle. Our industry, all telecom but particularly wireless, has inherited some bad habits out of our monopoly legacy. Let me use the creation of cellular as an example. Let's start with some history:

The essence of our vision of cellular, when we developed it in the late 1960s and 1970s, was the unleashing of the consumer from the wires that chained them to their homes, offices, and desks. We were going to replace the wired telephone as the communications tool of an increasingly mobile population. We made good progress from the birth of cellular in 1983, but then "digital" wireless technology came on the scene and somehow there was a change in attitude. We lost our vision. The dream was replaced by hype and exaggeration totally unrelated to consumer benefit.

Digital technology did offer advantages to wireless operators. There was an increase in capacity—more subscribers could share the increasingly costly radio channels—but the only real advantage to the consumer was a valuable increase in battery life. There was a trade-off—voice fidelity wasn't quite as good as in well-designed analog systems, and phones cost more. But there was a net gain in subscriber value.

Then the "air-interface war" started. It became a religious war, unhindered by facts, with billions of dollars spent to change things—but often for changes based upon hype and exaggeration, on meaningless acronyms and technology-for-the-sake-of-technology with no real contribution to the original vision. We got into the habit of talking about technology to the exclusion of what should have been our topic—the consumers and their needs.

Third-generation cellular, 3G, is the culmination of that era of hype. For a while, we actually believed the 3G hype, and some still do. But the engineering and economic facts have been evident for years.

The Hype: A huge increase in subscriber capacity and delivery of data at speeds of 2 megabits per seconds (Mbps).
The Reality: A slight increase in capacity (we've already extracted most of the potential improvement in capacity from air-interface technology), and data speeds of just 64 to 100 kilobits per second (kbps).

The Hype: Delivery of multimedia.
The Reality: We're still trying to figure out what applications are practica,l but *multimedia*, in the traditional sense, is just not economically or technically possible.

The Hype: Internet on the move for *everybody.*
The Reality: The Internet has the potential to make practical a host of new applications that improve productivity, convenience, and safety as well as entertain and educate—but do you really believe that this can happen through a 4 centimeter window at 64 kbps on a device designed for voice over a system that was also designed for voice? NOT A CHANCE!

3G will happen! But it will serve specific markets and applications. Voice will continue to be major factor in cellular systems, but there will be a new class of systems that are optimized for Internet delivery and are unburdened by the need for "universality" that adds so much complexity and cost to 3G. 3G will happen when the focus returns to the customer—where it is in every other industry, not burdened by the monopoly heritage of the telecommunications industry that requires the carrier to "own the customer." 3G will happen when new technology is embraced that drives capacity and performance to much higher levels than 2G or 2.5G—technology that exist today but hasn't yet become a part of the 3G story. For example, there are smart antennas deployed today in more than 90,000 cellular base stations with proven capacity increases of 10 times or more, all at *lower* cost—but the traditional cellular industry has resisted this crucial innovation. The industry *must*, and will, open its mind to such new technology, and those companies that do will be the new leaders in the reborn telecom world.

i-Mode gives us an interesting peek into the future. Applications on i-Mode are not very profound; some are even trivial. The data rate is only 10 kbps. But i-Mode represents the first crack in the "walled garden;" the i-BURSTMode carrier, NTT DOCOMO, invites lots of creative entrepreneurs to find and exploit market niches. i-Mode is just a crack in the walled garden because NTT DOCOM still bills the customer (remember the legacy of "owning the customer"?) But just imagine what these entrepreneurs could do with, say, a megabit per second that is delivered at *really* low cost.

No one system will fulfill all of our wireless future. When the telecommunications industry grows up—and that process is happening now—we'll start with a service or an application, or a device that brings value to our customer, and then we'll invent the systems that optimally deliver those services to the customer. 3G will be one of those systems, but look for others—they will be there.

The wireless industry is in its infancy, but it's about to blossom out. Engines of that blossoming will be a new business attitude that focuses on the customer—the open platform—and new technology, such as adaptive smart antennas, that multiplies the use of the spectrum and new systems, such as ArrayComm's i-BURST, that are optimized to serve specific, previously unserved markets. The blossoming won't happen quickly—disruptive changes seldom do—but we'll see major changes during the next 10 years.

And what companies will survive? The ones that break out of monopoly thinking, that start with the customer and embrace, that create technologies that serve the customer best, that carve out market niches (perhaps huge ones), that serve classes of customers better than others do, in short, those companies that adopt strategies that release them from the "copper cage."

Notwithstanding the long-term nature of my predictions, there will be short-term opportunities in the companies that adopt new competitive approaches that serve lots of markets and that offer content that is meaningful—opportunities in technologies that really perform and in services that make people's lives better. You'll have to figure out who the winners and losers are. But things will change—don't say I didn't warn you.

This paper was presented at the Economist Conferences Seventh Roundtable on Asia-Pacific Telecommunications in Hong Kong on November 26, 2001.

Then and Now: A Perspective on Recent Changes in the Telecommunications Industry

Edward Cornet
Managing Partner
Booz Allen & Hamilton

The telecommunications and Internet industry has changed dramatically over the past decade, but never have changes been as abrupt and unsettling as those in the past two years. In this paper, I'd like to briefly review where the industry was then and where it is now, discuss some of the root causes of recent changes, and explore what the survivors should be doing going forward.

Where Was the Industry Two Years Ago?

Stock prices were high and revenues were growing. Investments were being made in new competitors. Infrastructure was being built at an astounding rate, and established companies were bold with new acquisitions to expand their footprints. The industry was enjoying a time of "easy money" for just about any good idea. Internal projects for new product development and market research were easily funded.

During the previous four years, a thousand new companies had started up to take advantage of the Internet growth spurt and the less regulated telecommunications market in the United States. Competitive and incumbent local-exchange carriers (CLECs and ILECs) as well as long-haul carriers were investing in infrastructure to handle the projected explosive growth in communications and Internet demand. Service providers were multiplying with special emphasis on non-facilities–based services and application services.

Public companies had "alliance capital" created by their strong stock price growth driven by their promises of future revenues. The inflated stock prices gave companies increased equity to expand their businesses. Banks were willing to increase debt ceilings as stock prices rose, even though revenue growth was speculative. As new infrastructure was built, deeper depreciation wells were dug in the balance sheet.

Some of the alliance capital was used for acquisitions to expand market footprint or add broader value-chain service capabilities. Some alliances had no apparent strategic objective, but rather seemed to be more of an exercise of management power. Even alliances with strong strategic rationale suffered from little or no serious post merger integration activity to streamline costs or capture value. Management was allowed to get sloppy as enthusiasm for future growth became widespread.

Businesses capitalized on some exciting technology trends. Voice/data convergence, voice over Internet protocol (VoIP), seamless open networks, and video streaming promised to unlock hidden demand. Dense wavelength division multiplexing (DWDM) and Internet protocol (IP) technologies would drive the cost per byte to zero. Advanced wireline technologies, multiprotocol label switching (MPLS), asynchronous transfer mode (ATM), IPv6 protocols over cable, fiber, or digital subscriber line (DSL) would enable broadband everywhere. Long-distance voice and international Internet access would become affordable for all. Third-generation (3G) wireless networks, code division multiple access (CDMA)2000, and wideband CDMA (WCDMA) were on the horizon. Users would be on line everywhere, all the time. Fixed/wireless convergence would create a total access world. Investment bankers and others were willing to fund just about any good idea tied to an advanced technology.

The concept of access to anything, anywhere, anytime seemed possible—and right around the corner. The big questions were: how quickly were we going to get there? And if you hadn't started already, how could you catch up?

What Happened?

The number of competitors grew rapidly, diluting the existing demand. Competitive pressures drove down prices. Thus revenues failed to materialize as promised. Meanwhile costs continued to grow. Positive cash flow was delayed. Additional investment was required, but investor confidence was lost. Start-ups were unable to secure additional capital to fund operations, and bankruptcy followed. Many non-infrastructure–based companies folded entirely. New infrastructure companies were restructured with their assets valued at cents on the dollar. Even the larger, established companies with positive cash flow were affected—forced to stop further investment and cut operating costs to meet shareholder demands. The bubble had burst.

What Were the Causal Factors behind the Collapse?

1. *The most common problems were incomplete business models.* In the dot-com world, the focus was the concentration of "eyeballs" on the Web site or page hits that generated the hype versus real customers or revenue streams. The survivors had models based on fundamentals. For example, Amazon.com's foundation as a bookseller is based on a very sound financial principal. It was competing against local bookstores. The Amazon.com principle was to significantly reduce the costs to the reader. They recognized that about 35 percent of the cost of the retail price is tied up in unused inventory. The books that are on the shelves that are not sold must be shipped back to the publisher, and the publisher reflects that cost in their prices to bookstores. With the Amazon.com model, a single warehouse serving all of the United States—in fact many areas of the world—was able to cut out almost all of that 35 percent.

   Another good example of a solid business model is America Online (AOL). AOL's value proposition is much more subtle. Its business model is to use technology to create an Internet portal with repackaging of information coupled with a simplified user interface that opens up the World Wide Web (WWW) universe to the average consumer.

   Part of the reason that the incomplete business models received funding in the first place is a result of investor frenzy. Many venture capitalists got their money from the first wave of the dot-com craze either as investors or owners. They developed a sense of investment invulnerability, a Midas-touch self-image. For those who had not been involved before, there was a bandwagon effect. The new venture capitalist and the new investors were exercising less due diligence and relying more on instinct, anxious to be able to reproduce the magic of the first round of dot-com successes. Unfortunately, the investors and the new venture proponents began to believe their incestuous string of market projections. And that led to many companies being started that really had no business being in business.

2. *A second reason for collapse was hyperextension.* The hype of unlimited growth and easy money drove companies to invest in expanded infrastructure or corporate acquisitions far beyond the limits of reasonable returns (given today's 20-20 hindsight). Existing carriers or operators, or new carriers aggressively deployed infrastructure using new technology that did have significant cost advantage in the long run. This includes fiber optics, DSL, and fixed wireless technologies. Examples include Global Crossing, NorthPoint, Teligent, and Windstar. The market-cap hype gave them the financial backing to deploy infrastructure at several times more capacity than was reasonable for them to capture considering projected demand and feasible prices.

   Incumbents with existing infrastructure seemed at a disadvantage. They were saying, "How can we compete with these new guys? Our infrastructure is old. Our infrastructure is limited. Our current infrastructure can't compete on a cost to serve basis against these new players." Today they're feeling lucky that they were slow to react.

   The other area of hyperextension consists of companies that wanted to use acquisitions to expand their position in the value chain. Telecom network operators were buying service providers to gain presence in new markets, or network operators or service providers were buying system integrators to get more of that value-chain dollar. They had the money to do it because they had the inflated stock prices. They had the alliance capital. But they lacked the strategic plan and the post-merger integration capability to capture the value from the acquisitions. A good example is PSINet.

3. And last, but not least, *poor execution across several key functions was a major contributing factor to failures.*

   Product Definition, Marketing, and Sales
   I differ with many in the press in terms of why Iridium collapsed as a business. I don't believe that it was because the business model was flawed. I believe it was because execution was inadequate. They knew at least two years before they launched service that they had to have a dual-mode phone capable of penetrating buildings using an existing cellular network, while capable of working outside of cellular coverage via the satellite network. They knew that phone had to have a price of less than $500. Their extensive market research made this clear. But after spending almost $4 billion on the network, their Board refused to spend an incremental $25 million to develop an acceptable handset in time.

   Iridium and its regional investors also failed to execute in marketing and sales. The concept was born in the euphoria of the early 1990s, when cell phones were an oddity, and the view was that people would beat a path to their door to get service. But the service arrived in the market in 1998 when most wealthy people in developing countries had cell phones. The subset of people who needed the additional satellite service coverage had to be actively marketed and sold, but the effort was not there. Teligent and Windstar also had issues in the areas of marketing and sales, and product definition.

   Provisioning and Customer Service
   Provisioning and customer service were also fundamental causes of failure. The DSL CLEC failures in many cases are tied to these types of fundamentals. One of our clients had a 90-day waiting list for service for new customers. They couldn't provision fast enough despite increased personnel because they hadn't really worked out all of the difficulties involved in doing so. This was complicated by lack of cooperation

from the incumbent. The CLEC, however, could have foreseen most of the complexities and been prepared. As the problems arose, the CLEC didn't react well to the complexity and wasn't prepared for process improvement. The problems were fixed with a process redesign, but not before six months of prior marketing and sales efforts were wasted and a host of disgruntled early adopters dampened further sales growth.

There are other issues with customer service. Many service providers implemented new technologies but did not anticipate the needed changes in customer-service approach. By default, the customers were the guinea pigs and the customer-service people were unprepared to handle both the volume and complexity of service issues. Thus customer satisfaction declined and churn rose leading to slower than expected net revenue growth. They could make the sales, but they had to overcome growing churn to achieve net growth. Many of the newer mobile wireless carriers suffered (and continue to suffer) from this problem.

As a result of slower than expected revenue growth, everybody's stock price was down. Investors began to have second thoughts about further investments. There was admitted self-doubt on the part of the smarter major investors as they became more conservative because they had made calls on things that didn't pan out.

Many of the smaller, established companies ended up in Chapter 11 even after significant Draconian cost-reduction measures. Even the larger companies were forced to reduce head ranging from 30,000 in a giant company such as Alcatel to thousands in just about every good-sized telecommunications company, including major carriers such as Sprint.

In many cases, investments were deferred or cancelled. Research and development (R&D) or product development, or pilots or new network rollouts, were reduced in scope or stopped.

To compensate for slower revenue growth, capital-management programs were instituted looking at inventories, receivables, and supplier payment contracts. Suppliers were rethinking those vendor financing agreements that only 24 months prior had seemed like such a great idea in backing the network of a new upstart company.

And last but not least, the companies that were going to survive and felt comfortable recognized that they had a good product and that customers would be willing to pay a little bit more for it.

How to Weather the Storm

In the following there are some guidance to service providers, network operators, and equipment manufacturers on what should be done until the market sorts itself out.

What Should Service Providers Do?

- *Streamline their operations.* Go back to the basics of your business: provisioning. The waiting lists are still too long. Some installers are untrained, inefficient, and inept. There are too many callbacks, which hurt profitability. The service-quality complaint levels are still too high. In many cases, the provisioning processes are not well designed. Get customers provisioned quickly, correctly, and cost-effectively.

  Self-provisioning is a great concept. Many in the industry are working on the issue. It is a terrific idea. But it will need time to be fully developed, such as Microsoft's Plug-and-Play concept. Plug and Play has been around for several years as an idea. But even now adding a new piece of hardware or software to your computer embodies an element of risk. There's a big gap between concept and reality. Likewise, self-provisioning is a wonderful concept, and working toward it will be a rewarding task—but it is not going to happen overnight. And it is not going to happen easily. Keep at it.

- *Customer service should get back to the basics.* Take the time now to clean up customer service and turn it into customer-relationship management (CRM). The data in the industry points to poor customer service as the number one reason behind churn. In churn surveys, people say, "It is my coverage. It is my bill. It is my quality of service." Those are the reasons for the first customer-service call. Frustration builds as, during the first call, it takes several minutes to speak to a human being; then the human being asks you to repeat all the information you just gave to the automated voice response system, (causing increased frustration); and then you are put on hold for several minutes. If the problem is resolved favorably at this point, the service provider probably lives to fight another day. If the problem is not resolved, few have the patience to try again with the same service providers.

  Customers value their own time. Most don't have an assistant to do all this dirty work, so prompt and accurate service response is essential. Voice response systems have saved costs, but some implementations have not resulted in better service. The CRM processes and system requirements should be reviewed against the current metrics of churn, customer satisfaction, and cost.

- *Trim the service portfolio.* Over the years, service providers have developed a broad set of services. Look at what is selling and what is not. Try to understand why and why not. Look at what you are making a profit on and what you will be able to make a profit on. Make the hard calls, because you probably can't afford to support all of those services any longer.

- *Sharpen your customer focus.* Review customer profitability. Think about customer lifetime, customer acquisition costs, the full life cycle, and the total cost and profit of ownership (TCPO). View TCPO from the customer perspective. Think about the total cost and profit of service, and understand the needs of your customers. Take the time now to really understand your customers. Your customer data is a wealth of market information at your fingertips. You are probably not getting the best use of this information today.

- *Get creative on pricing and bundling.* But do it smartly. Bundling is a great concept, but it needs to be done to reflect the customer needs. Bundle to reflect true economies in your pricing and reflect the true value added to a customer of the combined service. The concept of "one bill" is sometimes the only excuse for a bundle. This doesn't cut it alone, not with the business and consumer customers that we have polled. They are much more sophisticated than that. They recognize that in many cases on the Internet, they can create their own bundle from multiple vendors and get automatic billing to their Visa or AMEX card for any combination. So, "one bill" is seamless to them. Let your prices reflect your cost to serve, the higher volume that you can achieve through pricing campaigns, forward pricing, and truly enhanced customer value in the context of the new competitive situation.

What Should Network Operators Do?

- *Replan for network expansion.* If you are operating a network today, your engineers know more about what is going on in the market than the best of the market research companies. They know the hot spots of the growth of demand, and they can tell you how much of that growth is coming from increased use by your current subscribers versus use by new subscribers. These are important vectors. It is the best information you can gather of where things will be going during the next six to 12 months.

  This information can also let you know where are you under-utilized and where are you over-utilized. This information should be used at the strategic planning level, not just for network planning. Network planners or network engineers need to have raised visibility in the company, because they have information that has important strategic corporate value.

- *Implement stop-gap measures.* Where can the infrastructure be upgraded rather than replaced? Where is a phased replacement or upgrade necessary and possible? How can under-utilized elements be reused or redeployed? The engineers can figure out what is possible. Again, engineering can add value at the corporate level.

- *Make the right next move.* Carefully plan your next major deployment. Vendors may be disappointed to delay that big sale. Carriers may have to wait to solve all of your current network's problems with the next-generation network. Choose the move that makes the most sense for your markets and your financial situation.

- *Make the next move right.* Think of this as an opportunity to really plan what you are going to do next. And not just the deployment of a network, but also how you are going to sell it, how you are going to provision it, and how you are going to provide customer service to it. Take a holistic look to provide a superior user experience. Select the right technology and develop a strategy for trials and pilots of the processes and systems. Take the time to ensure the quality of the end-user experience.

What Should Equipment Vendors/Network Integrators Do?

Right size your organization to the new market realities.

- *Trim the product lines.* Can you afford to have all of your current products in service at once? Rethink the R&D pipeline. Think about an old term, P^3I Preplanned Product Improvement, because the carriers are thinking that way. They're thinking about how to get by with lower capital expenditures (CAPEX). You are going to need to right size your capacity, whether it is the factory floor, fabrication facilities, R&D, product engineering, or system integration. You are going to have to right size it because explosive growth has stopped. Prepare for a more modest pace of growth in the industry. Those of you who are the survivors, there's a wave of consolidation about to occur, which will lead to subsequent right sizing until a profitable balance is again established.

- *Optimize capital management.* Look at inventories, supplier relationships, etc. There are a lot of things that can be done to free up capital and reduce operating costs.

- *Review supplier relationships.* How many different suppliers are required? Understand the difference between a vendor and a strategic supplier. A vendor is one of several suppliers capable of providing you a similar commodity at a similar price. A strategic supply partner has unique capabilities key to your business success. You can work together in product R&D and inventory control to support mutual future success. If you hadn't already put these on a strategic footing, now is the time to do that.

- *Nurture customer relationships.* The service-provider and network-operator customers that you have today should be the customers of tomorrow. And although they may be buying only small bits and pieces over the next 12 months, in many cases, those bits and pieces may be the foundation for their next major CAPEX. It is wise to selectively invest to help your customers really understand the value that the features and pricing of your new technologies can have in making those customers succeed with their customers.

Summary

The telecommunications and Internet market opportunities are still there. The fundamentals of the industry are sound. Five years ago, a 10 to 15 percent per annum growth was projected for service providers for this time period. Although these estimates were viewed as conservative or pessimistic two years ago, they are probably the baseline today. The problem is that during the last two or three years, people geared up for 20 percent per annum growth, which I don't think is going to happen.

The technology and business capabilities are just as great, but they have value-chain implications to be understood. Technologists, engineers, and product developers are developing new products that still obey Moore's Law. That is, they can create longer-lasting products with more capacity, more functionality, and more capability at lower cost. So, if the service-provider revenues are going up at 10 to 15 percent per annum, network operators will likely be in the 8 to 12 percent range, and equipment manufacturers will be in the 5 to 8 percent range. Those with better service concepts, better products, or better execution will rise above the averages as they gain market-share.

During the first quarter of 2002, there was a transition from a stop to the more modest growth rates just noted. In this lull, the industry has time to do some of the things that were neglected in the rush of the past three years. Regroup. Take stock of where you are. Rethink your strategy, where you want to go, and how you want to get there. It is time to establish a foundation for future growth.

Now, which companies will be the future winners? As for specific companies, I don't know. Hopefully, some of the recommendations that I have given will be useful to achieve success. The best guess is that the winners will be those that do the following:

- Conserve their current resources
- Develop an honest assessment of where they are
- Develop a clear strategy built on their unique market position
- Create a practical implementation plan to execute the strategy
- Persist in execution while learning and adapting to change

Scarcity and Complexity

Re-Defining Carrier Networks in the Age of Bandwidth and End-to-End Ethernet Solutions

Philip K. Edholm

Chief Technology Officer and Vice President of Network Architecture, Enterprise and Optical Ethernet

Nortel Networks

Executive Overview

In any system, there is a balance of complexity versus scarcity. When things are scarce, we implement complexity to allocate that scarcity to those elements requiring it the most. When things are plentiful, the allocation systems can be simple. One of the most interesting changes in any environment is when something that is perceived to be scarce becomes plentiful (or vice versa), upsetting perceptions about allocations and complexity. Today we are experiencing such a transition—from bandwidth as a scarce resource to plentiful capacity

The evolution of computing from mainframes with card decks to mini-computers to desktop personal computers (PCs) is an example of a transition from scarcity and complexity to distribution-reduced controls over a 30-year period. One of my professors, when I was a young computer-science student, related the following: When building 10 units of a system, you buy all the hardware you can afford to minimize the investment in software development; when building a million units, you optimize the software to minimize the cost of the hardware. While this concept is obvious to the most casual observer, the challenge is what to do when you are building 10,000 units—obviously, we are trading complexity in one part of the system to minimize scarcity or cost in another. Ongoing assumptions about relative scarcity and complexity works well in a world that is changing slowly, but these assumptions need to be re-examined when scarcity changes dramatically (the advent of application-specific integrated circuits [ASICs] and large-scale field programmable gate arrays [FPGAs] reduced the custom hardware volume point dramatically).

This paper anticipates that fundamental changes in network elements and traffic will dramatically shift the balance of bandwidth, complex control, and management that currently exists. The advent of highly variable data-rate edge traffic of multiple classes over a consistent end-to-end Ethernet/Internet protocol (IP) structure and the explosion of cost-effective bandwidth will enable a fundamental redefinition of the relationships of complex and scarce elements. The result will be a dramatic transformation not only in how we invest in network equipment, but also in how we manage and provision those systems. While this transformation has already begun in the Internet world, it will have dramatic impact on the more traditional enterprise networks as well as on the overall network infrastructure. This paper investigates these trends and their impacts on network architectures, provisioning, and management.

The Bandwidth Phenomenon

Traditionally, the mechanism of delivering services over carrier networks has been to implement circuits that provide connections between computers and sites. (In fact, the applications were designed to run on point-to-point circuits.) As data communications has become more prominent, new technologies, such as frame relay and asynchronous transfer mode (ATM), have emerged that are more suited to the bursty nature of data applications, while maintaining the circuit topology. However, at the core of today's network philosophy are concepts that tie together edge services, circuit provisioning, and core engineering into a tightly interwoven set of functions.

Within these networks, the management and operation of the network are defined based on a combination of resource availability and traffic characteristics. In the voice world, all circuits were of relatively fixed bandwidth, and networks were designed to accommodate that need. As data services became more prominent, the traffic variability led to new services, such as frame relay and ATM, with variable rate capabilities. At the same time, bandwidth continued to be a critical scarce resource in networks. This was made painfully clear as the demand laws of computing began to drive the network service demands. While voice demands are driven by simple growth in the number of users and average use (as a voice channel is "fixed" at 64 kilobits per second [kbps]), data demands are driven by Moore's Law (silicon doubles in capacity every 18 months—and applications and files follow suit), Metcalfe's

Law (the value of a network is an exponent of the number of users, and the traffic grows at an exponential rate—witness the number of Cc:'s on your recent e-mails), and major transformational events (client-server computing, the Internet, etc.). The result is that bandwidth demands since 1990 have been increasing at two to three times per year (and even more in the explosive time of Internet growth). The result has been a scarcity of bandwidth at many levels of the carrier infrastructure.

Coming from a circuit perspective and a scarcity of bandwidth leads to a plan of network operation that optimizes network implementation and operation to accommodate those parameters. So most carrier service networks today provision individual circuits and use that information to mange and allocate end-to-end bandwidth through the network. The concept of "end to end" results in a complex management task at both the edge of the network and within the core elements In other words, we trade complexity of operation and control to provide a guaranteed service and end-to-end provisioning of that service. The result is a minimization of scarce resources (bandwidth and associated components). This philosophy has extended to new networks as well. Both ATM and IP networks have employed a mechanism to reserve bandwidth on an end-to-end basis (resource reservation protocol [RSVP] for IP). The assumption for this type of mechanism is that bandwidth is scarce and must be optimally provisioned and allocated and that the average traffic requires service-level agreement (SLA) parameters guaranteeing delivery and latency.

An interesting side point is that the Internet, emerging as it did from an any-to-any environment, was operated and managed (within the fashion that the technology enabled) as a network where the core infrastructure was provisioned and controlled separately from the edge service connections. However, as the network was designed as a best-effort system, the capability to deliver more sophisticated service guarantees did not exist.

It would appear that we are on the verge of a profound transformation in how the networks are operated and provisioned. This transformation is based on three convergent forces: plentiful bandwidth, convergence to IP/Ethernet traffic, and multiple service classes that will dramatically change the way in which we think of network structures.

Through recent technological advances, bandwidth is becoming plentiful (while not free). This is the result of the explosion in optical bandwidth brought about by dense wavelength division multiplexing (DWDM) and new laser technology (jumping to 40 gigabits per second [Gbps]) as well as fundamental changes in the requirements and devices required for forwarding at network connection points. The convergence of traffic onto Ethernet (99 percent of all enterprise traffic starts and ends as Ethernet) and IP (now the dominant protocol) has reduced the complexity of the devices. As the tasks required have become stable, they can be moved into silicon. In fact, the advent of multiprotocol label switching (MPLS) (or generalized MPLS [GMPLS]) as a forwarding mechanism in the transport core holds the promise of delivering an exponential increase in bandwidth over the emerging optical capabilities. Optical bandwidth has been doubling every nine months since 1997, and the cost per bit has dropped by 50 percent every nine months in the same period. Together, this represents an increase that is eight times greater than Moore's Law and is increasing at about six times per year. The movement (begun in the enterprise) of using highly specialized ASICs and network processors to manage the traffic at intersection points appears to be capable of keeping up with this demand. The result is that we have a "bandwidth glut" for the first time since the advent of the computing age. This trend is extending to the edge of the network with the recent explosion of optical Ethernet in metro networks. By using Ethernet both as a basis of service offer and as a transport element, the bandwidth available in the last mile and in the metro is increasing exponentially. Service offers of 100 Mbps or 1 Gbps are now being delivered. When combined with the existing enterprise campus bandwidth (typically 100 Mbps per desktop), this portends a dramatic change toward bandwidth abundance.

The Traffic Phenomenon

The explosion of bandwidth demands, as driven by computing engines, has very different characteristics than previous traffic. It is highly bursty and cyclical. The variability at the edge of the network is extreme. Also, to support the next generation of applications (such as streaming, storage), bandwidth operational rates are much higher, further exacerbating the problem. At the same time, applications are converging to common transports (primarily IP and Ethernet). Where previously separate networks were often deployed for voice, mainframe data, e-mail, etc., the convergence brings all of these traffic types into a single network interface. This enables a re-thinking of the trade-offs between service types and how the traffic is managed across the network.

As different traffic types converge, the variability of requirement can be used to manage their individual demands, simplifying the network. A typical SLA can be defined with four variables: bandwidth, delivery guarantees, latency guarantees, and availability. By varying these four parameters, different classes of traffic can be easily defined that meet different applications needs. For example, voice requires relatively low per-user data rates but has high requirements for delivery and latency guarantees as well as high availability requirements. A contrasting best-effort service, potentially used for Web browsing and non–real-time apps, such as e-mail, would have higher bandwidth needs (especially instantaneous), while being able to use much lower delivery and latency guarantees and lower availability. Mission-critical data lies somewhere in between.

Convergence and Change

The impact of the three convergence elements (bandwidth, bursty, and different traffic types) will be dramatic. *Figure 1* shows a simplified representation of a projection of traffic types from 1980 to 2010 using percentage of total traffic. The vertical axis is percentage of total traffic. As can be seen, in 1980, 98 percent of all traffic was voice, and, by 2010, less than 10 percent of traffic will be voice (including videoconferencing). In addition to the voice/data transition, there is another factor that is impacting the traffic model. Prior to 1995, virtually all data traffic was mission critical. In other words, it was traffic that was absolutely required to run a business or other function. However, in 1995, the advent of the Web browser and the World Wide Web (WWW) changed that paradigm. Casual Web browsing and attendant bandwidth uses have created a new class of traffic, commonly known as "best effort." *Figure 2* anticipates the growth of best-effort traffic impact on the model. As can be seen, now the traffic percentages are not only becoming predominately data, but the best-effort traffic is also becoming a significant if not dominant part of the overall traffic. Finally, prior to the bandwidth explosion, networks were operated to maximize bandwidth fill. Significant activities were undertaken to assure that the network was operating at 80 to 90 percent of capacity whenever possible, maximizing the return on scarce resource investments. However, starting in about 2000, the impact of the bandwidth explosion has been changing the fill requirements. In fact, as the cost structures of DWDM, 10-Gigabit Ethernet, and next-generation MPLS systems impact, the cost of increased bandwidth becomes much less. The result is shown in *Figure 3*. Prior to 2000, the network capacity was only slightly above the demand, but that gap is increasing (or will increase) where the new technologies, such as optical Ethernet, are available.

The result of these changes is a rethinking of how services are delivered and provisioned, and of how the network is managed. Systems such as ATM and RSVP (see *Figure 4*) were defined when the relative balance of traffic types and fill required extensive management and reservations to deliver cost-effective solutions. However, as we look forward, we see a dramatically different world. As the different traffic types each have different requirements, by properly classifying the traffic and then managing the operational parameters of the infrastructure, we can easily deliver a SLA that meets the customer requirements. For example, by giving the small percentage of traffic that is voice a traffic class that has absolute priority of transmission and no discard, the class will be transmitted through the network without any impact of the volume of traffic in other classes. As can be seen from Figure 4, the combination of the emergence of, first, mission-critical data and, next, best-effort data, when combined with the cost-effectiveness of operating the network at a lower fill percentage will make the management of diverse services easy. This is further emphasized by looking at the trend over the past five years in enterprise campus local-area networks (LANs), where exactly these mechanisms for classification and management using simple class of service (CoS) without guarantees are common. The failure of ATM and RSVP to build campus LANs is a result of the ease of managing multiple service types (including real-time) over a network that has over-provisioned bandwidth headroom and simple CoS classification and queue-management operation. As shown on *Figure 4*, the advent of simple differentiated services (DiffServ) in the Internet Engineering Task Force (IETF) anticipated these changes.

FIGURE 1

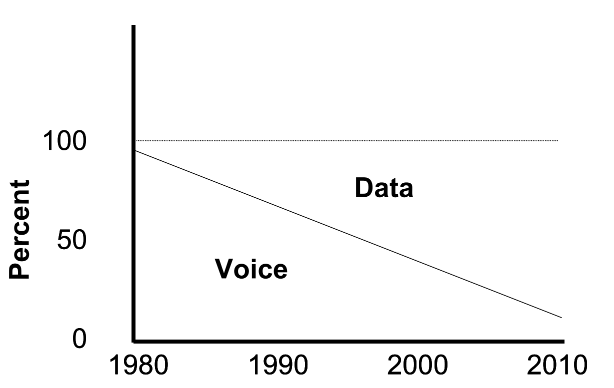


FIGURE 2

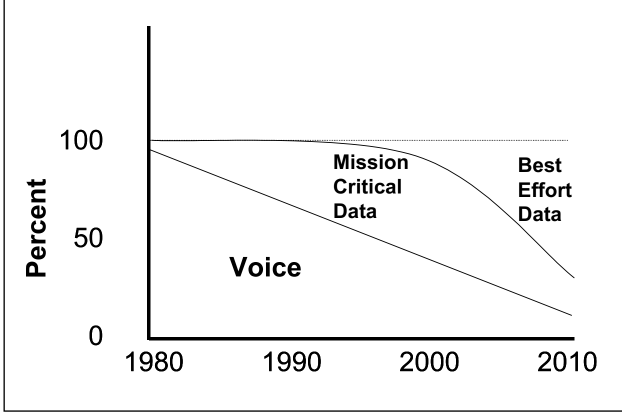

FIGURE 3

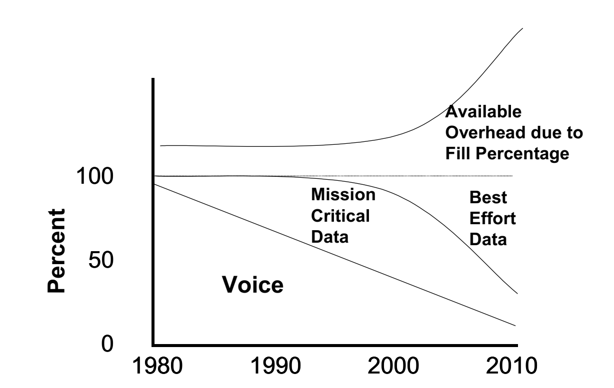

FIGURE 4

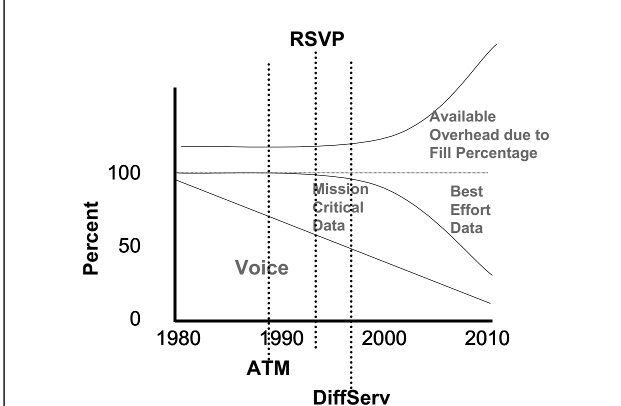

Reducing Complexity

By taking advantage of the changes discussed earlier, it may no longer be necessary to manage the network as end-to-end connections. In fact, managing the network as an access edge and a separate core will be a major change that will be enabled. *Figure 5* shows the demarcation of the customer (CE), the provider edge (PE), and the transport core. At the edge of the carrier network, there must be a user network interface (UNI) that defines the service characteristics on the interface to the customer. The UNI defines the forwarding mechanism (Layer 2 or Layer 3) and the SLA characteristics (bandwidth, delivery, and latency guarantees and availability). The SLA must be managed and provisioned on an individual port/customer basis. However, once the traffic has left the UNI and entered the transport, using the aforementioned techniques, traffic can be managed using simple techniques. As shown in *Figure 6*, this creates two distinctive management systems. The edge system configures and manages the UNIs based on the services purchased and the associated SLAs. Traffic is classified according to the SLA and input to the transport core. Within the transport core, individual flows are not the critical element. Rather, the aggregate rates in any given class on any given link become the key criteria. Therefore, while the edge is managed as individual customers, the core is managed based on link operation and predictive intelligence that will anticipate resource utilization. This may include predictive systems that can predict the impact of a new customer entering the network based on the locations and SLA parameters. This will enable checks of operational impact prior to allowing the new customer on the network (or allowing request-to-change SLA parameters).

The result of this stratification is dramatic reductions in operational expenditure (OPEX) while having minimal capital expenditure (CAPEX) impact. Today's carriers spend about 60 to 70 percent of their expense in the OPEX category. The explosion of bandwidth, combined with the complexity of multiple traffic types on the same interfaces/networks, will further increase the complexity. If today's mechanisms of individual provisioning and management across the entire network with end-to-end operation for each circuit (or virtual circuit) continues, OPEX will only grow, both in absolute dollars and as a percentage. However, if we assume that bandwidth costs are becoming nonlinear (doubling the bandwidth does not double the cost as it is the same fiber, the same chassis, etc.), a reasonable CAPEX will change this. In other words, spending 25 percent more in CAPEX will generate a 25 to 50 percent reduction in OPEX by stratifying the UNI service edge from the core. The results are as follows in *Table 1*:

The result is a 10 percent reduction in relative cost, while delivering services for which enterprises have indicated that they will pay incremental pricing (10–20x the bandwidth at 1.3–1.5x the price). In addition, the reduction in CAPEX to purchase complex end-to-end provisioning and manage-

FIGURE 5

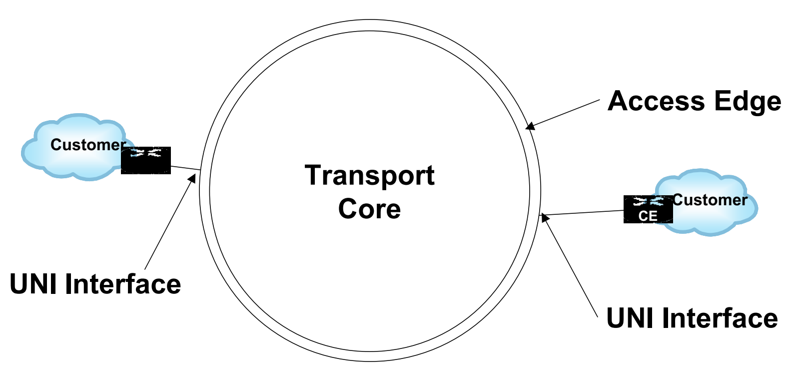

FIGURE 6

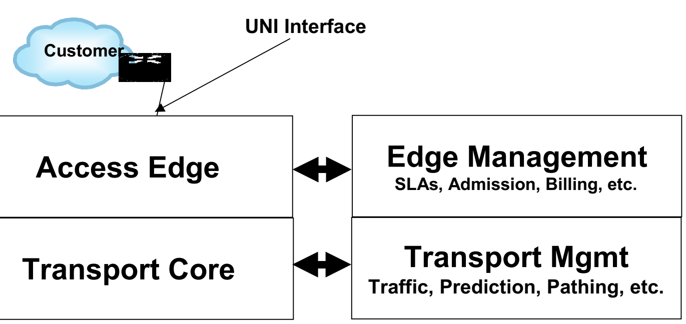

TABLE 1

	Today		*Tomorrow*
CAPEX =	35%	x 1.25 =	43.75%
OPEX =	65%	x 0.7 =	45.5%
Total	100%		89.25%

ment systems may in fact equal the added cost for transformation bandwidth, delivering another 5 to 10 percent of expense reduction. According to a study done by McKinsey & Company and Goldman Sachs, given the rapid growth of data traffic demand over the next few years, unless service providers are able to reduce OPEX by 25 to 30 percent per bit carried for each year through 2005, no reasonable amount of CAPEX reductions will allow them to meet targeted return on invested capital.

Architecting the Future

Delivering the aforementioned capabilities and benefits requires thoughtful analysis when defining architectures. Within the context of the network, the UNI is a thin layer at the edge, only used to define and manage services and assure that SLAs and classifications are properly managed and policed. The rest of the network can be thought of as the transport. Within the transport infrastructure there are forces that drive certain allocations of resources and intelligence. From a CAPEX perspective, *Figure 7* shows cost allocations based on cost per port/customer and per unit. On the left, costs allocated by port/customer are primarily at the edge. This is because each customer must have separate port, access, fiber, etc. However, these edge devices are individually inexpensive. As we move further into the network, individual devices become much more expensive, but they are far fewer in number and amortized over all of the network customers. At the very core, long-haul fiber is incredibly expensive but is the amortized base for all services. To minimize the cost of an infrastructure, it makes sense that (as the arrow shows) intelligence and complexity should be pushed up in the network. This "centralization" reduces complexity, CAPEX cost for the devices at the edge, and amortizes the function over the user base.

Figure 8 shows the same model but for network bandwidth. Individual bandwidth is greatest at the edge, especially in data networks where peak to valley edges can have 3–10x variations. As we move back in the network, the smoothing effect of statistical variations causes the per-customer bandwidth that must be supported to decrease. However, as shown on the right, the link speeds are highest at the core (and the attendant packet processing rates). For example, a network of 100,000 100 Mbps user ports (10 petabits), with an average SLA of 20 Mbps and a average use of 5 Mbps, would need a core capacity of only about 1–2 petabits. Assuming some duplication for capacity in failure and some inefficiencies of the core, the 2 petabit core is reasonable. Assuming this was implemented using 10-gigabit links, there would be 200 links in the core.

While cost tends to push complexity and intelligence up form the edge, achieving the bandwidth required tends to push it down from the core. Complexity is the bane of achieving speed, and complex decisions are virtually impossible at very high speed. The result is that virtually all networks are architected as shown in *Figure 9*. There are three layers: an inexpensive simple edge, a fast simple core, and a layer of intelligence between. This architecture often is depicted as a set of concentric circles, as shown in *Figure 10*, but the result is the same. This partitioning of functionality enables the operation of the network into a logical arrangement that optimizes both cost and performance. Past networks have either been designed or have generally evolved to this structure over time. For example, a frame-relay network has simple edges (point-to-point circuits—not necessarily low cost due to tariffs) connected to an intelligent node that provides the service structure. These intelligent nodes are connected together through ATM or synchronous optical network (SONET) structures that provide fast unintelligent transport.

Building the next generation of networks will involve rethinking our assumptions, as previously discussed, but doing it within a framework of an allocation of resources.

FIGURE 7

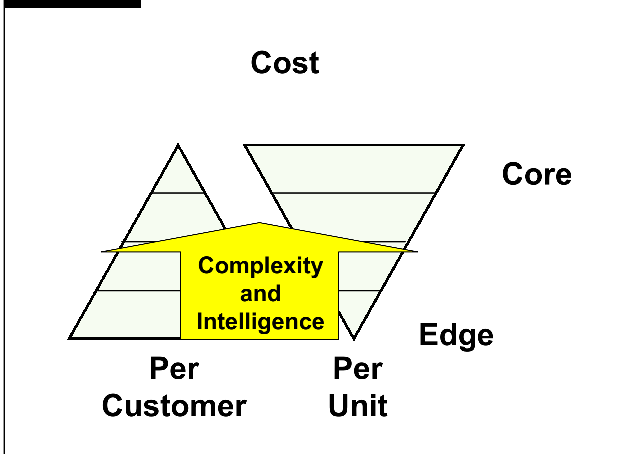

FIGURE 8

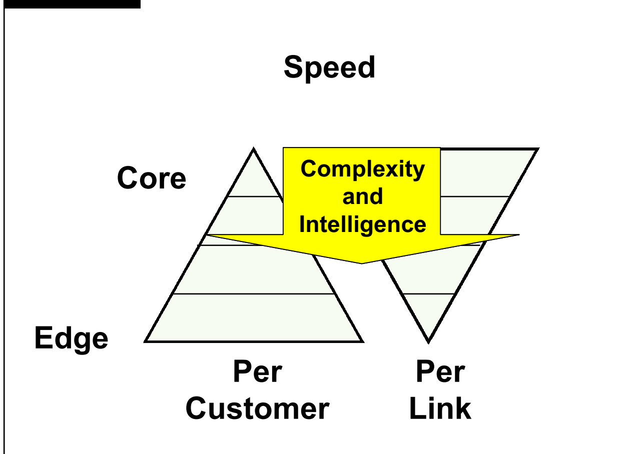

FIGURE 9

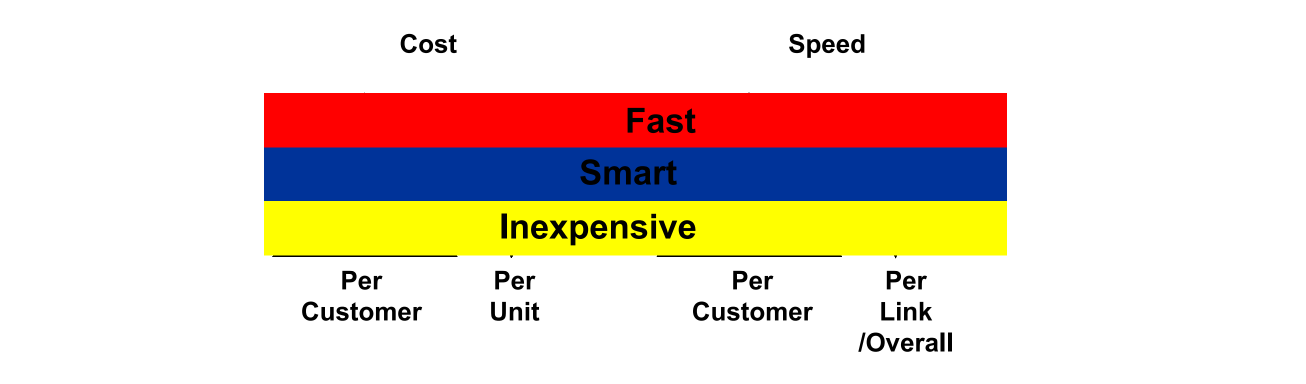

One critical element of this thinking is the relationship between the metro and the long haul. The emergence of MPLS and GMPLS along with high-speed optical appears to define the core of these next-generation networks. The challenge is how to intelligently connect these cores to the customers. Optical Ethernet, delivering services (either Layer 2 or Layer 3) over Ethernet connections, seems to be the preferred mechanism for next-generation edges. This solution allows the enterprise traffic (which is 98 to 99 percent Ethernet in the campus today) to remain Ethernet end to end. While traffic will remain Ethernet end to end, decisions in the processing of packets will be made a multiple layers. *Figure 11* shows the structure of the lower three layers of the network model circa 1990. As can be seen, the early explosion of creativity and invention in networks created a large number of competitive (or at least co-existent) protocols and media/control.

During the late 1990s, organizations converged on IP as the common Layer-3 protocol, and within enterprise campuses Ethernet became the dominant solution. *Figure 12* shows the 2001 protocol map. In all technology solution sets, each layer tends to converge on a de jure or de facto standard. The same convergence seems to be happening at Layer 2, where Ethernet is fast becoming the converged standard. This is based on the enterprise preference, the end-to-end values of commonality, and the cost of the components. As this convergence happens, the future protocol will be as shown in *Figure 13*. This convergence has significant impact on the way in which we process and move data. In the highly divergent networks of the past, where the layers implemented different standards, systems had to be built to do functions on each layer separately. As we consolidate, decisions can be made simultaneously between the layers. For example, a forwarding decision can be made at Layer 2, while a quality of service (QoS) function can be at Layer 3 using DiffServ. This blurring of the layers dramatically simplifies networks and will lead to the next generation of products—the specialized system. When the complexity in networks was matching and managing complex dissimilar protocols, the key was devices that dealt with the maximum in protocol and interface diversity. As we move forward, specialized devices, optimized for a specific point in the network and functional requirements limited to functions in Ethernet and IP at that point, will dominate. This has happened in the enterprise campus, and it is happening in virtual private network (VPN) nodes, in Web switching, etc.

Within this framework, the challenge is to allocate the intelligence to deliver services in a way that optimizes both cost and speed. Cost in this context is both acquisition cost (CAPEX) and ongoing operational cost (OPEX). As we have discussed before, trading bandwidth for complexity can generate significant returns in reducing operational costs. With these concepts in mind, an architecture for the future can be postulated with a distinct separation between the metro transport and the long-haul transport. Within the metro, an Ethernet transport yields significant benefits as it

FIGURE 10

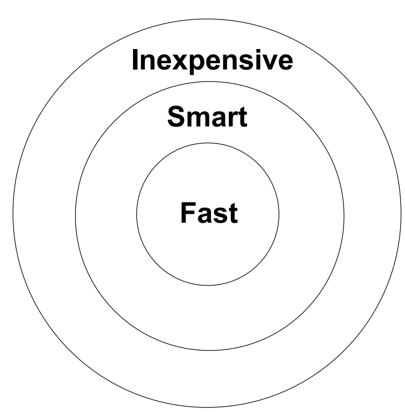

FIGURE 11

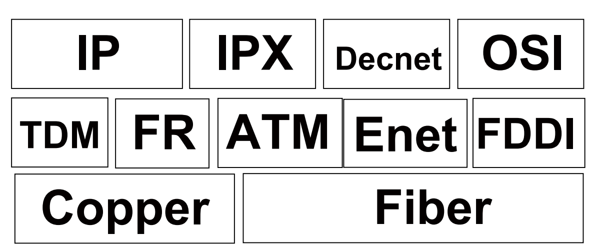

FIGURE 12

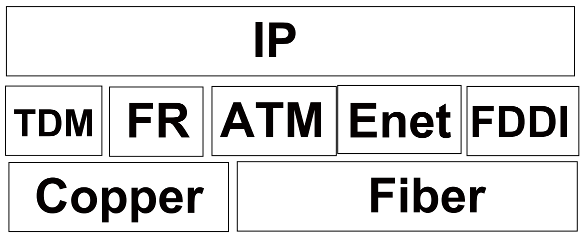

FIGURE 13

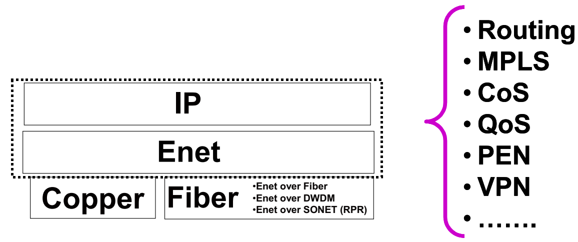

enables bandwidth to minimize the complexity of path and QoS decisions at the low-cost points generated from the enterprise LAN segment. Beyond the metro, into the long-haul environment, the simplicity of the Ethernet transport mechanism does not offer the necessary benefits of scale and traffic management. Therefore an architecture with the elements as shown in *Figure 14* combines the best of all worlds. In this architecture, the metro edge becomes a distributed or "logical" provider edge connected with a Layer-2 Ethernet transport to nodes that interface between the simple Ethernet metro transport and a highly scalable, traffic engineered MPLS core. The three elements of the logical PE are the LPE edge, the LPE Layer-2 switched transport, and the LPE core. In this architecture, functions can be allocated based on the previously discussed requirements. The LPE edge device has responsibility for SLA management and customer-service generation. The Layer-2 transport is over-provisioned for simplicity; the LPE core manages the complexity of the MPLS core network.

Figure 15 shows how the earlier layering of low-cost, smart, and fast can be applied to the resulting infrastructure. As can be seen, this solution optimizes all of the necessary elements. Service management is at the edge, where it belongs, managing the actual performance of the service delivery and enabling SLAs that can deal with the incredibly bursty nature of data. The metro transport is optimized for speed without being burdened with the complexity and intelligence necessary to provide large-scale national networks. The smart layer at the interface between the metro and long haul translates from the simplicity and cost-effectiveness of the metro to the more complex and scalable core. Here is the intelligence necessary to deal with the potential thousands of paths and connections necessary to build such networks. Finally, the long-haul core is very fast, based on a combination of MPLS and optical. This provides the high-speed capabilities to minimize complexity at reasonable cost.

The results of this architecture are significant. In the metro, it is possible to deploy the low-cost devices and inexpensive transports derived from the millions of Ethernet enterprise ports and devices. The edge devices can do the policing and management for the SLAs, including assuring customer separation through simple encapsulation and auto-discovery of

FIGURE 14

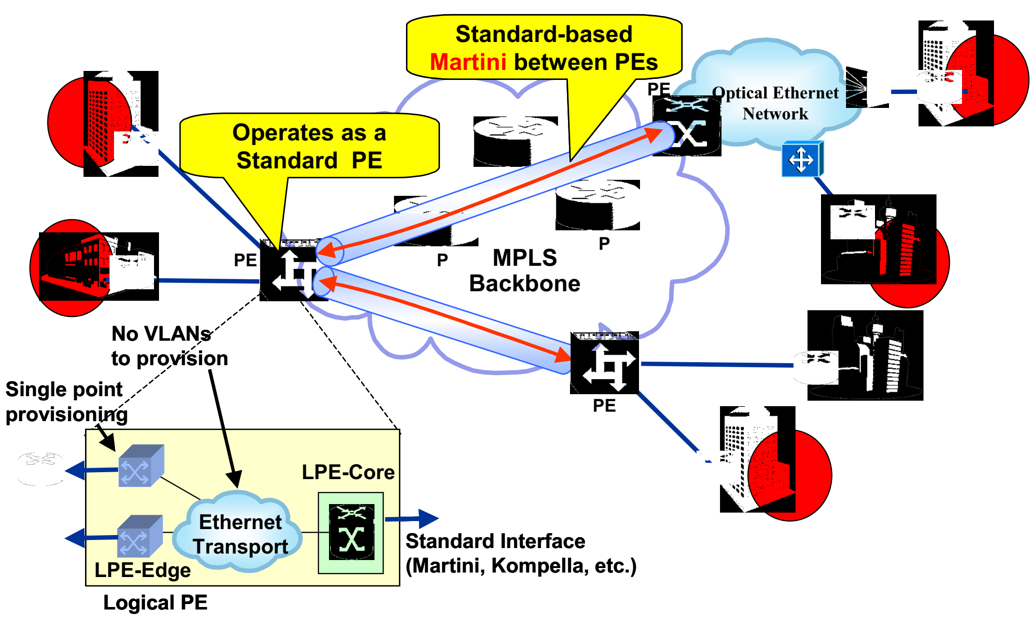

FIGURE 15

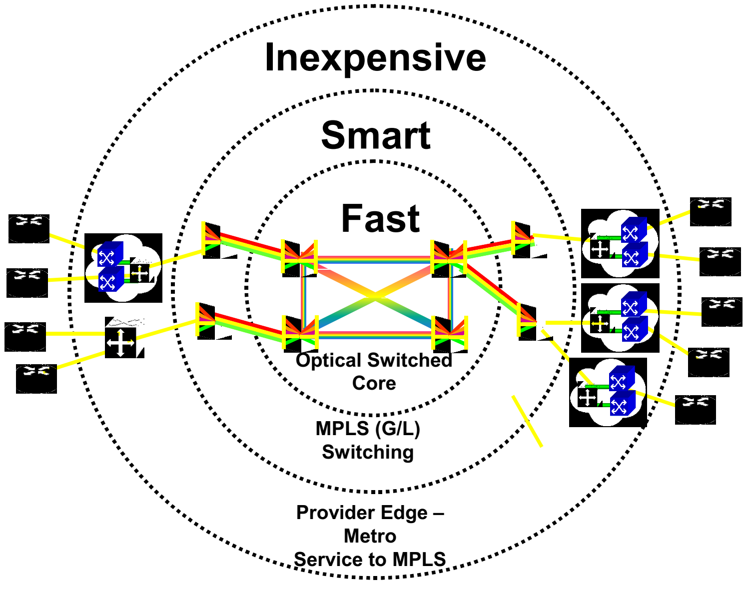
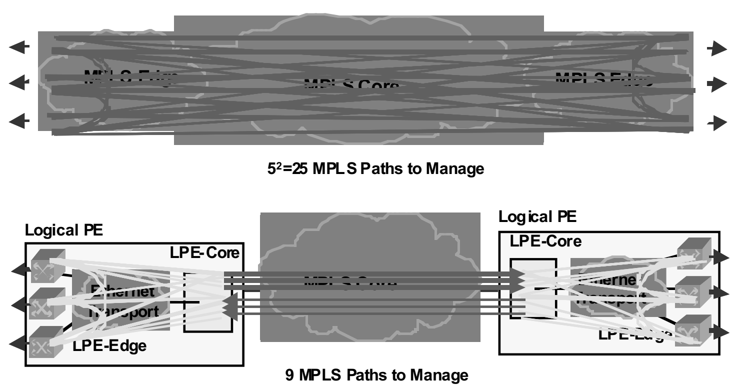


paths to other nodes. Between the metro and the long haul, the traffic is mapped into MPLS. MPLS is the logical alternative, as it enables traffic engineering and management across the core for these new services, while also enabling existing services to coexist through GMPLS. A large number of carriers are committing to MPLS as the way to manage their core backbones. (As the traffic is already separated by customer, the MPLS label-switched paths [LSPs] need only be between the metros, as they can be shared between multiple customers.) *Figure 16* shows the impact of this change. Instead of having to build LSPs for each customer connection or LSPs between all the edge devices, LSPs are only required between the metro (logical PE core) devices. As the number of paths and complexity expand exponentially with the

FIGURE 16



Fan Out	Number of Paths	Complexity
1:1	10n	$100n^2$
2:1	5n	$25n^2$
10:1	1n	$1n^2$

number of points (10 points connected is 10x9 or 90 paths; 100 points is 99x100 or 9,900, or 100 times as many), moving this point to the metro/long-haul edge and having 20–50 metro edge devices connected reduces the complexity by 100–10,000 times.

As bandwidth throughout the network is now much higher and the traffic types are varied, the network can be managed as an edge admission network and a core transport. As was discussed earlier, the edge can be managed for SLAs and customer requirements; the core links can be sized and managed for presented traffic; and the different traffic types will manage any load variation on a real-time basis. The result is a network that is very easy to manage and provision, both at the customer level and the overall transport level.

Conclusions

While the transformations anticipated in this paper will not happen overnight, they are in fact beginning throughout our networks. On enterprise campuses, the bandwidth explosion has already transformed the networks, and DiffServ-based CoS is used for IP telephony. Optical Ethernet, being delivered in some markets and under evaluation by virtually every carrier, will extend this bandwidth into the metro. Finally, the explosion of capacity in DWDM and the emergence of MPLS/GMPLS will deliver the core long haul.

Based on this combination of factors, it is entirely possible to anticipate that the beginning of the new millennium will be viewed in the future as the beginning of the transition from telecommunications networks ruled by the laws of the circuit and the age of scarcity to the new networks ruled by the laws of packets and plentiful resources. Surely the carriers and service providers that anticipate these changes will profit from the inevitable value that they create in the marketplace and the business capabilities that they deliver. The critical element is to understand how to migrate to the new future. Much as the buggy-whip manufacturer who realized his business was selling vehicle control systems prospered by moving to building steering wheels (while his competitors pushed blindly forward trying to sell whips to car owners and failed), the successful carrier/service provider of 2010 will have adopted these new paradigms, realizing that the business is not delivering circuits, but rather effective communications systems that extend the local communications into metro, regional, national, and global domains. A new world awaits us to bring it to fruition, and the transition is as profound as that from analog to digital or the wireless and Internet revolutions. This change will, in the end, redefine our perceptions of time and distance and enable a new set of applications and services that will continue the information revolution.

Telecom Markets and the Recession: An Imperfect Storm

Dean Eyers

Group Vice President and Worldwide Director, Telecommunications Group

Gartner Dataquest

Abstract

In difficult economic conditions, the global market for telecommunications services continues to grow, while the outlook for the equipment sector is mixed—some sectors will remain depressed through 2003.

Predictions

Gartner Dataquest makes the following predictions:

- The global telecommunications equipment market is expected to decline by 4.3 percent in 2001 but will recover and grow by 6.0 percent in 2002.
- Despite negative sentiment in the telecommunications market, revenue from global telecommunications services will grow by about 13.0 percent in 2001.
- The mobile handset sector may be experiencing its first real downturn, but infrastructure investment—mainly in third generation (3G)—is still increasing.

Overview

The current blind panic in the telecommunications market is no more justified than the blind faith that preceded it. Although many sectors and vendors are undoubtedly suffering, there are also bright spots in the gloom—not least of which is the fact that the telecommunications services market continues to grow strongly. The terrorist attacks in the United States on September 11, 2001, have been one factor in the downturn in the telecommunications market. However, in the medium to long term, Gartner Dataquest expects the demand for more bandwidth and for more secure, more redundant, and more distributed networks and services to remain strong. Continuing unstable economic conditions will put many of the weaker players at risk, but other telecommunications companies will emerge in a stronger competitive position.

Markets in Perspective

The telecommunications services market grew in all regions during 2001 and will continue to do so through 2005. Although the market for fixed, circuit-switch voice services is fairly mature, strong growth in the data services, packet voice, and mobile services sectors will combine to drive overall growth to more than 10 percent per annum. The telecommunications services market is generally less affected by economic cycles than other sectors, and there is much evidence that the impact of both the economic downturn and the events of September 11 will be minimal.[1]

Moreover, recent analysis of operator data and end-user plans for telecommunications spending indicate that usage levels and spending will continue to grow even in the regions most affected by the economic downturn.[2] While some of these companies and analysts may have planned for exponential return and radical revenue shifts, the pattern of steady growth is in line with previous Gartner Dataquest forecasts for 2001 and beyond.[3]

In contrast, the telecommunications equipment market has undoubtedly declined during 2001. North America and Western Europe have been hit particularly hard. The Asia-Pacific (and especially China) is the only real bright spot. The fixed infrastructure, enterprise communications, and mobile terminal sectors have all been adversely affected. However, there are still a number of subsectors that are experiencing reasonable growth—for instance, mobile infrastructure, optical metropolitan-area networks (MANs), and interactive voice response (IVR) systems.

The infrastructure segment will remain relatively depressed through 2002 and will pick up only slightly in 2003 as operators absorb the “overbuild” of 2000 and review their plans for next-generation equipment. Gartner Dataquest predicts that there will be a return to strong growth in 2004, as these revised plans are implemented.[4]

The mobile infrastructure market will continue to grow strongly in 2002 and 2003 as operators invest in 3G systems but will grow more gradually after that. The mobile terminal market will “bounce back” somewhat in 2002, buoyed by demand in the Asia-Pacific and by Europe’s eagerness for new products. From 2003, revenue growth in these markets is expected to be more conservative and will be based partly on a shift to higher-end products.[5] The enterprise market will return to overall growth in 2002, as users finally make delayed system upgrades and invest in technologies that will help to support their business against a background of staff reductions.[6]

Taken together, these equipment forecasts represent a large reduction in the expectations of a year ago. A combination of factors—subsequently outlined—have combined to greatly reduce the market potential in 2001 through 2003. However, by 2005, most sectors will return to levels that were forecast previously by Gartner Dataquest.

These forecasts do not support the widespread perception that the telecommunications market in its entirety—or even the equipment sector—is in complete meltdown. Certainly, there are highly visible companies and highly visible sectors that enjoyed very rapid growth during 2000 and are now experiencing dramatic decline. However, looking across the telecommunications market as a whole, the picture is somewhat different. For example, Gartner Dataquest estimates that the telecommunications equipment revenue of eight leading telecommunications vendors declined 11 percent year-on-year for the first nine months of 2001 against 2000. But, a broad-based sample, including smaller Japanese and Asia-Pacific vendors that are closer to the growth markets, shows a year-on-year increase of more than 5 percent. The fourth quarter of 2001 will be a telling one for many companies.

Table 1 shows worldwide telecommunications market revenue by region and sector from 1999 to 2005. *Table 2* shows worldwide telecommunications equipment market revenue by region from 1999 to 2005, while *Table 3* shows worldwide telecommunications services market revenue by region from 1999 to 2005.

Drivers of Economic Depression

Some of the origins of the downturn in the telecommunications sector predate today's general economic malaise. Like much of the information technology (IT) industry, telecommunications operators and equipment vendors were caught up in the dot-com boom. The growth of Internet commerce, services, and revenue has clear and direct implications for those providing the bandwidth and underlying networks.

When the dot-com implosion occurred, it hit the telecommunications industry in several ways, including the following:

- Markets had to radically readjust to the fact that Internet commerce would not grow at 400 percent per annum. Such large growth was never predicted by Gartner Dataquest.
- Stock prices were adjusted downward. The fact that a company is closely associated with the dot-com sector certainly no longer increases its stock valuation; indeed, some would argue quite the opposite.
- Venture capital was severely curtailed and continued only on a very different basis—moving quickly toward profitability is now the order of the day. Those telecommunications services start-ups that still exist independently have generally been forced to reduce spending dramatically and focus on short-term return on investment (ROI).
- Having invested heavily in network upgrades through 2000, incumbent operators, no longer looking over their shoulders in fear of competition from rapidly growing start-ups, could improve short-term profitability and

help placate unhappy shareholders by postponing further investment.

- Telecommunications equipment vendors that had geared up to meet the huge increase in demand indicated by their clients were caught with excess costs when the rapid increase in demand failed to materialize and their stock value plummeted.

The economic downturn, which began to be recognized in the United States toward the end of the fourth quarter of 2000 and has spread to many regions since, has simply added to telecommunications infrastructure vendors' problems. This has further depressed general expectations for growth and stock-market valuations.

In the enterprise and mobile terminal sectors, the impact of the economic recession was perhaps more direct—both businesses and consumers delayed purchases and looked to reduce spending. Purchases of telecommunications equipment have undoubtedly been affected.

The terrorist attacks in the United States on September 11 may have a mixed impact on the telecommunications market. The events have definitely created further recessionary pressure, extending the likely period before economic recovery can begin but potentially leading to stronger growth toward the end of the period of economic recession.[7]

Some telecommunications service providers are expected to delay investments further while they consider options in the light of evolving customer requirements. On the other hand, telecommunications equipment suppliers could even benefit from increased user demand for more secure, more redundant, and more geographically diverse networks and services that the terrorist attacks may stimulate.

Reasons to Be Cheerful: The Bottom Line

It is important to recognize that the aforementioned negative factors will mainly affect the equipment markets. The telecommunications services sector, if not totally immune, is certainly less susceptible to this economic slowdown. The innate demand for basic voice capacity in developing markets, and higher bandwidth in all markets, remains. It is much easier for a company to delay a capital expense decisions (for both business users and consumers) than to reduce reliance on a service that has become part of its business process. Also, the bandwidth and connectivity implications of Web-based services and applications will drive growth significantly during the forecast period, even if this growth is slower than some of the dot-coms would have had us believe.

Even the excess in capacity in the backbone will not last long as usage continues to grow, while there are still shortages elsewhere in the networks. Many operators are taking advantage of reduced competitive pressure to hone their plans for the next big push. While there are clear opportunities today, a number of next-generation network technology segments may show relatively slow growth for the next 18 months but will pick up significantly after 2003.

The enterprise equipment and applications sector is also evolving, with converged networks being the major long-term opportunity. In the meantime, customers cannot delay system-upgrade decisions forever: wireless local-area networks (WLANs), IVR systems, and applications that help improve enterprise efficiency are growth opportunities.

The mobile handset sector may be experiencing its first real downturn, but infrastructure investment—increasingly in 3G—is still rising. From 2002, next-generation phones should start to have a positive impact on volumes in key markets.

Overall, the explosive growth across many sectors in 2000 was clearly unsustainable. Gartner Dataquest expects that the telecommunications market will not return to the growth seen in 2000, but it will return to growth.

The Softswitch and the Besiegement of Telecom Incumbency

Elon Ganor
Chairman and Chief Executive Officer
VocalTec Communications, Ltd.

Arnold Englander
Vice President, Product Strategy and Planning
VocalTec Communications, Ltd.

Introduction: Incumbency Besieged

During the past two years, much has been written about softswitches from technology, network architecture, and vendor/product perspectives. Numerous articles and conference presentations have defined and argued the benefits of softswitches as the key to converged data and voice networks, to reductions in carrier capital expenditures (CAPEX) and operational expenditures (OPEX), and to the rapid, flexible, and cost-effective creation and delivery of enhanced services.

This paper disputes little of that. In fact, as a vendor of softswitch-based services platforms to carriers worldwide, VocalTec has contributed many such articles and has made many presentations of that kind.

This paper addresses how and why softswitch-based services platforms are excellent competitive weapons for the telecom industry battles being fueled by worldwide regulatory changes.

Looking at the telecom industry today, we see a redefinition of the business of established carriers and the entry of many types of newcomers. We see local carriers moving into the long-distance business, and long-distance carriers moving into local services. We see national carriers setting up operations in other parts of the world, and we see companies that were not previously telecom providers (such as electric-power providers) now becoming telecom carriers as well.

Overall, we see a multitude of challenges to a historically fundamental phenomenon in the telecom industry—incumbency.

The markets of incumbent local-exchange carriers (ILECs) are being attacked (or at least their high-value markets are being "cream skimmed") by competitive local-exchange carriers (CLECs). Local-exchange carriers (LECs) in general are girding for their markets coming under attack by what have historically been interexchange carriers (IXCs). Relatively new global managed services (such as XA Alliance's pan-Asian telecommunication service network) are winning markets and traffic out from under from incumbent carriers. The primary (and often the former monopolistic) carrier of one country is now setting up its own facilities-based operations in other countries, attacking the market of those other countries' incumbents (often former monopolies themselves). A case in point is Deutsche Telekom in the Far East and South America. One may think of this phenomenon as incumbents, acting outside of their region of incumbency, attacking incumbents defending their region of incumbency.

And to make this even more complicated, the globalization of business is straining the network and business models upon which carrier-hosted services—such as Centrex, bridge conferencing, and voice virtual private networks (VPNs)—were originally built. None of these make sense any more as "local" or "long-distance" services (if they ever did). In today's global economy, these services need to be both local and long-distance—while also being relatively distance-insensitive in their pricing. If these services were "natural" for either IXCs or LECs (because they were implemented using feature sets on either Class-5 or Class-4 switches), this "birthright" or predestined incumbency is being challenged by real business requirements. The requirement today is for globally hosted business services. These create new opportunities as to who hosts them, who sells them, and the types of facilities off of which they are served. Hosted services need to be provided on a global basis regardless of the country in which a business has their headquarters, divisions, branch offices, or "road warriors"—one of the more complex challenges to the notion of telecom incumbency.

It is noteworthy that while the besieged are easy to characterize (incumbents and often former monopolies), the attackers are not. The attackers include well-established companies (including incumbents elsewhere that are now stepping out of their own fortresses), start-ups, converged network "next-gens," and companies large and small entering telecom from some other business, such as electric power.

This sets the stage—or battlefield—for explaining why we believe that softswitch-based service platforms are powerful siege weapons for attacking the fortresses of incumbents operating in their historical region of incumbency.

Enter Softswitch

Incumbency in the telecom industry has come under siege as a result of country-by-country telecom liberalization, deregulation, privatization, and competition. This has taken place rather suddenly (by telecom industry standards) after a 50-year (in some countries a 100-year) status quo. This has raised a Hydra of countless simultaneous issues for which most telecom executives were hardly prepared.

This process spread rapidly from the U.S. Telecommunications Act of 1996, through telecom reforms in each of 27 European countries during the second half of the 1990s, to India's New Telecom Policy of 1999 (NTP-99). Today, this process, and the industry re-alignment that it is causing, is far from over.

The term "softswitch" started to appear in the late 1990s referring to a type of switch that would replace central office (CO) circuit switches used in the traditional public switched telephone network (PSTN). The original motivation and advantages intended for softswitches included the following:

- Supporting voice-over-packet networks in addition to (or instead of) circuit-switched networks
- Supporting open standards to enable multivendor, best-of-breed networks and services platforms
- Supporting the use of industry standard hardware
- Supporting service-creation environments (SCEs) to dramatically shorten and reduce the cost of developing, trailing, and deploying new services
- Supporting multiple telecom protocols, each best for its own purposes and functions but requiring integration and inter-working
- Enabling lower cost and smaller footprint, but scalable, facilities

The Softswitch Consortium, an international organization, was formed in May 1999. A large number of vendor announcements—some premature—took place at Jeff Pulver's VON (Voice on the Net) conference in the fall of 2000, and more mature softswitches have been announced, trailed, and deployed since.

It is not entirely clear whether or not the idea of the softswitch sprang from telecom reform and the besiegement of telecom incumbency. It is clear to us, however, that as early as October 2000, several of VocalTec's customers (large and small, former monopolies and start-ups) were starting to appreciate that one or more aspects of softswitches could help them attack telecom incumbents in their regions of incumbency.

The connection between softswitches and the besiegement of incumbents is based on the following points:

- Softswitch-based service platforms can provide services that are location-independent and largely distance-insensitive. Services in Tokyo, Beijing, and New York can be served off of a platform located in Berlin, and calls between Tokyo and New York can cost almost as little to the carrier as calls between New York and New Haven.
- Global hosted business services served off of softswitch-based platforms are neither inherently local or long distance—they are both. The incumbent local carrier, with its Class-5 switch functionality, has no inherent advantage in providing Centrex services to the likes of Mercedes-Benz offices around the world; nor does the incumbent long-distance carrier, with its Class-4 functionality, have any advantage in providing voice virtual networks to IBM campuses in Martlesham, Boca Raton, and White Plains.
- Softswitch-based service platforms can be granular and scalable. This means that the cost of entering new markets—new geographically and/or in terms of types of services—can be very much lower than it has been in the circuit-based PSTN world. It also means that carriers can grow their networks, platforms, and service capabilities as customers and revenues materialize in these new markets. This goes a long way toward undermining the advantages of an incumbent having provided services to a region for the past 50 years, especially when telecom reforms encourage the besiegers to adopt selective or "cream skimming" service availability strategies from which the incumbents may be precluded.
- More and more, softswitch-based service platforms are supporting SCEs that enable rapid development, customization, branding, and fine tuning of value-added services by means of visual programming languages and Web development tools that are understood by a large community of developers (very different from the scarce resources needed to program new serves on a "hard switch"). This means that softswitch-equipped carriers can develop new services and new bundles of services that are custom tailored to target markets—and do so many times faster than incumbents can develop generic services on their "hard switches."
- Softswitch-based platforms can support converged voice and data services that cannot be supported well (in some cases at all) using the circuit-based "hard switches" deployed by incumbents during the last 10, or even 20, years. Some of these services are high-margin value-added personal computer (PC)–centric applications. Others simply involve the consolidation of historically separate voice and data operational costs, and connectivity, both on the carriers' side and on their customers' side, that lead to important cost savings. Either way, this convergence of data and voice services is available more readily and at lower cost to the softswitch-equipped besiegers than the "hard switch"–equipped incumbents they are attacking.

The Besiegers, Their Objectives, and Their Requirements

As a vendor of softswitch-based solutions and one of the major providers of IP telephony equipment worldwide, VocalTec Communications' platforms help its customers grow their businesses in ways that gain advantage from telecom reform, often by besieging incumbents in their regions of incumbency. The besiegers are start-ups, converged network "next gens," or incumbents (elsewhere) expanding beyond their region of incumbency. These carriers are growing their businesses in a world shaped by telecom reform. This is a world where the distinctions between IXC versus LEC, long distance versus local, and wholesale versus retail, are no longer clear. This a world that gives advantage to carriers deploying location independent platforms, providing distance-insensitive and globally hosted services, incurring fewer risks in entering new markets and selling to global business customers.

In particular, these customers tend to be the following:

- Packet telephony–based wholesale long-distance (LD) carriers and "carriers' carriers" that provide international interconnect to affiliate carriers
- Retail LD managed communications service providers serving large global businesses
- Large CLECs and LD carriers expanding into CLEC–like business models that focus on high-value business services and require the following:
  - The ability to provide bundles of business services (including voice VPNs [V–VPNs], conferencing, call centers, Centrex, voice-mail, unified messaging, and PC communications) on a global—thus LD as well as local—basis
  - Layered service-management systems for multi-tiered service customization, personalization, and self-provisioning
  - Low entry costs yet a high degree of scalability, both of which are important for carriers entering new markets, and especially to support "cream skimming" strategies

VocalTec softswitch-based solutions are specially designed to enable carriers in Category #1 to expand into Categories #2 and #3 and to enable carriers in Category #3 to differentiate their local business services from ILECs by satisfying their customers' global as well as local needs. VocalTec solutions are designed to enable carriers to compete with ILECs by building out service footprints according to a very focused, risk-contained "cream skimming" strategies. This requires integrated service platforms that are both fine grained and scalable (for low entry costs and fast growth as revenues grow) and that provide SCEs that support the rapid development of highly customizable services and service bundles that are simultaneously global and local in nature.

Such softswitches must meet the following market requirements:

- Rapid and easy multiservice integration, whether the features of the service are served off VocalTec or VocalTec partners' feature and media servers.
- Support for hosted business services (including Centrex and voice-mail) on a global (enterprise-wide or supply-chain–wide) basis, rather than on just a campus-wide or city-wide (CO or NXX local-exchange area) basis.
- Parity and uniformity of subscriber service features with media gateway control protocol (MGCP) or session initiation protocol (SIP) media gateways or end points.
- Multilayered service provisioning, customization, and personalization. This facilitates and reduces the costs of services resale, selling customizable services to businesses, and customer self-provisioning and personalization.
- Inter-carrier security and address translation. This enables carriers to interconnect with affiliate service providers using unmanaged networks, including the open Internet.

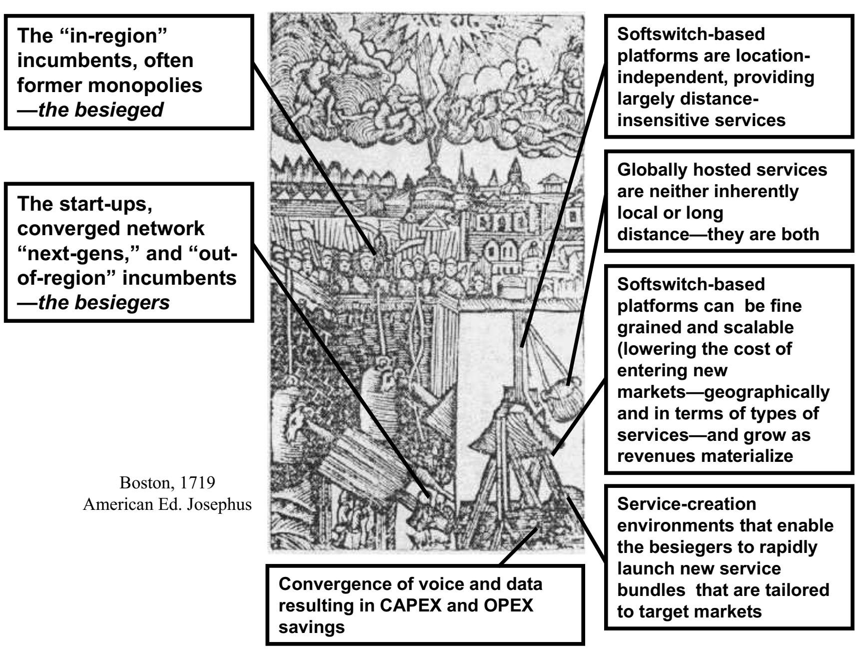
Softswitch and the Besiegement of Telecom Incumbency



Boston, 1719
American Ed. Josephus

- Easy integration with already deployed H.323 voice over Internet protocol (VoIP) networks.

Conclusion: The Softswitch as a Siege Engine in Carrier Battles Fueled by Telecom Reform

We have portrayed the current state of the telecom industry as a "besiegement of incumbency" fueled by telecom reform worldwide.

We described how the softswitch is a powerful siege engine for start-ups, converged network "next gens," CLECs, and incumbents (elsewhere) expanding beyond their region of incumbency as they attack markets of "in-region" incumbents.

We have pointed out that a "region of incumbency" can be literally geographic and/or "horizontal," such as LD versus local, and voice versus data versus the convergence of voice and data.

We have also discussed how some softswitches—because of their granularity, scalability, and location-independent and relatively distance-insensitive natures—lend themselves to "cream skimming" strategies aimed at high-value user groups such as the global Fortune 1000 and their supply chains. We contrasted this with the "in-region" incumbents' having to juggle the needs and profitability of metropolitan, campus, suburban, and rural customers in their local-exchange area, in many cases using their "one-size-(must)-fit-all," inflexible, legacy "hard switches."

We also discussed the advantage provided by softswitches that enable trunk replacement, carrier interconnect, and carrier exchange services on the same integrated platform that provides service bundles that include V–VPNs, Centrex, call centers, conferencing, calling cards, voice-mail, unified messaging, and PC communications on a global as well as local basis.

The softswitch-based platforms are remarkably well-suited to a telecom industry landscape in which the boundaries between wholesale and retail, LD and local, trunking and subscriber, telecom infants and octogenarians, and voice and data are all embattled front lines in the besiegement of incumbency.

What remains to been seen is the speed with which start-ups, "next gens," and "out-of-region" incumbents—the besiegers—will use softswitches as siege engines, and the speed with which the "in-region" incumbents will find ways to use softswitches to fight back, both in their regions of incumbency and by expanding their businesses elsewhere—thereby becoming besiegers themselves (see *Figure 1*).

The Troubled CLEC: Causes, Symptoms, and Solutions

A.J. Germek
Chief Operating Officer and Co-Founder
GuideComm

Introduction

The Telecommunications Act of 1996 dramatically changed the topography of the telecommunications landscape. The legislation almost single-handedly helped to transform this once-staid industry from one dominated by a small number of large firms into a highly competitive market area. The 1999 projection of a $100-billion local-services market[1] set off a rush to finance the development of the infrastructure required to realize this potential. Venture capitalists and private investors alone pumped $17.68 billion[2] into this market segment over a two-year period, spawning some 2,000 new competitive local-exchange carriers (CLEC). Most of these service providers experienced a period of rapid growth and skyrocketing market valuations. These results worked to reinforce the edict to build out the network and acquire customers, both at the expense of deploying the robust back-office operational support systems (OSS) necessary to run the business efficiently.

Subsequently, the latter part of 2000 and the beginning of 2001 brought several high-profile CLEC failures, and the stock market as a whole turned downward, with technology stocks suffering in particular. The competitive service-provider market has since cooled considerably, and many service providers, reviewing the expansion of the past five years, are now reconsidering their business plans. Moody's Investor Service warned investors in March of this year to watch for credit-rating downgrades and defaults for CLECs and expressed concern that some of these companies will have trouble paying interest on several billion dollars of zero-coupon bonds when those bonds start to require cash interest payments over the next two years.[3]

The market opportunity for competitive communication services still exists; however, CLECs have captured just 6.7 percent of the overall market, a relatively small percentage given the supposedly ripe market opportunity.[4] But as Neil Sheh, vice president of M/C Venture Partners says, "CLECs are still great business. They just need to be built properly."[5] An increased emphasis on OSS is the key component to the CLEC turnaround strategy, offering hope to financiers who want to recover their investments, and giving the CLECs themselves renewed hope of capturing an enormous, as yet untapped market.

Market Conditions

Winstar Communications, GST Telecom, e.spire Communications, ICG Communications, IAXIS, NETtel, Star Telecommunications, and NorthPoint Communications are just some of the service providers who declared bankruptcy within the past several months. Others, such as Teligent, are reporting serious financial difficulties. How did the industry get to this point? There are various theories and opinions, many pointing to the overheating of the high-tech market and the vulnerability of the dot-coms. However, many of the problems can be traced to conditions and causes specific to the CLEC industry.

Root Causes and OSS Impacts

A variety of significant problems have combined to create the perilous state in which many CLECs now find themselves. For each of these root causes, an overlooked OSS has contributed to or magnified the problem. Conversely, a sharpened focus on the OSS will deliver improvements quickly.

Management Team Composition
As with any industry, the success or failure of any enterprise, especially a start-up, is directly related to the vision, skills, and expertise of the management team and their ability to execute. With the explosion of the CLEC market and demand greatly exceeding supply, the management teams of many CLECs have included an uncommonly high proportion of first-time executives. CLECs have also experienced management-team turnover, fueled by richer opportunities elsewhere or lackluster performance. As a result, developing and executing a consistent business plan represents a significant challenge to CLECs. Market and service plans are continually altered, and the OSS and information systems (IS) strategies that support them are also in flux, producing an unstable environment and systems whose potential is never fully realized.

Overexpansion
An investment environment where money was readily available, combined with the huge market opportunity, fostered an "If you build it, they will come" atmosphere. The prevailing wisdom among service providers is that long-term survival is

dependent on increased size and scale, and that being first to market creates a permanent advantage.

These factors created a single-minded focus to build out the network. However, this focus frequently caused CLECs to outrun their logistics and their OSS, which remained incomplete or in a state of operational infancy. Provisioning, quality of service (QoS), and even invoicing became challenging assignments for the IS and operations departments. Systems strategies were often ill defined or incomplete. The systems themselves required substantial manual intervention to complete the process of taking an order, provisioning/activating the order, and billing for services rendered. Substandard OSSs produced inefficiencies that greatly weakened the CLECs' competitive position. Or as Royce J. Holland, chairman and chief executive officer (CEO) of Allegience Telecom, stated, "I think it has been established over the last three years that in order to be successful, you have to have a state-of-the-art OSS"[6].

Competition from the ILECs

The incumbent local-exchange carriers (ILECs) answered the challenge of the burgeoning CLEC industry by using a combination of financial muscle and marketing strategy.

Competition for control of the market spawned price wars. The oversupply of basic services reduced prices to the point where CLECs could neither make a profit nor recoup their investments. For example, the average price of a T1 circuit dropped from $2,500 per month in 1998[7] to $1,296 per month in 2000[8]. Service providers are offering long distance for as little as $0.03[9] per minute, whereas the cost for that same service was $0.28 per minute just two years ago[10]. Overall, revenues per minute continue to decline as usage minutes continue to grow, putting a premium on efficient network utilization[11]. To differentiate themselves, service providers must offer bundled packages of additional services for that same price, thereby increasing overall delivery cost.

CLECs might have effectively countered the price competition presented by the ILECs by offering rapid provisioning or QoS guarantees, each far more feasible for the CLECs building new networks than for the ILECs encumbered with legacy systems. However, because the CLECs lacked the OSS performance necessary to deliver on these guarantees, they had no choice but to shift their marketing focus to price competition, playing directly to the strength of the ILECs. Meanwhile, the ILECs were able to target their marketing campaigns toward the familiar values associated with these well-known entities: size, experience, and permanence. These exploited the CLEC weaknesses in performance, speed, and agilityæ attributes that would have been strengths with a solid OSS foundation in place.

Voice Technology

Most of the CLEC buildout was originally implemented with voice technology or circuit-switching equipment, which in today's market is quickly becoming a commodity or complementary feature associated with data services. Hardware manufacturers that financed equipment purchases at 125 percent of cost or greater were delivering huge quantities of circuit-switching equipment into the CLEC market, along with additional capital for operations. CLEC and ILEC networks and their service offerings were virtually indistinguishable. By investing the additional capital more heavily into their OSS, CLECs might have offered services and features that would have differentiated them from their competitors, avoiding strict price competition. The net effect, however, is that carriers are faced with financing notes coming due, including approximately $150 billion in high-yield securities[12] (i.e., junk bonds); and in most cases, either their OSSs are not mature enough to provide a competitive advantage, or their network infrastructure is not suited to offer the data services that represent the future of the industry.

Dilution of IS and Operations Talent

The technical talent within the communications industry was diluted even more severely than the executive talent by the great influx of new players. Within the IS and the operations departments, many of the personnel placed in mission-critical positions came from the ILEC environment, where they only had experience with a portion of an OSS or had no experience with building systems from the ground up on a priority and rapid-deployment basis. As a result, large investments often produced ineffective results, leading to staff and budget reductions for ongoing operations.

The Penalties

Stock market prices have dropped below the level of a reasonable correction, and valuations are reaching new depths more alarming than the previous unprecedented heights. The average CLEC stock price is down more than 83 percent from its high in 2000.[13] For example, Covad Communications' stock price plummeted from a high of $67 per share in March 2000 to a value of $1.20 per share as of April 12, 2001. Teligent's stock price, $100 per share in March 2000, was down to $0.48 per share on April 12, 2001.

This financial performance has choked off the traditional funding sources for the capital-intensive service-provider business. With the stock market pummeling publicly traded firms, new initial public offerings (IPO) in the service-provider space have all but ceased. Venture capitalists, who view the IPO as their investment liquidation strategy, are slowing the pace of investment and raising the hurdles for new ventures. "If they [CLECs] are going to raise money, they are going to have to show some return on investment," said Yankee Group analyst Rob Rich.[14] Bob Nicholson, a partner at Spectrum Equity Investors, predicted in September 2000 that 5 to 10 publicly traded CLECs that were holding high-yield bonds could default by the end of 2000.[15] He was not too far off his prediction. And as the debt grows, debt holders may become the owners of many communication companies, a role they are neither suited for nor interested in assuming.

The Business Challenges Facing CLECs

In spite of everything happening in the market, the CLECs must face and overcome the following challenges:

- CLECs must reassert their ability to move more quickly and nimbly than the established ILECs in providing services.

- Revenue streams must become more reliable and robust and not simply be executed as proofs of concept.
- Cash-burn rates must be carefully managed or reduced as access to capital markets continues to diminish.
- Issues regarding access to capital notwithstanding, network expansion must continue at a measured pace to achieve size and scale.
- OSSs must be right-sized and effective to deliver the promised revenues and levels of service.
- Low morale must be checked through vision and decisive leadership at the executive-management level.

OSS: Keeping Pace?

Attention to OSSs (or the lack thereof) stands in stark contrast to the enormous network buildout undertaken within the industry. In many cases, CLECs have ignored or underfunded their OSS and have not made effective OSS deployments one of their top priorities. The lack of efficiency and/or automation in the back office regularly leads to lost revenue and service issues. Manual processing and segregated management systems have resulted in excessively long provisioning times and error-filled orders. Inefficient diagnoses and resolutions of network problems have deteriorated customer relationships, producing excessive customer churn and delinquent accounts. Those issues notwithstanding, it has been CLECs' inabilities to support new data products and services that have most dampened the enthusiasm of both customers and investorsæbecause the reality of the e-commerce/communications world is that data is paramount.

Offering new products and services efficiently and seamlessly will enable CLECs to grow and prosper. And a robust, flexible OSS is a critical component to realizing that strategy. XO Communications, a company based in Reston, Virginia, is one CLEC that has embraced this view. And XO is one of the few CLECs that has invested wisely and built a flexible, scalable OSS. In fact, current XO CEO Daniel Akerson, former president at MCI, credits "the best back-office systems in the industry" with helping MCI overtake AT&T in the long-distance marketplace[16]. And as the chief executive at XO, he is championing the development and implementation of a robust OSS that is contributing to this CLEC's growth through expanded products and services.

For instance, XO offers a service called XOptions, which allows a customer to decide their local, long-distance, data, and Web-hosting needs and to choose a plan that charges one flat rate. XO delivers all these services for 10 to 40 percent less than customers would find elsewhere, and because of their strong back-office system, it is all delivered on a single bill[17].

A well-defined OSS system strategy, workflows, architecture (open, flexible, and scalable), component prioritization, and software selection are critical to success. For example, if successfully implemented, an OSS with an automated order-entry and provisioning system can often provide the following types of results:

- One CLEC reported a 23-percent increase in the number of lines installed from the previous quarter (when the company was using manual processes) to the first quarter of using automated order entry and provisioning.[18]
- Another CLEC showed 62 percent of their orders being filled in less than 5 days, provisioning volume of up to 9,500 phone lines per day, and order fallout rates that dropped from 43 percent to less than 2 percent.[19]

In the rush to build a state-of-the-art and expansive "physical body" (the network), most service providers were not able to give that body the "brains" (the OSS) to operate efficiently and effectively. Only now are the penalties for this failure starting to emerge.

Measuring the Health of the OSS

In addition to the obvious problems of unacceptably long order and provisioning lead times, excessive customer complaints, and attrition, a CLEC must also be able to detect the more subtle signs of underlying distress within an OSS. To identify an ailing OSS, a CLEC should check for the following problems:

- Long IS development and implementation timeframes
- Missing or inadequate OSS components
- Rapid growth in the IS budget without obvious benefits
- Shifting timeframes in the delivery of OSS and IS projects
- Efforts are focused on stabilizing current OSS components rather than adding functionality or coverage
- Revenue growth constricted by inadequate/lack of OSS support
- Provisioning lead times approaching or exceeding the incumbent service providers
- New services cannot be delivered through the current OSS structure
- Unfulfilled requirements and unmet customer expectations for software-produced services
- Confusion or conflict as to OSS goals, objectives, and timeframes

The Solution: Short-Term, Tactical Initiatives within a Strategic Architecture

After spending hundreds of millions of dollars on the assets, people, and systems to manage the networks and services, a company must then decide where to start to address the problem.

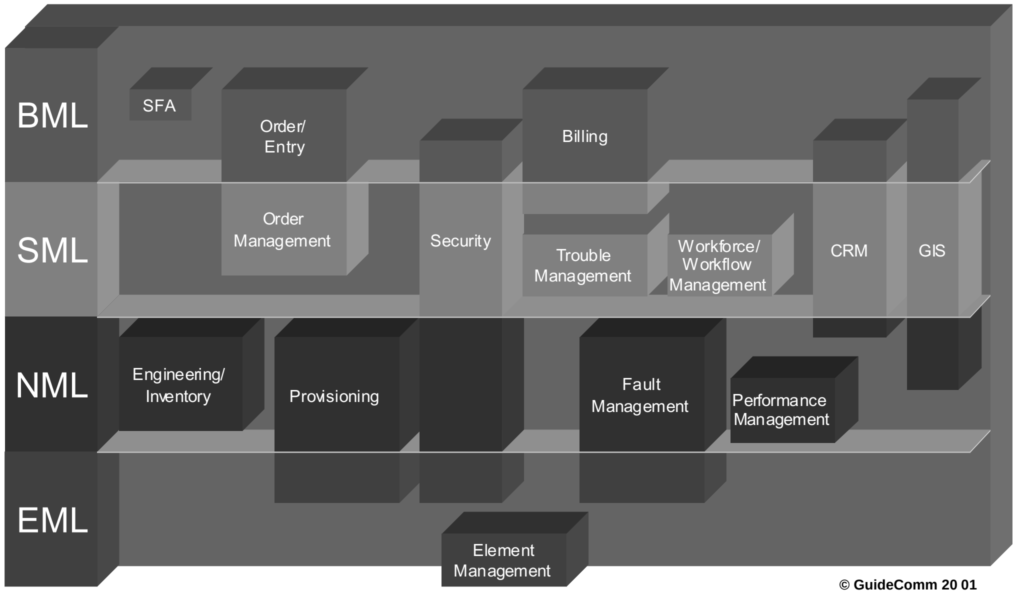
The overall goal in improving the health of the OSS must be to meet the short-term, tactical business objectives without harming the long-term growth potential and architectural integrity. This requires a critical analysis of the current OSS position relative to the overall OSS landscape (as depicted in *Figure 1*) and a decisive, positive approach for the future. The analysis and OSS strategic planning must account for revenue growth, reduction of expenses, enhanced performance, specific business objectives, investment options, and identifiable metrics. A well-defined OSS strategy and architecture offers support across all levels of the CLEC operation.

The guiding principles should include the following:

- A focus on effective results in short, fixed timeframes
- The ability to scale when the business climate improves and growth becomes imperative

FIGURE 1

Well-Defined OSS Strategy and Architecture



A targeted OSS analysis should produce an action plan that when executed provides a path to growth and profitability. An experienced OSS strategist can complete a targeted analysis within a 30- to 60-day period with an efficient, structured approach. The tasks to be executed as part of the analysis are illustrated in *Figure 2*.

After identifying the OSS implications and related business objectives, recommendations and alternatives for the OSS can include the following actions:

- Reprioritizing and rescaling markets and service priorities
- Implementing rapidly-installed new software components
- Reducing functional requirements to address critical and short-term needs
- Re-architecting OSS solutions for flexibility and scalability
- Eliminating non-essential, long-term functionality and projects
- Adding small-scale critical components and interfaces
- Determining functional outsourcing potential

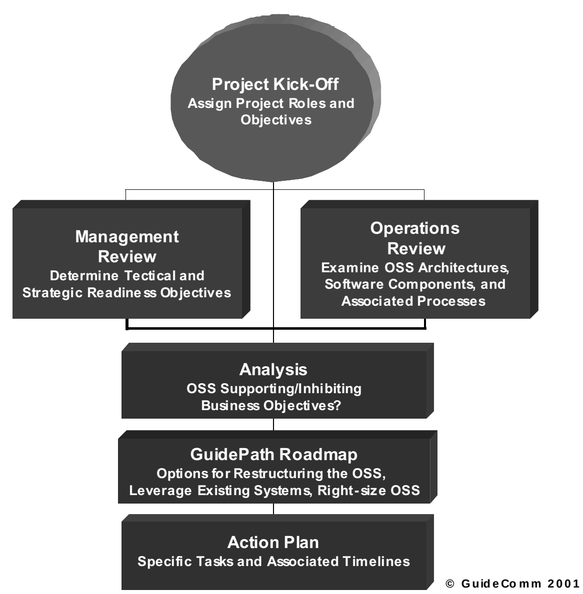
Based on the analysis and recommendations, the CLEC can create and execute an action plan that includes the tasks and budget against which success can be tracked and measured.

Independent Review

Any department or executive may have a commitment to the current OSS status. Marketing may have committed to service offerings or products. Engineering may have committed to network buildouts and equipment purchases. Operations may have committed to processes and staffing levels. IS may have committed to a comprehensive OSS plan and strategy. These vested interests can inhibit a critical assessment of the current OSS status and the development of a strategic solution.

FIGURE 2

Targeted OSS Analysis Tasks



Therefore, the OSS analysis needs to be performed by a third-party OSS professional who is not vested in the current OSS strategy or predicament but is driven to achieve results. The expert guidance needed to solve this dilemma will require business acumen as well as OSS expertise and an independent review.

Finally, a willingness on the part of the CLEC to dedicate the resources and leadership necessary to execute the finalized action plan is essential for the health of the OSS. However, once the OSS is on track, the CLEC will be positioned for survival and leadership in the ever-growing, ever-competitive communications market.

Evolution of Technology versus Carrier Adoption

Howard J. Gunn
President
Entrusted Communication Services

Abstract

The evolution of computer and communications technology and the application of new technology to solve current business problems are similar to a biological process. For a variety of reasons, it is relatively easy for U.S. business visionaries to come together with technology innovators to create a new offspring. Likewise, there seems to be a ready supply of enterprise "early adopters" who can see the business value of the new applications. The early adopters in a market typically help the embryonic application fulfill its stated purpose, or they kill it off in favor of even better applications that solve the business problem.

Many innovators and early adopters perceive a major gap between their market-driven evolution of new technology and the carrier adoption process of the carrier industry. The author believes the adoption gap is fostered by the "regulatory economics" of the carrier market, versus the "profit" motives that drive the enterprise market. This paper explores the perceived "gap" and how the Telecommunication Act of 1996 has brought the gap into clear focus in the carrier market.

The current gap is big enough to generate new efforts to resolve the problem. Newly proposed solutions to the perceived gap range from structural separation of wholesale and retail services to a return to monopoly yesteryear with some members of Congress ready to diddle with what has been called "the worst set of compromises and pork barrels ever passed by Congress." Based on the regulatory track record of Congress and the States, the author believes that any additional legislation will tend only to widen the gap between technology evolution and carrier adoption. The author also suggests that another regulatory fumble could lead to even more legal and market confusion than the set of regulatory changes that have been in the courts since the 1996 passage of the Telecommunications Act.

The collapse of the dot-com market, followed by the collapse of the new data local-exchange carrier (DLEC) and competitive local-exchange carrier (CLEC) markets were not caused by the innovators and early adopters killing bad applications in the market. These collapses—followed by the collapse of the long-distance carriers, equipment suppliers, and growing pressure on the incumbent local-exchange carriers (ILECs) stock prices—are probably a part of the technology evolution gap, stimulated by fundamental changes in public policy and the inability of regulators to create a viable open market in the local monopoly.

The paper concludes that the carrier technology-adoption process is changing slowly. The traditional adoption rate was similar to the pace that mainframe-computing operators accepted for personal computing and servers. Over time, dinosaurs supporting centralized computing and common business-oriented language (COBOL) programming either died off or evolved new technologies to support the distributed control paradigm of personal computing. New service control points (SCPs) are the first positive signs of a change in carrier adoption strategies. Even after the death of 40 percent of the carrier market—lead by Nynex, Pacific Telesis, U S West, GTE, and numerous CLECs—few carriers have started to plan a new technology adoption strategy for upgrading or converging their costly rate-base–driven overlay infrastructure.

Background

Congress passed and the President signed the Telecommunications Act of 1996. Although some have criticized the law as "the worst set of compromises and pork barrels ever passed by Congress," the law clearly reflects a significant change in public policy toward the local carrier monopolies. Prior to 1996, the laws protected public carriers from the impact of open markets. The new law enabled regulatory changes to free consumers from the power of the local monopolies.

The law created a way to grant new local carrier franchises that enabled the creation of CLECs and DLECs. The law also generated a mountain of legal issues that extends all the way to the U.S. Supreme Court. Some challengers are trying to protect the status quo monopoly, while others seek protection from the monopoly introduction of various scorched-earth pricing and proprietary service models.

Clearly, the most controversial issues are associated with the legal elimination of the local-exchange monopoly. This change in regulatory policy includes the involuntary unbundling of the current monopoly infrastructure and the Federal Communications Commission (FCC) mandate to price the unbundled elements at wholesale to new carriers using forward-looking total service long-run incremental cost (TSLRIC) methods. The unbundling of service elements and the TSLRIC cost model strikes at the heart of the local monopoly—the rate base.

The rate base in laymen terms is the accumulation of investments used to value a company, as determined by the regulating agencies and not the market. Over many years, this arbitrary regulatory valuation process evolved as a group of companies that acted as quasi government agencies known as public utilities. These agencies operated on a regulated cost-plus basis in power, water, cable, and telephone services markets, as well as other smaller market segments.

What makes the U.S. utility experience unique is that public stockholders own these cost-plus, quasi-public agencies. Without comment as to legitimacy or the historic value processes, in all cases, the rate base was created by administrative government actions that included federal, state, and, in some cases, municipal government oversight. The rate base and resultant carrier pricing strategies were initially created to reduce the capital risks in capital-intensive markets. The various rate-base companies were also driven by social mandates of government. In the carrier space, the mandates included "Universal Service," a government-controlled fair rate of return on the rate base and an indirect tax collection process that hid certain taxes in the service prices.

In the late 1980s and early 1990s, a variety of government efforts were initiated, trying to unbundle the rate-base cost-plus processes. For a number of reasons, fair-rate-of-return rate-base regulation and its arbitrary cost models was shifted to a mixture of government direct collections (taxes), plus a return on investment (ROI) income cap. The ROI regulation process was introduced as a way to stimulate a change in "utility economics." It was thought that these changes in process would stimulate an upgrade of the infrastructure. These early efforts culminated in the Telecommunications Act passed by Congress and signed into law by President Clinton on February 8, 1996.

The involuntary unbundling of the bottleneck monopoly facilities and the granting of new local service franchises coupled with TSLRIC methods were initiatives to circumvent the rate-base issues on an economic plane. The TSLRIC approach implies that the value of the bottleneck facilities should be valued at the cost to reproduce them with current technologies and not the arbitrary "regulated valuation" created over the last hundred years.

As an example, assume a hammer as a carrier unit of unbundled capacity. Today, hammers sell for $20. The FCC mandated that the valuation of all similar hammers should be $20. (The cost of a unit of capacity is its estimated reproduction cost using today's technology.) This new valuation would be used to set the wholesale price for renting old hammers to new carpenters, until they could afford to buy their own hammers. The problem is that the rate base contains millions of hammers that on paper carry a residual regulated valuation. This arbitrary rate-base valuation is similar to the million-dollar hammers associated with many cost-plus contracts, where unit valuation and cost allocations are jockeyed to fit budgets and other external variables.

The problem of not using the current market price of a hammer for setting unbundled prices is just as complex as using the arbitrary regulated valuation of hammers. The traditional carrier suppliers are accustomed to developing products and pricing strategies that ship million-dollar hammers to cost-plus operators. Because of this distorted regulatory valuation process, the carrier suppliers have typically had limited product success in open markets.

The last new technology adoption processes in the regulated market were products introduced in the 1980s (hybrid analog-line and time-divided switches, synchronous optical network [SONET] and asynchronous transfer mode [ATM] transmission systems). These adoptions occurred long before distributed processing and the deregulation of the local exchange. Although the cost of the vintage technologies has declined from about approximately $600 per subscriber to $200 per subscriber, new hammers using current technologies are selling for less than $100 per hammer.

The reasons that carriers do not adopt the new lower-cost technologies at the rate of technical evolution are varied and complex. The rest of this paper explores some of the structural reasons for the technology adoption gap versus the new technology evolution rate.

The Stage Is Set

The relatively new technology companies that have created the $100 hammer technologies perceive a major gap between the introduction of their technology and the adoption of their technology by carriers. Some type of gap exists in their mind, as evidenced by the 12-year interval since new technology adoptions by carriers. Many think the gap is caused by the difference in technology. Although this difference in technology could be a contributor, it is also reasonable to assume that the actual rate of adoption is a combination of the slow transition away from the cost-plus rate base, the confusion in the regulatory processes caused by the Act, some poor decision-making by management, and the current product process in the hammer business.

From the technology perspective, the stage is set for tremendous business growth. Today, 50 million people use data services. Today, only 22% of the U.S. enterprise market has high-speed access, and less than 2% of the mass market has high-speed access to data services. Given this stunning market situation, why has the carrier market collapsed? Why have major suppliers (Lucent, Nortel, Alcatel, Motorola, etc.) and many service suppliers (WorldCom, A&TT, Sprint, Enron, Williams, Covad, Exodus, etc.) flirted with the penny stock range? Why are digital subscriber line (DSL) prices increasing when supply is expanding and the volume of purchases is increasing?

Would faster carrier adoption rates solve the supplier and carrier market problem? Would involuntary unbundling or the monopoly-proposed rebundling of data service be better ways to solve the problem? These are good questions that will be addressed during the next several years.

The best way to understand today's carrier market turmoil and potential solution is to review the regulated market. First, it is important to consider that incumbent monopoly carriers are not stupid. They are well versed in the art of controlling the availability of goods and production resources. This art of market control is the very nature of a monopoly. The incumbent operators clearly understand that one more day of monopoly is better for their stockholders than any deal the government will cut with them with respect to the involuntary unbundling of the monopoly bottleneck facilities. No one should be surprised that they are trying to rebundle data services, enter the long-distance service markets, and not unbundled current bottleneck elements.

From an incumbent perspective, delay is clearly a good management tactic for thwarting the will of Congress—with the hope that Congress or the courts will change public policy with respect to the dissolution of their monopoly power. Again, without any intent to pass judgment, it is clear that open-market concepts only make sense to those that do not have a monopoly.

In traditional open-market terms, monopolies are harmful. Their centralized control of production resources, capacity availability, and prices ultimately works to the detriment of consumers. The open market of the computing industry is often used as a paradigm comparison to monopoly.

The open-market computing industry has fostered an entrepreneurial environment that enables visionaries to come together with technologists to foster new technologies for solving real business problems. In fact, this open-market marriage of business and technology has become an almost biological process, fostering new offspring and creating new markets.

For a variety of reasons, in the U.S. open market, there exist a relatively large number of innovators and early adopters in the enterprise business segment. These early-stage buyers can see how the new hammers help them to solve their business problem and gain a competitive advantage. They rapidly adopt the advances and then push the carriers for ubiquity to reach outlying locations. It has been at this stage of creating ubiquity that the engine of new technology, running at high speed, runs into the carrier that does not seem to be moving at all.

The first signs of the pending collision between the open-market technology evolution and the monopoly carrier adoption strategies occurred in the late 1980s and early 1990s. Carriers were adopting centralized control mixed analog digital switches, SONET, and ATM. Consumers, on the other hand, were adopting personal computers (PCs), distributed processing, and local-area network (LAN) technologies. The debacle of integrated services digital networks (ISDNs) illuminated this divergence from the carrier-based centralized control systems.

The regulatory rate-base and monopoly logic seemed to be that if an analog telephone line is worth $30 and a private data line is worth $90, then two digital lines with voice and data service features and a signaling channel (2B+D) must be worth at least $120. In retrospect, the monopoly pricing of ISDN in the United States was seemingly established to control the new service adoption rate and minimize the analog-line replacements, at the expense of the new technology.

Even worse regulatory logic seemed to be applied to T1 services. If a point-to-point T1 line was worth $5,000, then a switch enabled Primary Rate line running on the same wire must be worth a lot more. Needless to say, the old hammer makers priced their new technology to the monopoly market reality. Traditional carriers effectively avoided the cost of the digital buildout by not only overpricing the technology, but also making it almost impossible to get. A T1 would take anywhere from 90 to 180 days to install, and the buyer in many cases had to pay for the buildout.

But, sound monopoly practice in a rate-base environment was being exposed to the light of a deregulating environment. In 1988, the FCC deregulated the local carrier private-line market. Newly authorized specialty carriers captured a large percentage of the Primary Rate and T1 market. Monopoly carriers responded with T1 price declines, trying to use monopoly price control to manage the new deregulated market. It didn't work—the prices and margins collapsed for the incumbents, and a significant number of buyers went with the new carriers anyhow.

The new hammer makers, though, where flabbergasted by the ISDN technology adoption results. First, it should be understood that most new hammer makers were coming from an entrepreneurial open-market background. Their experience implied that if they could provide twice as much communications capacity and remove 100% of the transmission impairments of analog lines on the same two-wire infrastructure, then everybody should buy a new hammer.

Although the visionaries and technologists achieved their technical goals—as evidenced by the delivery of the fastest growing data service of all time (Frame Relay Q.921 is part of the original ISDN specifications)—the adoption rate of ISDN carrier subscribers was abysmal. At best, about a million new Basic Rate lines were sold during a 10-year period at the prices quoted by the carriers.

The second open-market technology adoption collision occurred with the advent of the Internet in the mid-1990s. Again, visionaries and technologists, in cooperation with government, created an exciting new medium for the rapid exchange of data. Some 50 million subscribers bought computers and modems at the enterprise and consumer level to use this new medium of knowledge exchange. Nine thousand new Internet service providers (ISPs) sprung up to manage the modem pools that connected the analog telephone network to the new data infrastructure. Some 10 percent of the subscriber base bought a second analog line in the period from 1990 to 1998 for unfettered access to the new data services.

Carrier adoption of the distributed control Internet technology was almost nonexistent. Carriers sold the analog hammers to a screaming throng of data buyers. Carriers even sold some of the ISDN lines as private-line access to the ISPs. Few of the carriers became successful ISPs, where managing the new distributed server and modem pool technology was the key to success.

Although the carriers stayed out of the new distributed processing data market, the switching and transmission manufactures that made the hammers for the carriers saw a different picture. The new hammer makers where producing technology that could tentatively replace the current carrier technology. This confusion had significant impact on the ability to sell the old $600 hammers. The carrier suppliers responded by reducing prices and buying up many of the new hammer makers, under the expectation that their carrier customers would enter the data market. The suppliers hoped for the development of a replacement market for the embedded transport and switches. The carrier suppliers, like many on Wall Street, failed to consider the implication of replacement technology and regulatory rate-base economics.

The Irresistible Force Meets the Immovable Object

Carrier adoption strategies and the rate-base economics for replacement technologies do not match up well with the direction or the speed of new technology evolution or uses. In most cases, carrier adoption of new technology is driven by the monopoly/oligopoly desire for new revenue from an installed base of current subscribers. In these cases, carrier adoption means building a new technology or application-specific overlay (adding to the cost base) and marginal pricing of the new services to capture new revenues, in addition to the current service revenues.

What isn't obvious in this monopolistic process is that this strategy sets prices for the new technologies in such a way that the price limits demand to those who are willing to pay the incremental premium price on the cost-plus infrastructure assumed in the overlay.

It may not be obvious that the adding of a new technology as an overlay is not generally intended to optimize the carrier cost structure. It is also not obvious that carriers intentionally use the unoptimized infrastructure cost, plus the new technology overlay cost, to protect the current services revenues and ultimately delay the displacement of current or even obsolete technology (replacement). As an example, a typical carrier operates 15 to 20 different application-specific and, in most cases, technology-specific overlays. The impact of these overlays on service prices and the business strategy of the monopoly have become the immovable objects that drove the adoption gap and stimulated the worldwide effort to deregulate the utility markets.

Technology, driven by the enterprise early adaptors, is not typically focused on the generation of new revenue. Enterprise advances are more typically focused toward the re-engineering and ultimately the replacement of existing processes that constrain the enterprise. The enterprise adoption rate is usually driven by a business need to improve decision-making or reduce per-unit costs. Acceptance of technology that can increase speed of information exchange, facilitate data availability, train the organization, collect necessary data and/or minimize cost per unit of revenue are readily deployed to gain a competitive advantage.

The irresistible enterprise force of "better, cheaper, and faster" are currently evolving technologies that favor client control, distributed computing, peer interactions, personal customization, and remote servers—the antithesis of the traditional centralized control and service overlay that drives new overlay service revenues and the carrier adoption market. Moreover, the enterprise speed of adoption of distributed computing and new software is creating a relatively short duty cycle of three to five years. This cycle is in stark contrast to the carrier adoption and duty cycle of 20 to 30 years or more between waves of technology.

The Product Life Cycle and the Carrier Duty Cycle

The product life-cycle concept can be thought of as the process of a product moving from sellers to buyers in a type of orderly progression. Buyer types range from innovators to early adaptors, to early majority, to late majority, and to stragglers. Each phase in the product life cycle calls for unique strategies to deal with the different types of buyers in the various market segments.

The carrier duty cycle is not at all like the product life cycle. The duty cycle is the interval of time that a certain technology exists as a dominant force in a monopoly market. The forces of the open market do not impact the duty cycle. From a regulatory perspective, utilities were granted "monopoly" status to minimize the cost of capacity. By restricting the investments, a product could be designed for an extremely long useful life—independent of its economic life, depreciation life, tax life, market life, or financial life. Rotary phones that lasted for years were an example of this duty cycle concept. In carrier terms, the monopoly position enabled technologies to be deployed with 40-year duty cycles (power plants, telephone switches, sewer systems, etc.).

For a number of reasons, the power of personal computing has produced a three- to five-year duty cycle as the users progressed from Commodore, Apple, and x86 PCs to today's 1.2 gigahertz (GHz) or more supercomputer that sell for less than $2,000. Software applications have tracked this same short duty cycle, as evidenced by Windows 95, 98, ME, 2000, and XP.

This short duty cycle and rapid adoption rate has been tough to support in the computing market. The forces of technology adoption driven by this cycle has already bankrupted an entire generation of host computer suppliers, an entire generation of minicomputer suppliers, and even a high percentage of the PC suppliers, trying to keep up with the ever-expanding demand for personal computing resources and communications between these 50 million users.

In terms of carrier duty cycles, there have only been three waves of carrier transmission technology since 1886, when the phone was invented. The first wave was analog transmission. This technology maintained a 100% market-share until the mid-1960s, when asynchronous digital transmission systems were introduced. The third wave, synchronized digital transport called SONET/ATM has been shipping since the early 1990s.

Analog transport still dominates the carrier transmission market. Asynchronous digital is still being shipped (T1 is the primary service link to digital service, and T1 is not a SONET–based signal). SONET/ATM is still in its build-out phase, with limited use as a replacement, after some 12 years of production. For all practical purposes, the transport duty cycle and replacement market is limited to replacing failing copper cables and the displacement of backbone routes through the addition of new optical SONET/ATM lines that upgrade the embedded analog and asynchronous digital infrastructure.

Switching system duty cycles have also been extremely long. Switching has gone through five waves of technology since 1886. The first wave of switching was manual operators and cord boards. This wave started in the 1880s and lasted till 1978 or so, when the last cord-board exchange was retired. The second wave, mechanical switching, started in 1899, when Almon Stowger invented the first automatic switching machine. The mechanical switching wave lasted until the mid-1980s, when the last new start shipped from Automatic Electric. The analog stored program switching (SPC), or third wave, began in the early 1960s with the introduction of solid-state electronic switching fabrics with centralized computer-controlled calls. The analog switch wave isn't yet complete, some 40 years later. The fourth wave, or digital switch era, started in early 1976 with the 4E in Chicago and the TRW ITS 4 in Ora Loma.

This centralized digital switch wave has barely crested, 25 years later. New start digital tandem business was so brisk that both Cisco Systems and Lucent Technologies bought new technology digital tandem hammer makers within the last several years (Summa 4 and Excel).

The fifth wave, generally labeled fast packet switching, began in the early 1990s, with the introduction of ATM self-routing switch fabrics with optical line interfaces that are SONET compatible. This wave of centralized switches arrived in the middle of the transition from centralized hosted computers to distributed processing PCs. The switches also arrived in the middle of the transition from rate base to open systems.

From a technology standpoint, the irresistible force of distributed computing embraced by the distributed enterprise ran into the immoveable object, the rate base and duty cycle, consisting of host controlled central switching and dumb transport systems that dominate the carrier networks. While the enterprise was rejecting ATM for its purposes, carriers were installing it for theirs.

It became apparent in the late 1990s that a technology gap existed. Why it existed, why it was widening, and how to close it seemed to confuse new enterprises and Wall Street. In most cases, this confusion is reflected in the financial results of the start-ups entering the carrier market.

As, an example, new enterprises operating as CLECs embraced the old monopoly carrier technologies, built multiple overlays without a rate-base–driven revenue stream, and went bankrupt. New enterprises operating as ISPs built distributed computing centers and went bankrupt. New enterprises operating as interexchange carriers (IXCs) and MNOs dug holes, filled them with sand, and went bankrupt. None of the bankruptcies were caused by a failure of the technologies or the lack of customers for the new enterprises. They failed in their fight with the incumbent monopoly.

The only new enterprises that seem to have survived built their new carrier business on resold lines and SCP software. Prepaid long distance, prepaid local service, prepaid wireless, and a variety of caller ID, call centers, and 800 services have come to market and thrived during the last five years.

Illusion or Conclusion

As discussed in this paper, the evolution of technology and the carrier adoption cycles have very little in common. Technology evolution is driven by a buyer's need to improve a business process and gain a competitive advantage through early adoption. Carrier adoption is driven by a need to increase revenues from existing customers. Because the adoptions are targeted at premium market segments, adoption is typically based on simple overlays that are priced to avoid or minimize change in the current revenue flows. Based on the current realities of the carrier adoption process, any new technology evolution must lend itself to the overlay market, not the convergence market. The successful evolution and adoption of SCPs by a number of carriers is an example of the process.

As described in this paper, incumbent carriers with a large installed base of paying subscribers and monopoly control over their market gain virtually no benefit from adopting new or replacing old technologies. As such, synergy and convergence terms in the enterprise market have virtually no benefit for the carriers. In fact, because of equipment duty cycles, carriers benefit the most from the adoption of incompatible application-specific overlays and selling new lines at higher prices.

It should be clear that the author is trying only to explain the ambiguity between technology evolution and carrier adoption. The paper is not intended to be an advocacy for or against the involuntary unbundling of the local exchange or the adoption of processes to circumvent the rate-base economics. The paper is simply trying to point out that monopolies do not benefit from unbundling or the creation of a wholesale local market. Given the relationship with stockholders, it makes sense for the carriers to present roadblocks, create obstacles, and develop pricing plans that ultimately disadvantage the CLECs.

Lastly, the paper tries to describe the difference between product life cycles and the carrier's view of technology duty cycles. Given that duty cycles are fostered by the rate-base economics, it seems highly probable that most carriers have not even begun to consider any next-wave adoption plan or replacement technology.

Integrated Access Devices: Bridging the Gap between Modern IP Networks and End Users

Peter Hall
Chief Operating Officer
Braintree Communications Pty Ltd

Integrated access devices (IADs) and intelligent protocol conversion is nothing new. However, the importance of the two is increasing rapidly as new-generation Internet protocol (IP) networks become more readily available for small-to-medium enterprises (SMEs).

The importance of IADs is rapidly increasing due to the slow uptake of modern IP networks by the SME market. Modern networks offer numerous added benefits to SMEs, so it is difficult to understand why the migration to the modern networks is slow. To explore the issues facing the SME market that is influencing the slow uptake, we will discuss the role that IADs and protocol conversion can play in overcoming this problem.

There are many facets to the SME markets reluctance whilst home users and larger corporates are experiencing the benefits that modern networks have to offer. Why is it that the SMEs maintain their existing legacy networks?

To understand the situation, we need to look at all stakeholders involved with migrating SME end users onto IP networks. The stakeholders exist of three major parties in the communications process: the carriers, the service providers, and the end users.

To understand the end-user environment and reluctance to migrate, business needs to understand the end user's perspective in migrating their businesses to a new network infrastructure. Do the benefits of the new network outweigh the costs involved in accessing this network?

The SME market does not argue that modern networks offer more benefits in comparison to their existing infrastructure. SMEs can gain access to new services, faster connection times, more reliable services, and long-term cost reductions. If SMEs can easily relate to the benefits, then why not migrate to the new networks?

There are three hurdles associated with migrating to modern networks facing SMEs, with one common underlying theme. The three hurdles consist of high capital costs in migrating, higher employee training costs, and higher support costs.

The underlying theme is the increase in costs in migrating to modern networks. Although SMEs can understand the benefits associated with the new networks, the costs associated with migrating are far too high for the majority of SMEs. SMEs do not have access to large amounts of disposable capital that would enable them to migrate. SMEs cannot justify migrating to the elite option if their existing basic network infrastructure performs the job adequately and reliably.

To overcome such reluctance, carriers and service providers need to address the end-user hurdles. The first financial hurdle is to replace all existing legacy equipment with modern appliances. Modern network protocols are significantly different from many legacy network protocols. Customer-premises equipment (CPE) needs to speak the correct language (protocol) to be able to migrate to the new network. Therefore, SMEs will need to replace all existing equipment. This is simply an unrealistic financial burden that many SMEs cannot justify. There lies the largest hurdle in the reluctance to uptake new networks.

The second hurdle is the increased costs in employee training. All employees will need training on the new equipment, which will not only be expensive, but also slow and frustrating for the SME. Most SMEs may need to replace all existing equipment simultaneously, not allowing the migration to be phased in over time. This places a significant financial burden on SMEs through employee training and business downtime.

The third hurdle is the support costs. Learning on the new equipment SMEs will no doubt require ongoing support as they adapt their new network to "fit" their business processes.

After understanding the situation from the end user's point of view, we can now look at the problems facing the other stakeholders in the communications process. Business needs to understand the importance of migrating existing customers to modern IP networks.

As modern IP networks evolve, it is becoming increasingly important for the carriers and service providers of communications networks to migrate existing customers from redundant legacy networks onto these modern networks. The modern IP networks consist of numerous cost-saving benefits for the carriers and service providers, particularly in network management and maintenance.

Carriers and service providers also have limited services that they can offer to existing customers on these legacy networks. New services that are being developed are increasingly designed for the modern IP networks with the aim to phase out costly legacy networks.

However, carriers and service providers do not want to tell customers throw to out all of their old hardware because there is a new network. They are faced with competitive discounting to entice customers onto the new networks.

Rather than trying to sell new products that are compatible with modern IP networks, carriers and service providers need to consider the SME markets that do not have access to disposable capital or the business case to upgrade their existing equipment.

When looking at what is connected to existing networks, there is a big list of legacy protocols. Carriers and service providers could not say to major customers that the network is being replaced with IP only. IADs are a solution to integrating the communications equipment already installed at the site with a view of migration to IP using intelligent, yet seamless, protocol conversion. This allows rapid roll out of new networks with minimal customer resistance and future services deployment without using a technician.

IADs and intelligent protocol conversion cost-effectively entice end users to migrate to modern IP networks. IADs allow end users to connect their existing equipment onto the modern networks without having to purchase a new office full of equipment.

IADs can offer a fully integrated solution for a business's entire communications network into a single carrier line, significantly reducing communications costs. SMEs today use a variety of separate lines dedicated for specific functions—for example, several public switched telephone network (PSTN) lines for the phone, fax, and personal computer (PC) with Internet connection, a dedicated line for electronic point-of-service (POS) financial transactions, and a leased line for security monitoring equipment. Four or more separate lines dedicated to individual functions. Some IADs on the market overcome this by offering a fully integrated solution for a business's entire communications network. IADs can connect any asynchronous or synchronous devices, such as PCs, with Internet connection, a standard telephone/fax system, security monitoring equipment, POS terminals, and other services to a single network connection (see *Figures 1* and *2*).

FIGURE 1

Typical Australian Retail Infrastructure Set-Up

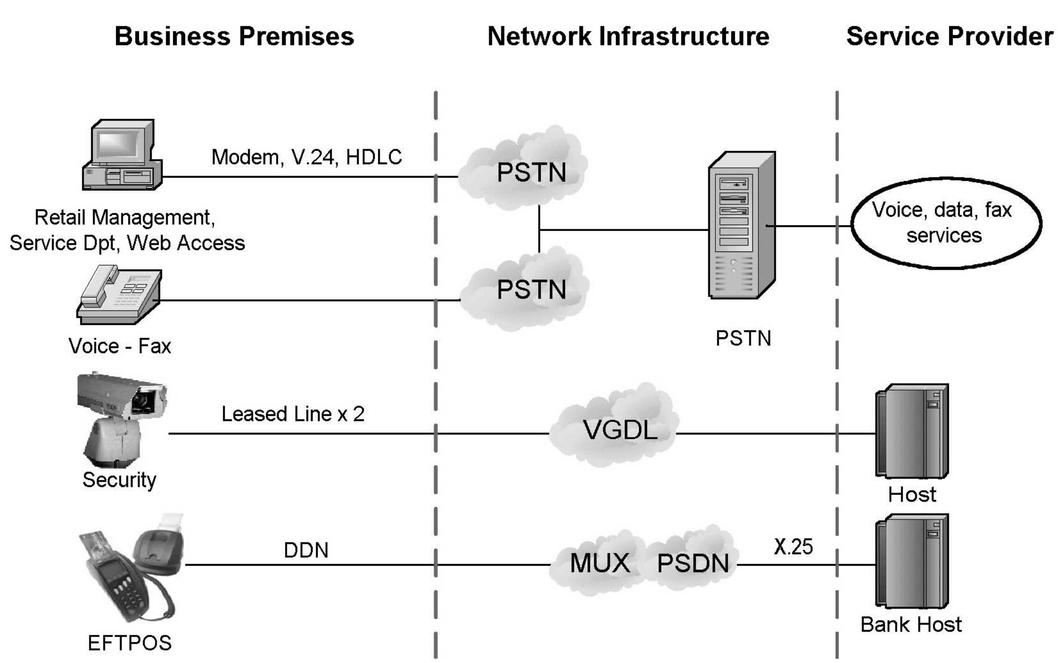

FIGURE 2

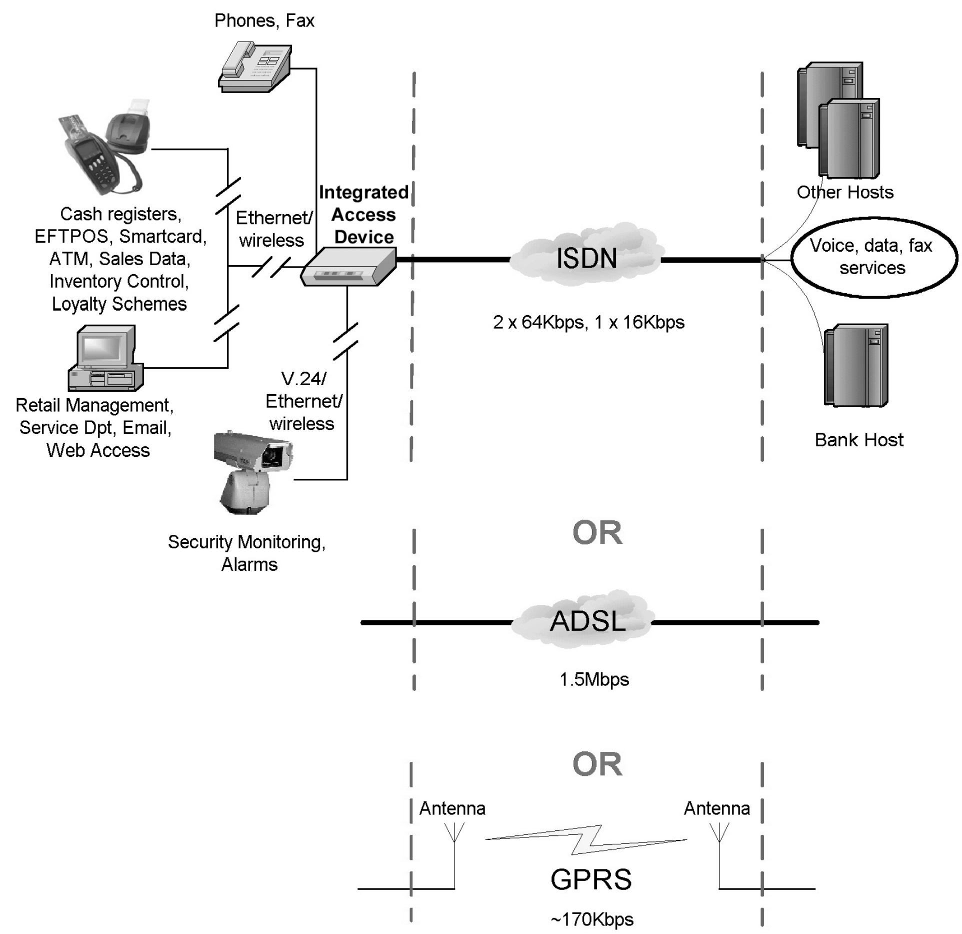
IAD Capabilities Will Differ According to Individual Product Specifications



IADs currently on the market are a simple plug-and-play technology that makes installing a modern IP network easier than a new VCR. The plug-and-play technology allows users to plug into the network, immediately minimizing down time. Quick and easy installation and use is another important aspect in migrating end users to modern networks.

The carriers and service providers could offer these access devices as inclusive with the installation costs. Carriers and service providers have the business case to carry this initial cost that will, in the long term, reduce their costs significantly by phasing out legacy networks faster. This will allow SMEs to quickly migrate to modern IP networks that will benefit all stakeholders.

Australia's largest telecommunications carrier successfully addressed these issues by offering an IAD with their integrated services digital network (ISDN) as part of the installation cost. This product enables end users to immediately connect their existing legacy equipment to an ISDN service without the capital cost increase to burden the SME. This solution is currently being successfully deployed throughout the Australian retail industry.

The carrier and service provider can remotely manage and maintain the network from a central management center through the IADs. This enables remote downloading of new software, which allows the simple deployment of network upgrades. This provides an extended life cycle of the IAD by adapting to the requirements of the users and their businesses. Network diagnostics can be managed without having to send a technician to the user's premises. This will decrease the downtime that a user may experience in a network failure.

Network management becomes easier, more cost-effective, quicker in downloading new services, and easier and quicker to maintain—all without the need for field technicians to go to the user premises.

Put simply, the IADs remote management capabilities simplify and centralizes the manageability of an entire network, easily reducing the costs incorporated in managing and maintaining the network. Remote management also provides the ability to move with new directions in communications, significantly increasing the devices potential and life cycle.

A retail petrol seller in Australia usually contains several businesses: gas pumps, mechanics, food stores, and takeout, such as Burger King. With the IAD, it is possible for all of these businesses to use the same connection, significantly reducing communications costs.

These devices will enable carriers and service providers to quickly phase out expensive legacy networks that are fast becoming obsolete. Maintenance and management can now be performed remotely, reducing costs significantly. Both the service providers and the carriers can offer new services to customers that can be offered only on the modern IP networks. The end user can now access the benefits available on modern IP networks in a cost-effective and timely manner.

With the reduction in new communications equipment purchases experienced in 2001, it is important to have the mechanisms to allow companies to access new technologies without the huge capital expense. With this in mind, the importance of protocol conversion and IADs will increasingly play an important role not only for SMEs, but also for the business population wanting to keep up with cutting-edge technology infrastructure.

SMEs want reliability of service, speed, security, simplicity, and upgradeability. Having the latest technology would be great, but on a cost basis it is not feasible for the majority of the SME market. IADs bridge this gap between the modern networks and the end user. All stakeholders in the communications process can benefit from this intelligent protocol conversion device.

Seeing the Real Telecom Future

David Heard
President and Chief Executive Officer
Santera Systems

Few industries have experienced a more jarring change than that which has shaken the telecommunications industry in recent years. But significant change continues in our industry. To see more clearly the future of the telecom infrastructure business, we must first examine the forces that are driving these trends.

Emerging carriers such as competitive local-exchange carriers (CLECs), integrated communications providers (ICPs), and data local-exchange carriers (DLECs) face potent new cost and profitability pressures. They must deal with significant and growing pressure to deliver increased capacity, maintain voice and data revenues, and roll out popular new services, all while controlling both capital and operating expenditures. Even though data traffic is growing rapidly, most networks still rely on voice to produce their largest and most consistent revenue stream.

These drivers are growing at a critical juncture in the history of telco network infrastructures. For many operators, their installed switching technology is at, or nearing, the endpoint of its useful lifespan. For the industry as a whole, the time is rapidly approaching for a major reassessment of its fundamental approach to the telecom switch.

Technology Cycles

As with many other developing technologies, the telecommunications switch undergoes a periodic and largely predictable cycle of evolutionary innovation.

With the advent in 1897 of step-by-step switching systems, telephone companies introduced rotary dialing and enhanced both the privacy and capacity of their networks. A generation later, in 1938, the emergence of crossbar systems reduced both the power and maintenance requirements of the telecom switch. In the early 1960s, the deployment of electronic systems heralded the introduction of transistors, stored memory and speed dialing, call forwarding, and other features.

Then, in 1976, with the roll out of first-generation digital technologies, the industry entered what once was called the "modern" era of telecom switching. Digital switching dramatically increased the carrying capacity of the telecom network, while supporting the introduction of time division multiplexing (TDM) and the eventual deployment of the integrated services digital network (ISDN), advanced intelligent network (AIN), and other enhanced features.

Those current-generation switches, which form the installed base for telecommunications networks the world over, are rapidly nearing the upper limits of their traffic capacity as well as feature and service-delivery capabilities. Astute managers recognize the need for new solutions. The questions now are how to plan for, select, and deploy the coming generation of telecom switching technologies.

Time for a Switch

As is true at every cyclical turning point, today's emerging switch technologies must meet the immediate requirements of current telco networks *and* the future demands of a changing marketplace. Some have described this as the need to satisfy both now-generation and next-generation (NextGen) objectives.

To ensure a smooth migration from current-generation technology to NextGen switching efficiencies, network operators need a switch that delivers comprehensive legacy capabilities and the ability to satisfy a demanding set of emerging performance, regulatory, and survivability demands. That's no small order.

But given the growing competitive pressures in most markets—and the fact that many service providers simply will not install another outmoded legacy switch in their networks—the time is ripe for the emergence of an entirely new type of switch.

With the advent of the softswitch model, network operators will enjoy dramatically reduced costs, expanded density, and the efficiencies of the distributed call-processing model. NextGen switches will be smaller, simpler, easier to maintain, and capable of supporting a still emerging new wave of revenue-generating services.

By providing a single integrated switching platform, this new class of switch provides a scalable, long-term solution for both incumbents and the new competitive carriers. These more advanced switches will combine the core and edge functionalities of both the voice and data networks, and will allow services to be switched in TDM, Internet protocol (IP), asynchronous transfer mode (ATM), or frame-relay formats.

Capable of being deployed at the network edge or at the central office (CO), co-location, CLEC point of presence

(POP), or remote switching center, these more advanced switches deliver superior density and flexibility, and more powerful network controls. This new species of switch will, in effect, bridge the chasm of the looming circuit-to-packet evolution, while opening a seamless pathway to new applications and innovative business models.

A Switch Checklist

Switching is a significant challenge for telecom equipment providers.

Big name producers of traditional switch solutions—hit by layoffs, stock slides, and acquisition rumors resulting from the general slowdown in telecom equipment purchases—seem to have lost the focused drive needed to develop and deploy a new generation of network switch technology. Legacy players have tried to bolt add-on features to existing equipment. But those point-solutions often create little more than stop-gap solutions and new potential network points-of-failure. Many suppliers, vulnerable to shifts in funding and technologies, lack the resources needed to launch the new species of switch technology that network operators now require.

To appreciate the difficulties faced by the supplier community, we should first understand the requirements of a true NextGen switching solution.

Any advanced switching solution must deliver a comprehensive set of Class-5 capabilities as well as a flexible platform for providing enhanced revenue-generation data services. This technology will ideally incorporate both current-generation TDM and emerging-generation packet fabrics, an innovative architecture that will support both native and any-to-any switching modes with unmatched density and growth capabilities.

Specific NextGen switch requirements include the following:

- ***CALEA:*** Under the Communications Assistance for Law Enforcement Act (CALEA), telecom carriers must adapt their networks and services to provide authorities access to voice content and call data communications originating from, terminated at, or forwarded by any subscriber under authorized surveillance. All carriers must meet this requirement, but not all switches provide a simple and efficient CALEA solution.

  While some suppliers address CALEA with expensive and failure-prone network add-ons, true NextGen switches will support a seamless, powerful CALEA capability in both the TDM and packet fabrics. These advanced switching technologies will leverage today's more capable protocols and use media gateways to establish the one-way connections used to implement CALEA bearer monitoring. These new switches will also allow data calls to be tapped and transported for off-board analysis.

- ***Survivability:*** Network reliability and availability will be key competitive factors in tomorrow's telecom environment. To satisfy the survivability demands of the PSTN, this new generation of switches must deliver proven five-nines reliability through the use of no-single-point-of-failure redundancy at the hardware, software, control, and bearer traffic levels.

  Specific reliability features should include physical and logical redundancies, continuous self-test, and sanity monitoring. Key common control hardware and all external fast Ethernet connections must feature redundant, constantly available configurations.

  Feature exchange platforms should also be designed for optimum availability and redundancy protection. This level of survivability is assured through the use of multilayered software and process separation, built-in hot-swappable power converters, and comprehensive, automated monitoring and alarm systems.

- ***Network-Level Survival:*** As subscribers demand ever-higher levels of availability—and considering the threat conditions in the post-September 11 environment—network operators must now also address a far broader and more demanding set of network survivability issues. The basic concept of building separate, virtually managed core switching elements is reasonably well understood, but in today's more security conscious landscape, network managers want switches that offer a higher level of survivability.

  Forward-looking switch designers are now refining a virtual-cluster approach that would deploy two or more mirror-imaged master switch controllers (MSCs) capable of surviving a single disastrous network event. Using active standby coordination, central control functions would be separated into multiple physical locations, each of which is capable of controlling the entire switch fabric. Should an event result in the loss of any MSC, key switching functions would instantly and automatically be switched over to another operational machine.

- ***E-911:*** Carriers must now also deploy switching platforms capable of meeting today's more demanding enhanced 911 service requirements. The best new switching solutions allow carriers to route emergency calls by priority, to bypass network traffic controls, and to quickly pass control of the call from the network to the appropriate public-safety agency. Switches that employ a TDM matrix can measurably reduce the risk, complexity, and cost of delivering enhanced emergency service capabilities.

- ***LNP:*** Originally mandated in the Telecommunications Act of 1996 to enable local competition, local number portability (LNP) is a critical feature expected in today's telecom landscape. Carriers of any size require LNP capabilities to efficiently implement Federal Communications Commission (FCC)–mandated LNP services, so they can manage any magnitude of telephone-number porting orders and changes quickly and reliably.

- ***VoB:*** Voice over broadband (VoB) is poised to drive what many expect will be the next major expansion of service capabilities, and service providers will need switching technology capable of supporting full VoB functionality. The key features needed in a

VoB–enabled switch include ATM access with dynamic routing and high port density; a voice gateway with enhanced density, compression support, and ATM adaptation layer 2 (AAL2) over subscription; and full Class-5 capabilities, including automatic messaging account (AMA) billing and full feature support.

- ***Legacy Support:*** This new class of switch must also provide full support for a wide range of legacy applications, including primary rate interface (PRI) and signaling system 7 (SS7)–International Mobile Telecommunications (IMT) interfaces, transactional capabilities applications parts (TCAPs) for LNP, and simplified message desk interface (SMDI) for voice-mail services.

Coming Dislocation

What kind of supplier is capable of delivering this new class of switch? There are currently four key tiers in the switch infrastructure supply marketplace. Tier One is comprised of traditional high-end players such as Nortel Networks, Lucent Technologies, Alcatel, and Cisco Systems. Tier Two is defined by somewhat smaller switch industry competitors, such as Ericsson, Siemens, and others. Tier Three is known to some as the "Emerging Giant" sector and is distinguished by development-oriented companies that hold the promise of moving upwards toward Tier Two or Tier One status. Tier Four players are traditional start-ups that continually struggle to attract capital but that may someday emerge with viable technologies and business models.

As anyone conversant with today's telecom industry knows, players in Tiers One and Two as described here are currently under tremendous marketplace pressures, with one or more Tier One companies currently divesting themselves of switch-related business units, and Tier Two companies also showing signs of abandoning the switching field to pursue other business strategies. Some have speculated that, within the switching sector, Tier Two will collapse altogether, while Tier One will undergo a massive shakeout that will leave just one or two current players still in place.

For this reason, a number of informed industry observers now consider Tier Three's Emerging Giants to hold the most promise as a source of telecom switching innovation and solutions.

The distinguishing characteristics of an Emerging Giant are best-in-class switch technology and a fully funded business plan. These future winners will also posses unmatched experience in carrier networking and clear operational plans for the deployment of NextGen switch technologies. And, of course, a qualified supplier will offer a comprehensive program to help network operators and service providers understand, integrate, and operate a productive NextGen switching network.

Carriers have a great stake in this coming dislocation, because their networks and ultimately their core business models depend heavily on the availability of workable and competitive switching solutions.

There is little doubt that NextGen switches must and will emerge from the current market upheaval. When they do, they will bring a wealth of benefits to both network operators and their subscribers.

NextGen Advantages

Virtually any incumbent or competitive telecom network can benefit from the qualities of a NextGen switching solution. By integrating easily with legacy systems, interfaces, and applications, these new technologies actually extend the useful lifespan of installed infrastructures. But because they also support a seamless circuit-to-packet migration, these new switches also encourage the integration of third-party services and the rapid deployment of popular and profitable new service features.

As true carrier-class technologies, this new class of switch can deliver the 99.999 percent reliability needed in today's public switched telephone network (PSTN) environment. These platforms can scale quickly and economically to serve as few as 2,000 to more than three million subscribers from a single network cluster. When compared to current or proposed alternatives, the best of these new switches can reduce capital costs by more than 50 percent, while reducing network operating costs by as much as 70 percent.

Conclusion

Those are the driving forces, technology requirements, and promised benefits behind the migration from current- to coming-generation telecommunications switch solutions. Depending on their business model, network operators may be at, or nearing, the decision point that will determine their own switching strategies.

By understanding the issues relating to switching infrastructure, telecom managers can see more clearly the future of their own evolving network.

Data Services Profitability: Learning from the Voice-Feature Business Model

John Holobinko
President and Chief Executive Officer
Aplion Networks

The communications industry is facing a change of epic proportions. The underlying revenues for basic voice and data services upon which this industry was built are under a virtual siege. And there are no killer applications identified on the horizon to bring the industry out of its current malaise.

Beware of What You Wish for…

The greatest service providers' dream was creating cheap bandwidth. Yet, cheap bandwidth has provided none of the economic benefits that the industry anticipated. Instead, cheap bandwidth has led to oversupply and rapidly falling prices. Profit margins have not increased. Instead, they have been declining. Prices for bandwidth no longer reflect the cost of providing that bandwidth, but instead only what the customer is willing to pay. Enterprise customers embraced the concept of cheap bandwidth, not to buy more of it, but rather because they view the cost of bandwidth as a necessary business overhead whose cost should be reduced as much as possible.

Technology Advancements Are No Longer an Advantage

For the first time, technology is changing faster than the industry's ability to absorb these changes. The ability to expand transmission bandwidth capacity is no longer limited by technology, but rather by today's economic conditions. Those who have argued that the industry's economic bottleneck is local access must explain why service-provider local access networks can be purchased at pennies on the dollar (e.g., Winstar's assets) as service providers go out of business.

Convergence has been an utter economic failure. While service providers and venture capitalists embraced the idea and built solutions to transport data, voice, and even video traffic on the same wire using Internet protocol (IP), enterprise customers have overwhelmingly rejected the business proposition. Proof is that today, frame relay and asynchronous transfer mode (ATM) services revenues continue to grow faster than IP services revenues. In the eyes of business customers, the loss in security and performance by leaving these trusted services was not worth the benefits that IP transport promised.

The Industry Challenge: Incremental Revenue, Profitable Services

If a reversal of the current economic malaise in the industry is to occur, it cannot be through restoration of the old basic voice/data bandwidth services model. There is no single killer application that will save the industry. If there were, it would already have emerged in eight years of industry searching since the Telecommunications Act of 1996 created the basis of today's market.

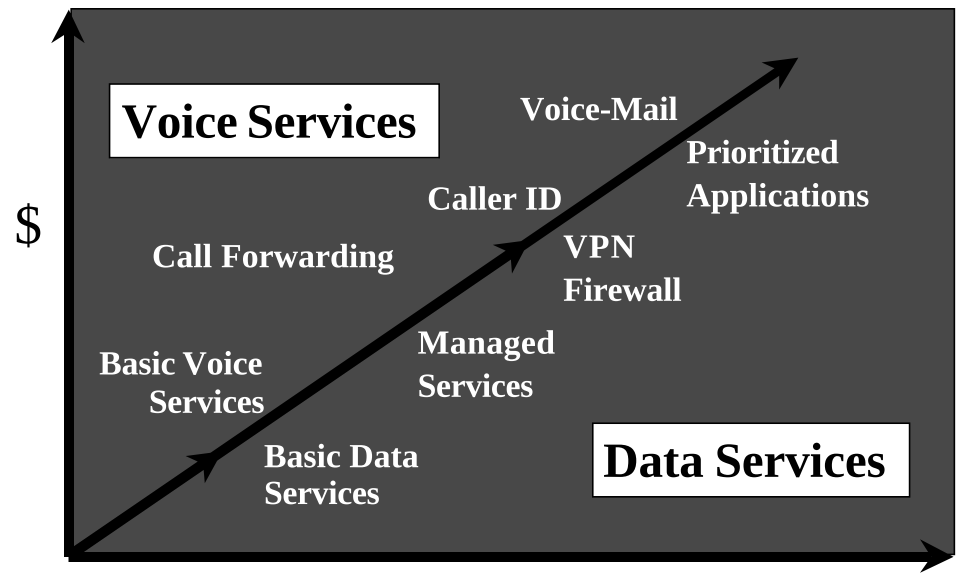
Rather, the challenge of the industry is to gracefully evolve to a new economic model in which communications services are easy to offer and maintain and have high profit margins. Yet what kinds of services offer this potential and what types of customers are willing to buy these services?

Data services represent more than 80 percent of today's consumption of bandwidth, yet provide less than 20 percent of overall service revenues on an industry basis. On a profitability scale, the numbers are even worse. Clearly, data services represent the greatest opportunity for increasing revenues and profits (see *Figure 1*). Correspondingly, enterprise customers have the most to gain from communications services and are therefore willing to pay more for data services if they provide more direct business value. This is a big "if." Few of today's communications services provide direct customer value. To provide direct value, the service must do one of three things: It must improve enterprise business efficiency; help them serve their customers better; or provide functionality that they cannot otherwise afford.

Spiraling IT Costs: The Industry's Best Friend

One of the fastest growing areas of enterprise costs is for information technology (IT) services (see *Figure 2*). Even as

FIGURE 1



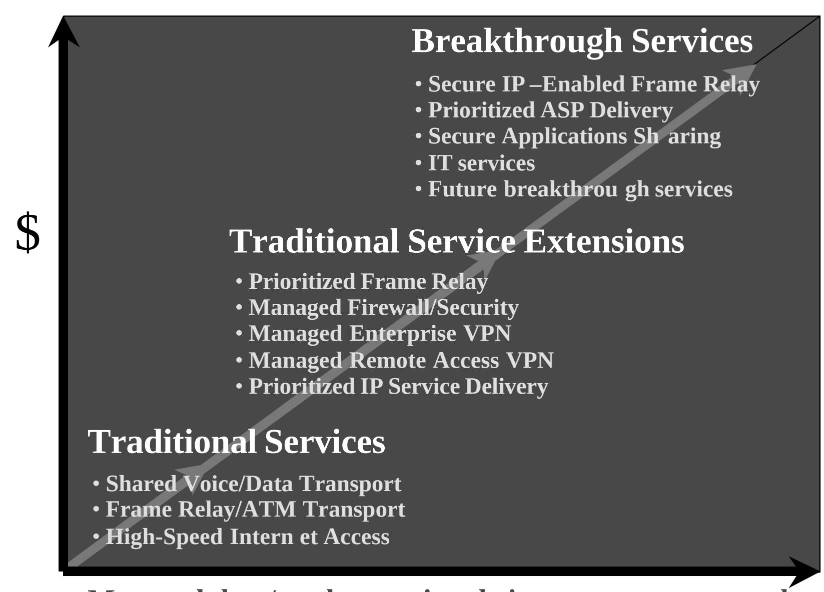
Managed data/ packet servi ces need to be as pro fitable as managed voic e features.

the economy has weakened, enterprise IT expenditures are not falling. IT professionals are expensive. New IT applications have high up-front costs. It is this condition that represents a large business opportunity for services providers: The ability to provide managed services to enterprise customers represents a potentially huge area for revenue growth for service providers, because it displaces more costly IT expenditures for the enterprise customer. Increased managed services revenues to the service provider represents either a cost savings or greater return on investment (ROI) to the enterprise customer, compared to the expenditures for hardware, software, and IT support personnel that they would otherwise have to make.

Managed Services: Great Potential, No Profits

Many service providers have known that managed services are a market that they must address. Yet, they have had lit-

FIGURE 2



Managed data/ packet servi ces bring gr eat revenue a nd profit opportuni ties.

tle, if any, success in providing these services. Historically, they have been costly to implement and difficult to maintain. As a result, the prices that must be charged to customers make them unattractive to the majority. And for many of these services, the ability to guarantee service levels on a continuous basis has been difficult or impossible. Therefore, managed data services have continued to be a source of service-provider difficulties.

It is easy to understand why the underlying cost to provide these services is so expensive. It is not the network infrastructure, which represents only 20 percent of service costs. The life-cycle costs to support these services represent 80 percent of their cost. A managed service typically requires reprovisioning of the network; additional equipment at the customer premises, central office (CO), or both; and expensive truck rolls in order to implement and maintain each service (see *Figure 3*). With these high up-front and sustaining costs, most managed data services have only a marginal chance of being profitable, and then only in out years. Service contracts must be typically two years or more, which further reduces customer acceptance.

Some service providers have outsourced selected managed services to companies that specialize in providing one or two managed services, such as IP–based virtual private networks (VPNs) and firewalls. In this scenario, the outsourcer installs and manages the service. The service provider has no control over service costs, and its revenue consists of only a small percentage (e.g., 25 percent) of what the customer pays for the service. This limits the service provider's ability to generate additional profit margin by leveraging pricing, customer penetration, or underlying service costs, because they are all outside of the service provider's control. Furthermore, responsibility for service problems is still placed squarely on the service provider by the customer.

Data Services Management Is Too Complex

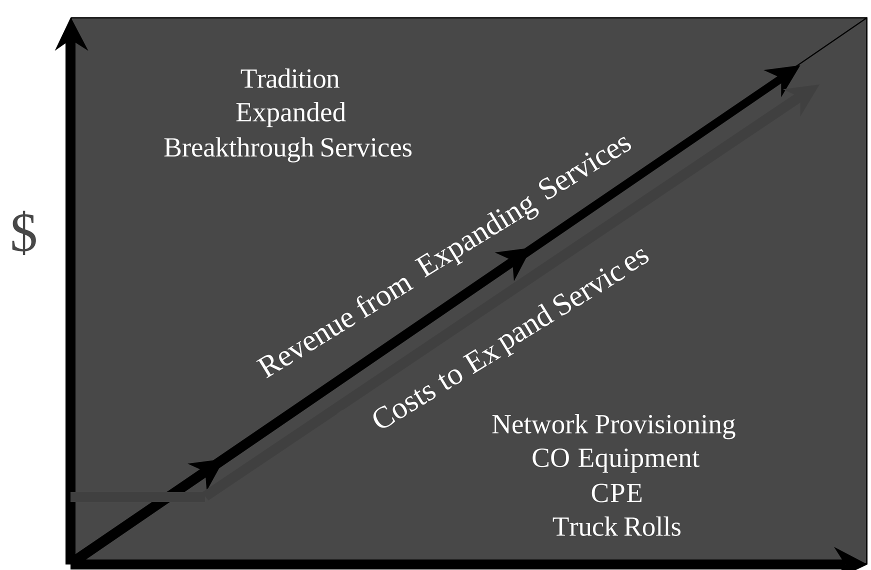
The equipment in today's networks, whether connection-based or packet-based, does not have the ability to manage actual services. Today's networks—including the switches, routers, and multiplexer equipment—cannot themselves recognize the difference between applications that run over bandwidth. They can only manage and prioritize traffic as defined by circuits, not the actual traffic itself. Therefore, to provide quality of service (QoS) requires a separate circuit to be managed across the entire network. Whether these circuits are frame relay permanent virtual circuits (PVCs), ATM virtual circuits, or IP–based multiprotocol label switching (MPLS) tunnels, the complexity and the overhead are similar, independent of technology.

Recognizing and prioritizing by application takes additional equipment for each customer. For the service provider, installing, integrating, and maintaining this equipment for each managed application adds cost and complexity. The burden for integrating multiple hardware and software elements necessary to instantiate the service rests on the service provider. When multiple data services are implemented, features of one service often cause unintended interactions with another of the services, resulting in service problems. It is no wonder that service providers find that the initial cost of offering these services makes them initially unprofitable. As the number of customers rises, the service life-cycle costs do not scale, but rather, in many cases, get worse (see *Figure 4*).

The "Best of Breed" Fallacy

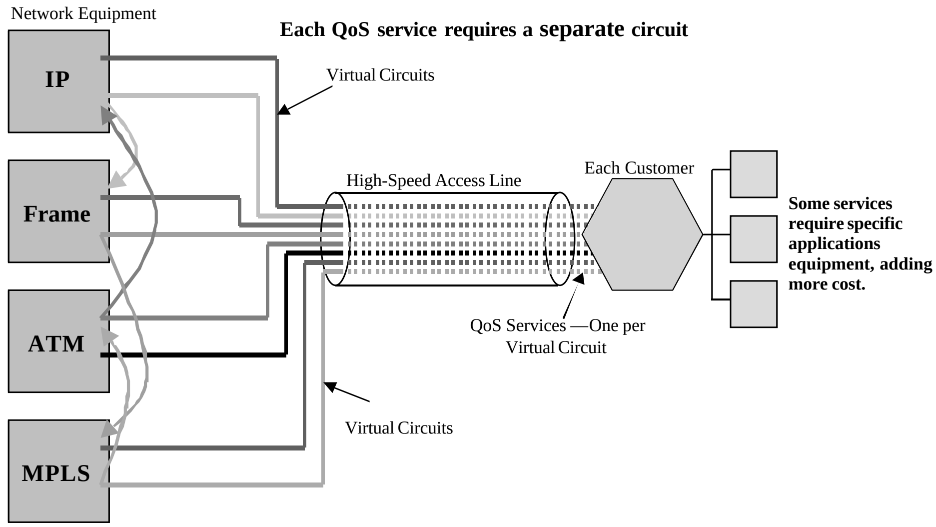
Historically, service providers have evolved to an equipment selection process in which each network element (NE) in the transmission network can be selected independently of other NEs. This gives the service provider maximum flex-

FIGURE 3



The life-cycle costs of managed services are obstacles to success.

FIGURE 4



Why are current service costs so high?
Life-cycle costs are 80% of the total cost.

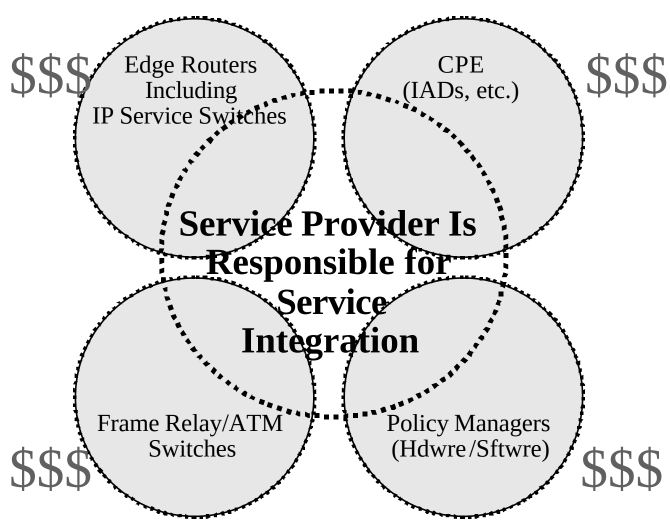
ibility. This "best-of-breed" selection process works for traditional bandwidth-based services because transmission-layer technology is very mature, including standards that have been developed over many years.

However, managed services are relatively new. In the case of managed data services and advanced applications services, there exists no mature model upon which all equipment and software can conform to at the *service level*. Therefore, the service provider is responsible for all service integration and the resolution of conflicts due to interactions between various vendors' software and equipment (see *Figure 5*). In the case of advanced data services, "best of breed" has not been a successful business model. It has resulted in the high service life-cycle costs that prevent these services from being priced reasonably and becoming highly profitable.

A Proven Model for Success: Voice Features

Voice features continue to provide the highest profits of any communications services. There is a good reason for this. When implementing these services, the service provider

FIGURE 5



Equipment integration is complex and expensive when deploying managed data and packet services.

bears little of the costs associated with installing and maintaining advanced data services. For example, when a customer orders call forwarding, the service provider does not have to provision a new circuit across any part of the network. The service provider does not have to install new equipment. A service call does not have to be made to the customer—no truck roll is initiated. Instead, these services are installed, activated, and maintained simply by a point, click, and deliver software process.

The reasons for the unequalled success of voice services are important to the data industry. When advanced voice features were initially introduced, individual voice switch vendors provided a complete solution at the service level. The vendors, not the service provider, took on the total responsibility to integrate the necessary software and hardware to implement these services. The equipment vendors also provided full interoperability between the various voice service features that they offered to insure that changing a parameter in one service did not deleteriously affect another service. Thus, single vendor solutions enabled the service provider to implement services rapidly and inexpensively and to generate profits that continue to today.

A Managed Data-Services Model Based on Voice Features

There is no question that customer demand exists for managed data services, given that they can be priced attractively compared to enterprise customer IT costs. The challenge is to remove the current costs and complexities that make them so pricey and difficult to manage.

The goal is to have the capability to implement managed data and packet services with a simple Point-click-*Deliver*[SM] model, similar to how voice-feature services are implemented (see *Figure 6*). For managed data services, Point-click-*Deliver* means eliminating circuit provisioning, additional equipment, and truck rolls each time a service is sold and delivered. In other words, generate highly profitable service revenues now.

To accomplish this requires that a single vendor take on the responsibilities for providing a services solution that eliminates specialized equipment for each service. It requires a solution that can enable the current network to become a smart, software-enabled network that can recognize and prioritize *services* instead of simply managing *circuits*. The solution must relieve the service provider of the complexities associated with service integration. This can now be accomplished within the service provider's existing network infrastructure, current customer connections, and without affecting existing customer services.

Such a solution consists of three main hardware and software elements (see *Figure 7*):

- An intelligent services switch at the network edge that is interoperable with frame relay, ATM, IP/MPLS, and time division multiplexing (TDM) equipment
- An inexpensive intelligent service agent at the customer premises
- Intelligent service software that runs at the service provider's network operations center (NOC), which reduces the installation and implementation of services to simple software commands that are downloaded to the intelligent service switch and service agent whenever a new service is desired

If all three elements of a smart network are provided by a single equipment manufacturer, then installing and managing services can be made as simple as installing voice features. Customer connections can be provisioned once at the time of initial connection. Service speeds and priorities are then controlled by the simple software commands to the equipment on each edge. Circuit provisioning across the

FIGURE 6

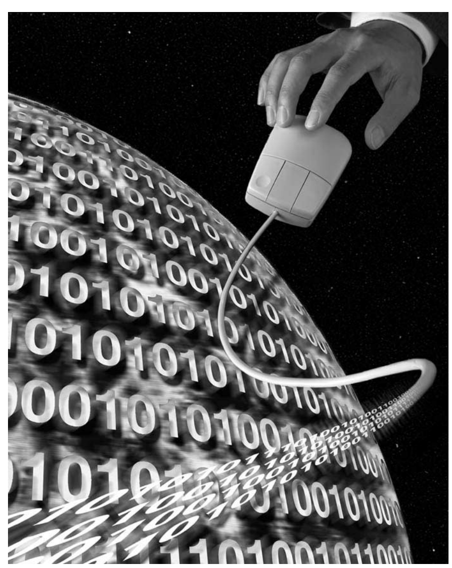


FIGURE 7

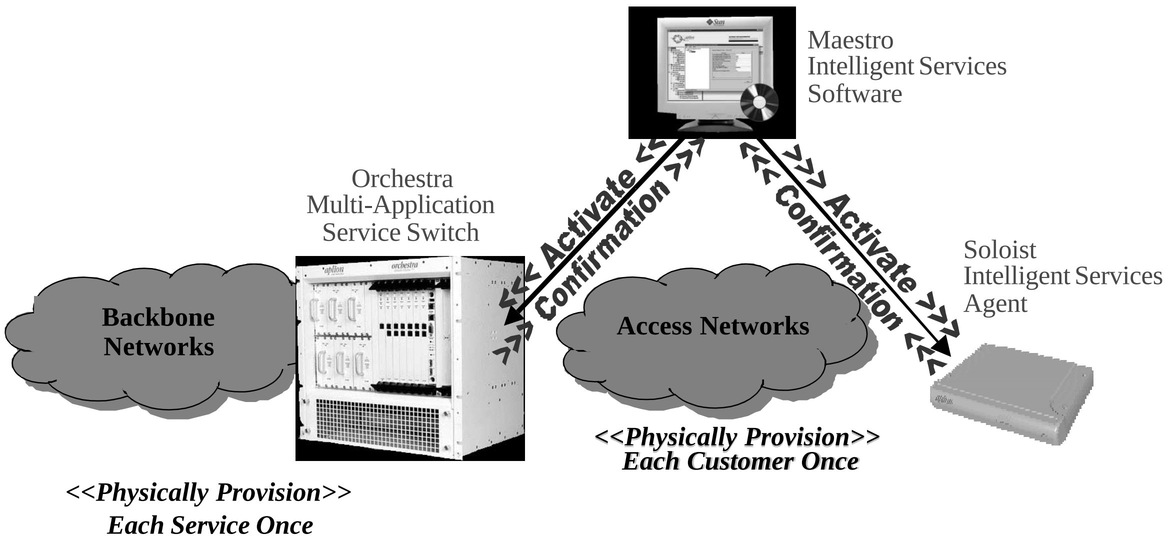


network backbone and through the access network can be decreased by more than 90 percent. Each time a new service is implemented, no additional equipment is necessary. The new functionality is simply downloaded to the equipment. Similarly, changing technology and service definitions can be implemented without the expense of changing hardware.

By eliminating the major service life-cycle costs of managed data services, they can be priced reasonably and generate excellent profits. Managed services can be aggressively marketed with free customer trials, because the cost of installation becomes so low.

Resistance to the Voice-Features Model

There are many service providers that have criticized the voice-features model. They argue that having dependence upon a single vendor was at times frustrating for the service provider. They had to wait for a vendor to complete a feature before it could be offered. It limited their flexibility. These arguments are unquestionably valid. Yet during the last 15 years, voice features have provided exceptional industry profits. It is only after many years of stability that next-generation software-based voice switches have emerged, which enable the service provider more flexibility to control their own services and to combine features from different vendors ("best of breed").

Now compare this to managed data services, which from their infancy have been implemented using a "best-of-breed" model, where individual NEs from different vendors are used to create, deliver, and prioritize a service. For the service provider, integration complexity has skyrocketed. Profits are virtually nonexistent. Services take weeks, if not months, to implement. Initial service installation costs are so high that most services do not break even for more than a year.

Clearly, a "best-of-breed" process is attractive when services are mature and already generating high revenues and large profits. It has not been successful for emerging services, such as managed data services.

It's Time to Learn from Voice-Features Business Success

The success of the voice model is unquestionable, while the "best-of-breed" model for managed data services has been a complete and utter failure. In retrospect, this should not be surprising, given that voice-service features did not move toward a "best-of-breed" model until they were extremely mature. For managed data services, today service providers need a complete managed services solution. They need a Point-click-*Delive*r model that gives them a simple, flexible, and inexpensive means to offer an extremely wide array of managed data services, easily configurable to each customers specific requirements, without network and equipment constraints.

With the rapid decline of basic voice-service and basic data-service revenues and profits due to the "cheap-bandwidth" conundrum, service providers need to quickly enhance their revenues at low capital cost. Managed data services represent a powerful engine for additional revenues over existing networks and customer connections. The service provider's fastest path to new revenues and profits is to move to a smart-network model in which a single vendor provides fully integrated managed data services solutions. A Point-click-*Deliver* process for managed services is much more lucrative for rapidly increasing revenues and profits of data and packet services as well as customer acceptance.

The Effect of Fast Technology Transitions on Companies' Survival

Abdelmaksoud A. Khalifa
Chief Executive Officer
Quttan Electronics

One of the most important things that should worry most chief executive officers (CEOs) now is product life cycles in almost all industries. It has shrunk, but in no industry has it become shorter than in the electronics industry—especially within the communication sector.

Customers are very demanding now and driven more by trends than ever before (thanks to the the information revolution and the Internet). This is creating risks as well as opportunities for companies within the communications field. However, the short-term payback from research and development (R&D) has been disappointing for a very high percentage. An increase in many companies' rate of cash burning, which outpaces their rate of income, is threatening these companies' survival.

The industry's shaking is leaving no one at rest. There are some exceptions in countries where communication companies are well protected by the government, but even this may change as the World Trade Organization (WTO) attempts to enter the doors of all the world's countries within the next few years.

We can take as an example the unrest in the home entertainment industry. Initially, cable television was enjoying stable profitable position, until mid-1980, when new technologies arose. Now there is competition between cable on one side and assymetric digital subscriber line (ADSL) and interactive digital satellite systems on the other side. If we were to compare the infrastructure cost differences between these systems, we would find how difficult it is for the cable industry to manage these costs now—how difficult it is for cable television (CATV) operators that have had to cut their charges in order to face the challenges brought about by the arrival of new technologies. Cable companies are in a bad situation now because of the high amount that they have heretofore invested in infrastructure as well as licenses. If they migrate to the new technology, they would not make use of their current assets. At the moment, they still have good market-share, but the competing technologies are becoming ever cheaper and are slowly but steadily eating away at that share. This paper is not intended to focus on the entertainment business, however this is a good example of how fast development in technology will affect companies' long-term investment and payback.

In the communication industry in general, the picture is more dark than in the cable television and home entertainment industry, because customers' tastes in their means of communication are always quickly changing. Perhaps one of the reasons why the cable television industry is not collapsing may be that end users do not care how their television channels or broadband arrive to their televisions—be it via special cables, air DSTV, or a telephone line—all they really care about is picture quality, price, services, types of programs, etc. But, conversely, the general communications client is directly interested in handset size and fashion, download speeds, mobilization and roaming facilities, etc. This is perhaps why they are quicker to migrate to the newer technologies in communications than customers in any other industry. This fast transition is the main problem.

Companies could face two situations in this transition:

1. ***Soft Transition***: This will mainly depend on the technical differences between the new and old technology. If the difference is not wide and the old technology could be used as base structure for the new one, then the transition could be called "soft" and will not threaten the company's survival or financial health. An example of this would be the cellular-phone change in Europe from the extended total access communications system (ETACS) to the Global System for Mobile Communications (GSM) standard. Despite the fact that the transmitting and switching equipment was totally different, the operator could still use a large part of its assets—mainly its towers,buildings, billing system, etc.
2. ***Hard Transition:*** In this case, the new technology comprises novel technical concepts that do not relate to the old technology, but functions better and is, most of the time, cheaper. One example of this would be voice over Internet protocol (VoIP) versus voice over normal cable or satellite channel for long distance. The old technology is based on 4KHz telephone channels over, for instance, satellite, while the new voice over Internet technology is a totally different system

that depend on gateways and routers to manage calls. Besides there being a huge difference in the investment between the old and new technology, there is also a great difference in that any company from any country could operate the new technology with no limit. We could conjecture that X company, located in tax heaven, could perhaps successfully compete with, for example, AT&T, which may be paying more taxes and licensing fees. Furthermore, labor costs would be different, as well as material costs. Such a dangerous transition could casue companies with the old technology to go bankrupt. The financial statements of AT&T for the last two years is a good indication of how they are feeling this heat—but thanks to their very large market-share and financial health, they can buy time to change.

To face this dilemma, there are several options available to companies. None of them is 100 percent failsafe, but each company should choose the one that best matches their position:

- ***Avoid projects with a long payback period.*** By doing so, companies will minimize the risk of having their investment in a technology become obsolete, and their initial invested capital will be recollected from the project before any unhappy surprises can arise. The disadvantage of this option is that big projects never have a short payback, and choosing only short payback projects could lead a company's market-share to dwindle and the company's size to shrink.
- ***Establish a very strong R&D department.*** The advantage is that this team will lead company creativity, and the company will thus generate new products frequently. Moreover, the R&D department could improve the company's understanding of new technology development and could also work as early warning system for any new technology that might threaten the company's current technology. The disadvantage is that R&D is costly matter and thus only companies with strong financial health can have the lead in R&D.
- ***Focus on services, not production***. The advantage of this is that the company does not have much exposure regarding direct investment in a technology. Because it only does marketing, the company does not have any investment in technology development. As it markets the technology available to it, the company can shift very easily to a new technology. The disadvantage is the company doed not have any competitive advantage, as it is promoting a public technology—competition is very tough, and the company's margin could disappear or become very slim.
- ***Diversify.*** Companies could diversify their business within the communications sector into different sectors in different markets. The advantage is that any loses due to a technology change could be offset by margin from other divisions. Due to their diversification, such companies will deal with variety of clients, which will thus reduce the impact of one division's clients' migration to a new technology. The disadvantage is that such companies could be marginal in all sectors—and not leaders in any of their business portfolios—which will make them weak against the market leader in each segment.
- ***Look for market niche.*** Companies should look for market niche because they can generate good profit from that niche. One example would be the long-range cordless phone, which is a market niche that is served by less than five companies worldwide. These companies control their technology and their customers. The advantage of this that the profit is good and technology change is forced by the companies themselves. They choose the time and capital for the investment in a new technology and are not forced to follow a market trend. The disadvantage is that if growth in a market niche is slow or nonexistant, those companies that are used to having a nice percentage of profit could find that this niche is vanishing or has vanished, thus forcing them into the open market, where they may not survive the mass-market games.

Many CEOs are now focusing more on survival than on making money. A lot of focus is on the stock market and making the stock-market analyst happy, as they are the key for achieving the needed capital for investment in this year's new technology. This is fine for now, but what about next year's new technology. Companies cannot continue investing in new technologies indefinitely—they need time to rest, to get paid back for their investment. This will never happen with companies' merging and becoming bigger and bigger—which provides short-term relief through cost-cutting due to the merger of manpower, but in the long term becomes much more complicated.

One solution might be a collaboration of R&D involving all leading companies in the field. In this way, they could enforce the latest technology and the huge R&D cost could be shared among the group members. One example of this is the development of the Bluetooth technology, which five big companies have been leading. Unfortunately, the launch of Bluetooth has not gone as expected, because costs were five times higher than were hoped. Nevertheless, one collaborative group's troubles does not guarantee trouble for all who endeavor to collaborate in such a manner.

DSL Deployment: The ISP Perspective

Lorraine Lopez
Vice President, Broadband Operations
EarthLink

This paper presents a case study of one Internet service provider's (ISP's) experience with digital subscriber line (DSL) deployment. The ISP serving as the vehicle of the study is EarthLink, currently the second largest ISP in the United States.

Key Strategies

ISPs are vital to broadband's success, but ISP customers are not insistent on a particular kind of Internet access. The customers demand fast Internet access, but if DSL is not an option in a given area, the ISP's proposal of access through cable or a microwave multipoint distribution system (MMDS) will be readily accepted.

Ongoing communication between the ISP and its customer is essential to maintain the ISP's reputation and market share. The quality of a customer's experience should be at the top of the ISP's list of strategies, followed closely by the aggressive expansion into new DSL markets and the concurrent pursuit of cable network agreements.

EarthLink focuses on services rather than on carriers and uses multiple vendors and technologies to achieve its ends. In this way, it provides its customers with access to the Internet and with important services such as e-mail. In addition, the type of access can be changed with no impact on the customer.

The services offered by EarthLink are competitive with those offered by other ISPs: high-speed asymmetric DSL (ADSL) or symmetric DSL (SDSL) access to the Internet, self-installation, dynamic or static Internet protocol (IP) addresses, dial-up access, e-mail, and 24-hour technical support. To attract new customers, the ISP offers free equipment, set-up, and installation in the United States. Unlike some ISPs, EarthLink has found that its customers are sensitive to pricing and can be lured away by attractive offers from other companies. The offer of free equipment and installation combines with the ISP's pricing strategy to keep its customers from straying.

Variable Degrees of Success

The relationship between ISPs and local-exchange carriers (LECs) has often been tense, as LECs have traditionally regarded ISPs as competition. Gradually, however, LECs are recognizing that ISPs are their best customers, and with these improved relationships market expansion and penetration go smoothly.

Although automation of the ordering process is improving, significant problems remain. Different systems are not necessarily compatible, and if a vendor's ordering system has a system enhancement that does not match the ISP's, even a minor glitch can wreak havoc. All parts of the chain—the ISPs, the LECs, and the incumbent LECs (ILECs)—are affected by system changes in the other parts, and those incompatibilities can significantly slow down business.

Technicians are gradually coming to understand their installations more completely. A few years ago, technicians were oriented specifically toward either hardware or software, and the person who physically installed a mast and then climbed the mast to install a parabolic dish was not the same person who entered the house, loaded the software, went through a checklist, and talked with the customer. Today, a single person frequently performs that wide range of tasks. Extensive training programs have helped technicians to be increasingly competent and comfortable in both worlds.

Self-installation is making inroads in the industry, as it eliminates an important number of truck rolls. With the proper guidance and support, self-installation can be very successful, and the costs of deployment will consequently be cut; however, a number of truck rolls will always be necessary. Some customers would rather pay for a truck roll than spend the time involved in self-installation. Even so, the savings in truck rolls and technician time offered by self-installation are significant: The average customer call for self-installation lasts only 10 minutes.

In fulfillment, too, ISPs and vendors often fall short, as only a few people in the industry today have expertise in this area. EarthLink has fewer problems in this area than some, as 98 percent of its customers in Genuity territory are doing self-installation.

Exception handling and escalations are two familiar elements in any ISP's business. The unusual position of the ISP between the LEC and the customer often requires the ISP to approach the LEC with a request to expedite a customer's account to deliver service as quickly as possible.

An ISP's Deployment Concerns

The biggest challenge facing ISPs is living up to market expectations. Customers expect DSL to be like narrowband—easy to install and inexpensive—and that is not currently the case. DSL service is plagued by communication problems and ongoing system troubles punctuated by frequent upgrades and software "improvements."

The customer's experience is further complicated by potential finger pointing between LECs and ISPs. Most customers care less about a problem's origin than about its solution. Customers are often faced with what appears to be unresponsiveness on the part of their providers, and that leads to frustration. DSL can appear extremely complicated from the customer's point of view; in contrast to the troubles associated with DSL service, the customer can call a cable company and be installed in only a few days.

To remedy the difficulties of deployment, ISPs would like to see better coordination between industry partners coupled with on-line sales, provisioning, and order tracking. Ideally, a customer should be able to track his order in detail—for example, logging on and seeing that the service has been ordered, but that the line presents problems and is being checked, or learning that the equipment has been shipped and that the filter and software will follow soon.

In addition, ISPs would like to see loop turn-ups in 24 to 48 hours, and they need enough equipment and capacity to handle delivery of that service.

Generally, ISPs find that DSL is a good service, but customers want fast access and do not care if it comes as DSL or cable. To keep customers, ISPs must keep them informed of their order's progress all the way from the original request for service to the point at which the service is up and billable.

IP over Optics: A New Approach to IP Service Transport

Yaki Luzon
Founder and Vice President, Marketing
PacketLight Networks

Michael Mesh
Founder and Chief Technology Officer
PacketLight Networks

Internet protocol (IP) traffic uses heterogeneous networks and equipment and runs over multiple topologies. The goal of network designers is to handle IP traffic in light of changes and dynamics in networks and technologies in the marketplace.

This paper describes an approach to the transport of different types of IP traffic. The focus of this approach is the metro transport, though it can be expanded beyond that.

Challenges in Transferring IP Traffic

IP traffic has many faces (see *Figure 1*). It can come as a T3 or Gigabit Ethernet (GbE). It can go into the network as a packet of synchronous optical network (SONET) or asynchronous transfer mode (ATM). In many cases it is transported over a SONET network, or SONET rings, without being connected to the existing metro network that carries other services such as voice.

Legacy Networks

A large amount of legacy equipment exists and must be dealt with, whether it is in the edge or the core of the network. There are also multiple protocols. IP runs over ATM and over SONET. SONET is either channelized or concatenated; it runs T1 or T3 rates and up to optical carrier (OC) signals (OC–3, OC–12 or OC–48). GbE is an emerging protocol in the metro network that is targeted mainly at the transport of IP traffic. All of these have to be accommodated simultaneously.

Typical Transport Solutions Today

In many cases today, the network solution is based on converting the different protocols into the protocol used in the core of the network, transferring them into SONET. These interfaces are actually converted twice. Usually Layer-3 processing at the edge is done in order to get into the transport network, since it must be accommodated to SONET transport. At the other end, the traffic has to be converted again to connect to the core service networks in the central offices where the core of the IP network is located (the routers).

Processing in these cases may include quality of service (QoS) handling at the edge and protocol conversion, as well as concentration of the IP traffic into the optical network.

Principles Of IP Service Transport

A new set of principles is necessary:

- Transfer IP traffic across the metro network in its native mode (protocol agnostic transparent edge)
- Take multiple sources and aggregate them in a central point, rather than handling them on a one-by-one basis from each node, to save on the connectivity in the central offices
- Process once at the central location, as opposed to at each and every node in the network, to simplify the edge of the network and save cost
- Switch by service type and not by a specific interface that comes in. It is possible to bundle multiple interfaces and switch them according to the type of interface that they were brought into, their source, or their destination. This allows more flexibility in managing the network.
- Assure that any type of service can be mapped to a wavelength, and multiprotocol label switching (MPLS) and generalized MPLS (GMPLS) can be used as a control plane
- Use MPLS tags to mark different types of services, and provide traffic engineering and QoS

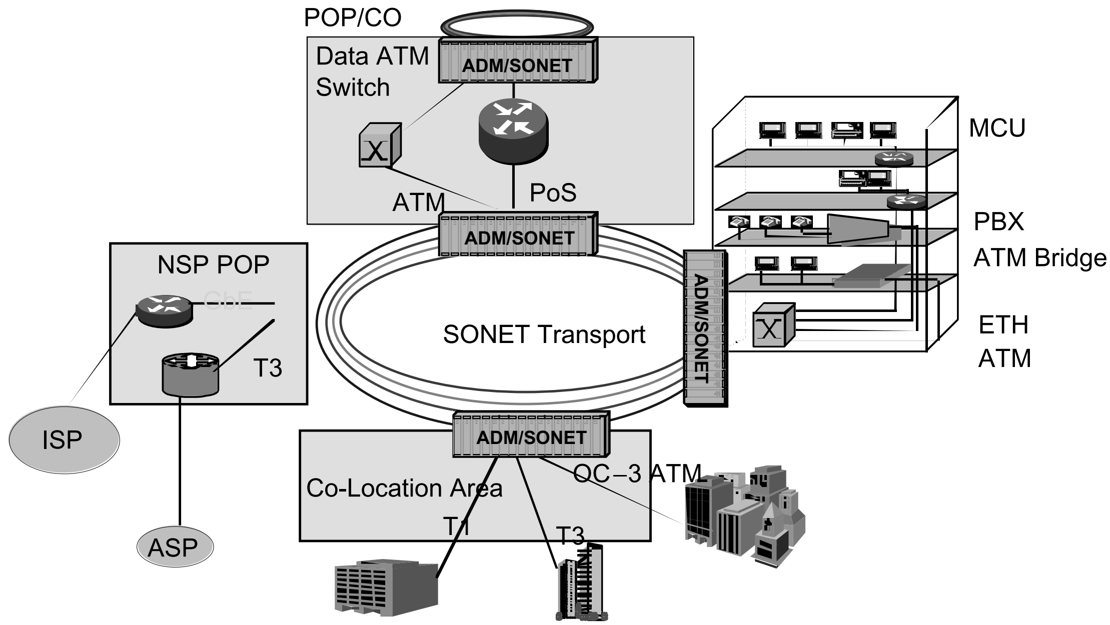
The proposed method utilizes the above principles, taking all the different types of interfaces and mapping them in their native mode into the fiber by packetizing them—the transparent-edge concept (see *Figure 2*). It also takes advantage of the high capacity of the fiber by not concentrating traffic before mapping it to the optical network.

Service Transport

Processing is no longer needed on every node, and transport is not limited to any specific topology. Fiber-optic connectivity allows a combination of topologies including rings, trees, and mesh. In many cases, the data networks are mesh in nature because of the equipment that exists for handling

FIGURE 1

Networks: IP Over…



data. On the other hand, the transport network is mostly built as rings. Wavelength connections with dense wavelength division multiplexing (DWDM) can be used to create mesh networks over ring topology. The connections to different types of networks are done at the central location (see *Figure 3*). The IP traffic transported can be transferred over pure IP networks to the routers, all-optical networks to other locations, ATM as a router interface, or even TDM networks that come out of edge routers and are aggregated in the central location.

Using MPLS for Multiservice Transport Solutions

An MPLS control plane is used to connect between service applications and service core networks (see *Figure 4*). This is done in stages. The first stage, at the edge of the network,

FIGURE 2

Transparent-Edge Concept

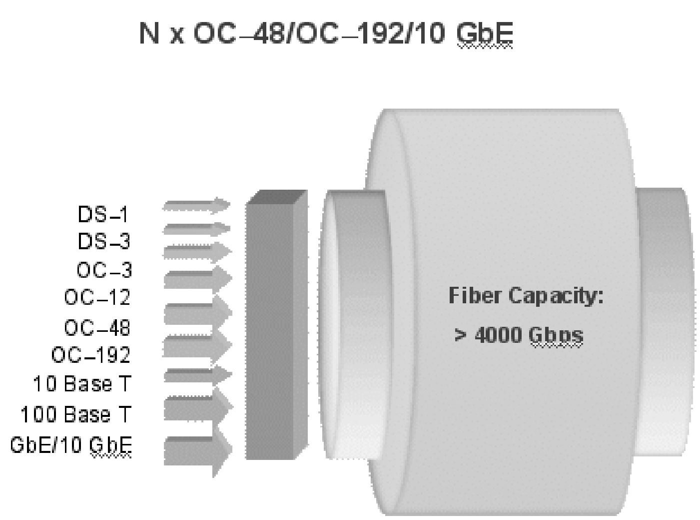


FIGURE 3

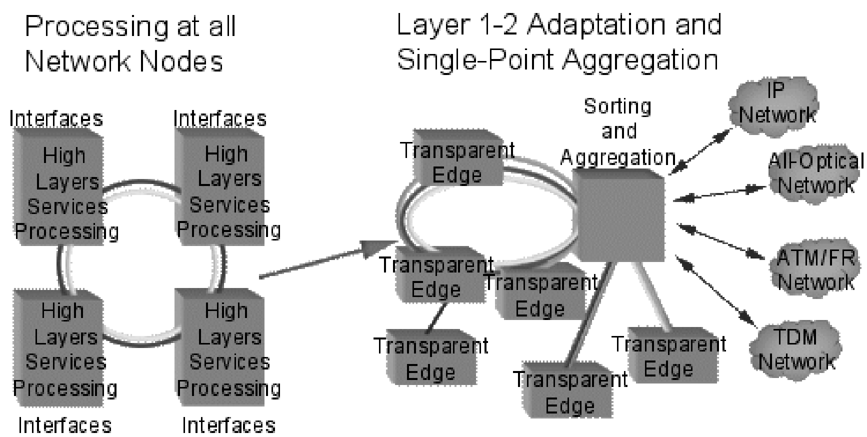
Service Transport



uses multiplexing and MPLS tags to mark the physical-layer protocol and the specific QoS definition; the multiplexed traffic is sorted and mapped based on this label addressing to the different types of network on the other end—the core of the network. Between these two steps, traffic is aggregated and mapped to wavelengths maintaining the MPLS tags. Service switching at the core maps the traffic to the particular network or to other transport networks for remote, central-office connectivity. This service switching uses these MPLS tags as switching control. The end result is that different types of IP traffic collected at the edge can be combined and carried through the metro, then mapped to the particular types of IP networks.

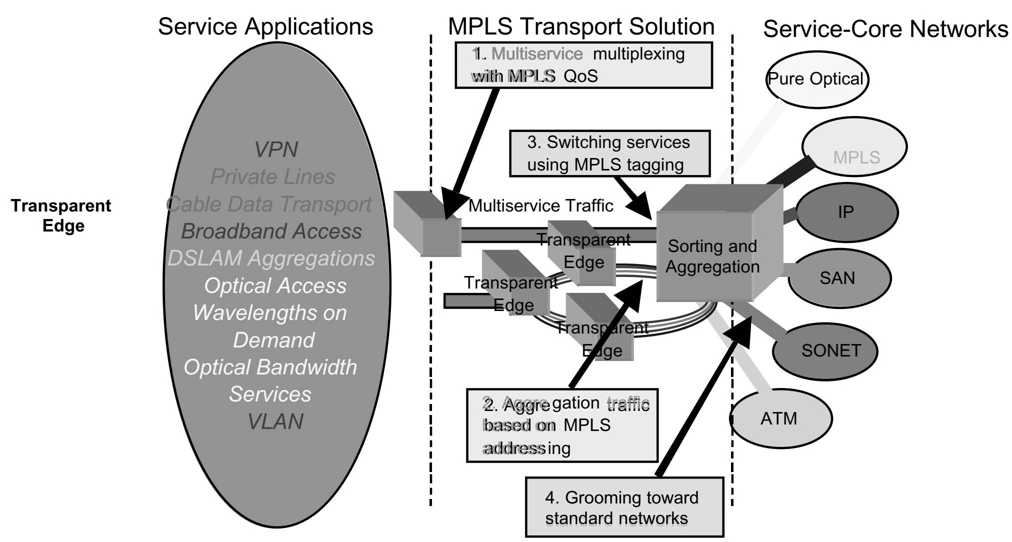
Control Plane MPLS and GMPLS

MPLS and GMPLS provide the capability for traffic engineering and QoS control. This allows for the optimization of routing at lower layers—Layer 1 and 2—without going up into Layer-3 IP traffic and trying to map data from those to MPLS.

This enables the creation of connections based on MPLS protocol. And in the future, when the network becomes all-optical, it will allow the use of the same principle protocol to allow service switching directly over optics and smooth migration to these all-optical networks.

FIGURE 4

Using MPLS for Multiservice Transport Solutions



When connecting into the core of the IP network, it is possible to choose the connection by the application and the application type it is coming from. There are multiple methods that correspond to the specific nature of the original traffic. If it is Ethernet or GbE, it will usually be kept at the Layer-2 stream. In some cases of packet over SONET (POS), in order to aggregate these traffic flows they need to be terminated at Layer 3 and then connected to the router at the central office.

In other methods, this can be handled through tunneling; in time division multiplexing (TDM), the channelized TDM is groomed into higher bandwidth channels. All of these are targeted to collect the IP traffic at the edge and connect it through a minimal number of interfaces at the core.

A specific example is that of an Ethernet aggregation (see *Figure 5*). Edge devices that are virtual local-area network (VLAN) aware or unaware can transfer traffic through a transport network, while maintaining the original network application and network structure. A combination of VLAN translation and MPLS tagging allows the transfer of data through the transport network and aggregation on the other side while preserving the original nature of the data flows. Therefore, carriers can have the original structure and type of network application going across the metro network with minimal connectivity at the core of the network.

Similar level of aggregation can be done for TDM traffic.

Summary

This proposed solution is agnostic to the IP physical layer or to the protocol used to transport the IP traffic. It allows the use of different fiber-topologies. The transparent edge provides simplicity and low cost at the edge. It also allows for the aggregation of traffic from different sources in the central office.

The use of the MPLS control plane allows the introduction of GMPLS in order to migrate to an all-optical network and, in the future, run IP over fiber as well as different types of physical-layer services. MPLS provides the ability to handle traffic engineering and QoS, to use tagging across the network, and to transfer the different types of services to the relevant networks. The system is open, since there is no processing at the edge or conversion to a specific protocol. The introduction of new types of transport mechanisms is therefore very easy.

What does this mean to the carrier? It provides simplicity in planning and provisioning at the edge, immediate and future cost savings, and future-proofing by allowing migration from any existing network to an all-optical, all-packet network.

What Third-Party Developers Want

John Marshall
President and Chief Executive Officer
Intelis

Third-party applications developers write enhanced-services software for different service providers (SP). What is it that these third-party software developers seek? This paper will discuss those needs, as well as some of the products these developers might create, the role of the application programming interface (API), and why SPs would buy products from third-party developers in the first place.

Why Buy Products from Third-Party Applications Developers?

There are many third-party applications developers writing software. Why would an SP do business with such a company? SPs using a typical switch are basically playing on a level field with their competitors. They might differentiate themselves on service or price, but as far as functionality is concerned, they are all pretty much the same, meeting 80 percent of customer expectations (see *Figure 1*). Adding different services from third-party developers allows SPs, in conjunction with their switch vendors, to offer products that differentiate them from their competitors, meeting and—with the right SP—exceeding those expectations (*Figure 2*).

Third-party developers tend to focus on market niches, drilling down on a certain application or niche market, which allows them to become experts in that area. They typically have fewer customers so they know their customers intimately and can concentrate on their needs. By working so closely with the SP, they can provide products that allow the SP to differentiate itself from its competitors.

Products Available from Third-Party Developers

One application available from a third-party developer is a Web-based Centrex system that will use the Internet to control the switch. Although it still uses voice frequency over the plain old telephone service (POTS) system, the Web is used to control that user experience.

Web-based subscriber call control is another application used in conjunction with a POTS phone. When the phone rings for an incoming call, a Java applet on the Web browser flashes on the screen with the user's caller identification. The user can click a button to immediately send the call to voice mail, forward the call to an assistant or receptionist, or even let callers know that the user will be with them in a minute, allowing callers to hold or leave a message. With such applications, the Internet is used to modify the experience of the incoming caller.

Subscriber-configurable call treatment based on caller identification or time of day is another useful application available from third-party developers. Users can configure their phones to intercept calls before they ring and give the caller a choice of ringing the call through for an emergency or getting a call back at a more convenient time. For example, if a family's small children are put to bed between 7:30 pm and 9:00 pm, a call during those hours can disrupt the entire schedule. With the subscriber-configurable call treatment, any incoming calls would hear a message saying, "Hi, this is John. We are putting the children to bed right now. If your call is an emergency, press 'one' and the call will go through. Otherwise, leave a message and we will call you back after 9:00 pm." If messages have been left, the phone will automatically ring at 9:00 pm and give the subscriber the messages.

Many other services are available from third-party developers, including follow-me/find-me/single-number applications, vertical market-specific applications, and many more.

How Third-Party Developers Help SPs

By working with third-party developers, the SP can offer customers and subscribers high-margin, sticky applications that reduce churn and differentiate them from other SPs.

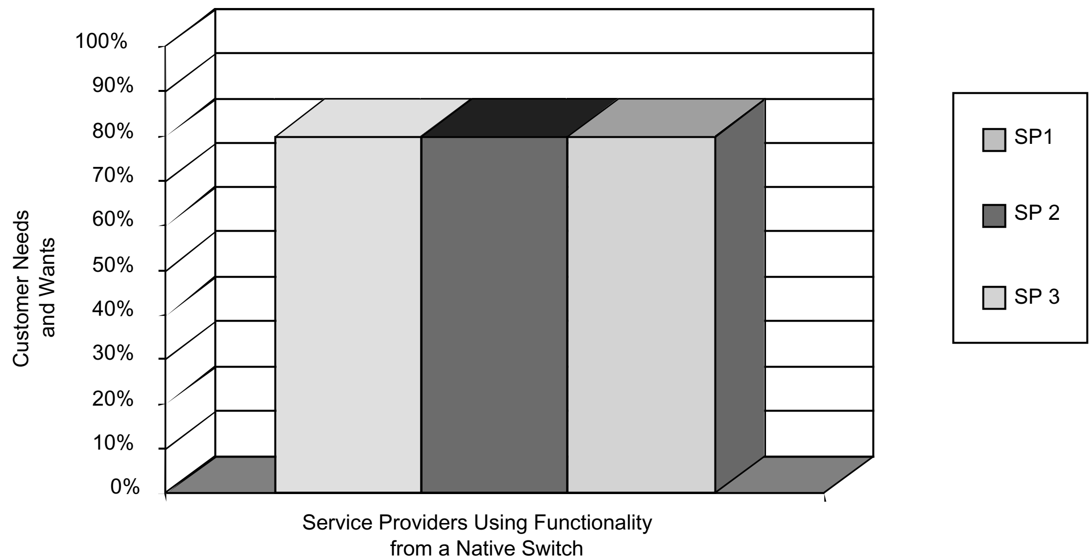
Third-party developers also can help SPs reduce the cost of sales by providing them with products that can be sold to targeted vertical markets. Perhaps the SP wants to have a selection of Class-5 features dedicated for real estate agents. With that type of product, competitive local-exchange carriers (CLEC) could focus their marketing and sales on real estate agents rather than on a wider audience. Having services or features for a specific vertical market considerably reduces the cost of sales.

Role of the API

The key to third-party application development is an API to interface applications to an SP's network or switch (see *Figure 3*). An API allows the third-party application to talk to the switch and essentially control or receive messages from the public switched telephone network (PSTN). The

FIGURE 1

Meeting Customer Expectations Using Functionality from a Native Switch



SP's customer is not interested in protocols. Customers care about the services and enhanced features available when they pick up their phones. The API is very important to third-party developers because they want to deal only with the applications they develop. Their expertise and value is in the application.

Needed API Traits

What must the API actually be able to do? First, it must be able to signal third-party applications on call events. The API can let the application know when subscribers pick up their phones or dial a number. The application may want to know what number was dialed so that information can be manipulated. Second, an API should allow the application to manipulate the dialed digits. Third, the API should allow the application to change switch parameters—change the ringing pattern or dial tone, for example. A special dial tone could indicate to the subscriber that a voice-mail message is waiting or that some special feature is activated. Different ringing patterns could be used to indicate calls from the subscriber's boss or from a known automatic number identification (ANI).

FIGURE 2

Exceeding Customer Expectations Using Products from Third-Party Developers

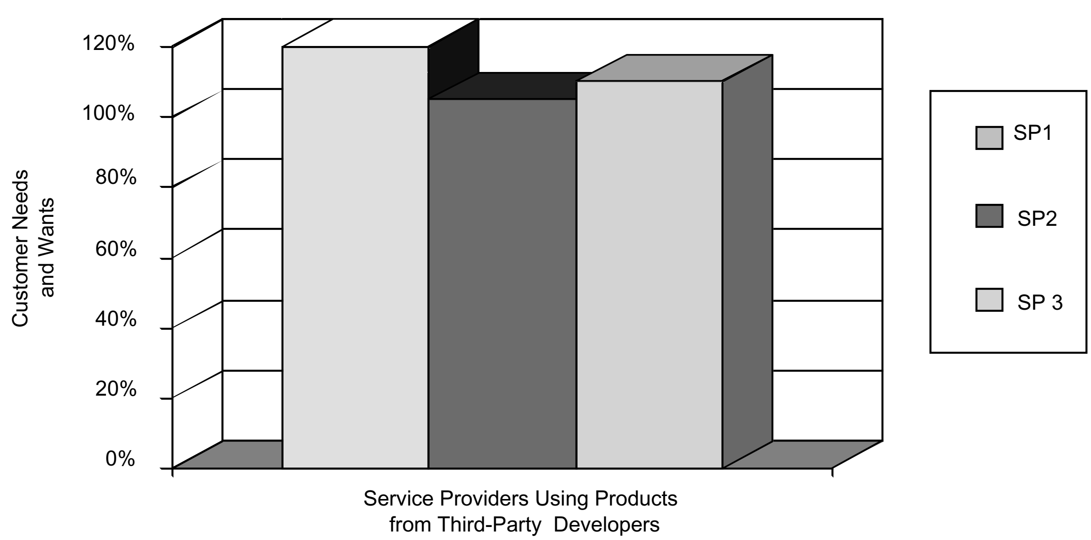


FIGURE 3

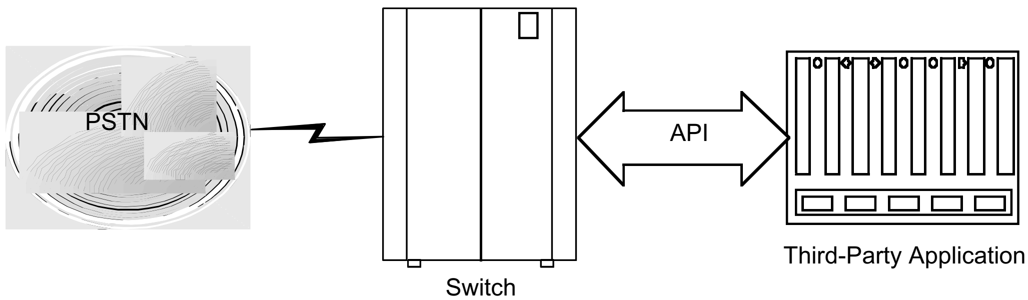
What Is an API?



Desirable API Attributes

Third-party vendors want to see an API that works with multiple switches and multiple switch vendors. A certain amount of human effort is needed to port an application to a particular API, so the more switches and the more places the third-party developer can use to get an API, the more advantageous. The API really wants to remove the developer from the details of that call. Third-party developers are far more interested in the application as seen by the user than they are in the details of the telephony of that call. Obviously, third-party developers would love to see a rich set of features in the API. If the API does not support certain functionality, neither can the application. Therefore, the API must be robust. As new technology comes out with new protocols, that API needs to be flexible and move on with them. The API should support new technology as it becomes available, transparently if applicable.

Standards

From a third-party developer perspective, standards are great. Many standards have been discussed or are actively being developed, including session initiation protocol (SIP), Java APIs for integrated networks (JAIN), and Parlay. However, none of these standards is currently in production. Third-party developers cannot afford to wait for standards to settle down before they get into enhanced applications. How do the developers work around the lack of standards? To develop applications today, the third-party developer isolates the application from the API with a thin layer of API–dependent software. As the enhanced telephony applications are created, the various switches can be supported by modifying only this thin layer of software. When the standards settle down, the developers can simply write a new thin layer of software to interface the application to that standard.

Summary

Given an appropriate API, a third-party developer can provide SPs with applications that sell for high margins, reduce churn, and focus on vertical markets, thereby reducing the cost of sales.

Building-Block Architectures Rescue Vendors Serving the Metro Optical Market

Lonnie Martin

Founder and Chief Executive Officer

White Rock Networks

Roughly $4 billion of venture capital was invested since 1995 in nearly 50 start-up companies that set out to capture their fair share of what is seen to be a burgeoning buildout of carrier metro optical transport infrastructures. Whether end-user bandwidth demand is growing 50 percent per year, 100 percent per year, or 300 percent per year, or whether there will be 20 carriers to deliver this bandwidth in the future or 200 carriers, the resultant need for optical transport equipment to eventually eradicate the metro bottleneck is very large and still growing.

New, New Networks…Or New, Old Networks?

All 50 start-ups set out to dramatically improve metro optical transport as it was practiced at the time. The largest portion of these start-ups set out to integrate the functionality of several adjacent network-element types into one system (yielding fewer boxes and fewer vendors). And the rest figured that the only way to dramatically improve the carrier's life was to invent new transport technologies altogether. The former wanted to make existing networks much better, the latter suggested that fundamentally new networks be deployed. Ever since the Internet bubble burst, and along with it the fortunes of many new carrier networks, the reality has sunk in that the financial feasibility of new networks is more important than the technical feasibility. Said another way, *evolving* existing networks to make them better has won out over *jettisoning* the old network in favor of a new network.

Yet irrespective of whether the 50 start-ups set out to deliver *new, old* networks or *new, new* networks, the architectural approach of the products deserves examination, too. And it is the purpose of this paper to discuss the traditional *integrated platform* approach and to contrast it with a new paradigm recognized by White Rock and others involving the invention of a *building-block* architecture to solve the same problems much better.

Dramatically Reducing a Carrier's Total Costs Is The Goal

Carriers must dramatically reduce their costs while simultaneously keeping up with service bandwidth growth. It is now well known that a carrier's survival will come only from dramatically lowering its cost to deliver its burgeoning data traffic and/or earning more money off that traffic. And, in fact, a principal way for start-up vendors to break into an established carrier has always been to save them a lot of money over incumbent vendor equipment—saving the carrier either capital dollars or operating dollars, or both.

How are these savings traditionally accomplished? One method often pursued is to integrate the functions of several existing systems into one system.

What metro network elements might one consider integrating? Synchronous optical network (SONET) add/drop multiplexers (ADMs), optical ADMs (OADMs), asynchronous transfer mode (ATM) switches and/or Internet protocol (IP) routers, time division multiplexing (TDM) cross-connects, and maybe service-layer processors or digital subscriber line access multiplexers (DSLAMs). And scale questions need to be answered for each of these functions. The resultant system, most often referred to as the multiservice provisioning platform (MSPP), is the equivalent of *squeezing 100 pounds into a 50-pound bag*.

The building-block architecture was invented to overcome some of the penalties of an MSPP architecture and to improve upon the result, yet do it in a *disintegrated* manner.

Metro Market Reality: It's A Diverse Application Space

From the carrier perspective, there is no single, easily described metro market to serve. The topology and customer density of metros differ as much as Manhattan and Tulsa. The end users being served differ as much as those wanting optical carrier (OC)–48 and those wanting 10BT Ethernet services, and the tough job for a carrier is never knowing where his next customer may turn up. There are fiber-rich environments and fiber-poor environments. And adding to the complexity for an equipment provider wanting to serve many carriers, the carriers differ in scale and market strategy and product offerings as much as AT&T and Covad.

In fact, the metro market space is so diverse that it is hard to imagine a single product or single approach that could cost-effectively serve most situations for any length of time. And this leads to the first penalty of a highly integrated product architecture.

Integration Penalty #1: Application Breadth = System Compromise = Sub-Optimization = Cost Penalty

The key problem of highly integrated architectures is that they compromise the cost of serving discrete transport applications to potentially serve several. That's because MSPP backplanes, control systems, and chasses must be architected to accommodate the full breadth of applications, including the so-called corner cases. This breadth has a direct impact on a system's common equipment, e.g., shelf size, backplane speeds and connectorization, power consumption, common control, etc. Common equipment has a cost, and the broader the breadth of applications, the more cost. Hence, it is an extremely rare architecture that is able to accomplish best-of-breed cost performance for any particular application over any length of time while still having the ability to address several applications.

Predictably, the eagerness and creativeness of 50 start-ups to dramatically improve metro transport for carriers by integrating all of the capability that these carriers would ever need into a single system has yielded some of the physically largest and most complicated systems ever seen in this space. Unfortunately, these systems tend to have high common equipment costs, which means that the carrier's *first cost* (the cost to deploy for his first customer) is high. Furthermore, too often the benefit of an MSPP's application breadth is of little benefit at specific sites where only one or two transport applications really exist.

In short, a systems vendor's engineering department has a very difficult system architecture equation to solve, and the trade-offs are numerous and multidimensional. Marketing wants the product to serve a very broad set of applications, and it would like the product to be the cost leader for each of them *and* for various combinations of them. To beat the competition, engineering must come up with a novel architecture, and it must decide what technologies it needs to create and what technologies it can depend upon commercially to accomplish the overall objective in a reasonable time and for a reasonable amount of money—and it must calculate the product's competitiveness two or three, or four years down the road, when the product is finally out of engineering and ready to sell. This last caveat leads to the second integration penalty.

Integration Penalty #2: Breakthrough Technology Is Hard to Predict or Count On—and That Can Kill You

Who among us can correctly predict the arrival of technologies that could make our product's functionality dramatically cheaper? On one hand, telecom systems vendors are now blessed by the so-called *horizontalization* of the telecom equipment business (as happened in the computer business in the 1980s/1990s). If venture capitalists have funded 50 optical metro transport systems companies, they have also funded hundreds of opto-electronic and optical component companies. Yet, on the other hand, this diversity of component talent and technology, and the pace of change of that technology, makes the systems architecture job very difficult, because so many decisions must be made with imperfect information. And the worst thing to do is count on a nascent technology ahead of its time.

Integration takes time—and the more that there is to be integrated, the more time it takes. If marketing and engineering try to integrate too many functions into the same systems architecture, then two or three cycles of component technology could transpire before an integrated product is finished. Most people observe that today's component obsolescence rate is nine to 15 months, and yet it may take two to three years to complete an integrated systems design. Hence, if the wrong technology choices are made at the front end during architecture design, then the resultant system could be uncompetitive by the time it's finished.

But it is potentially worse than that. Integration also adds to systems complexity—the more functions to be integrated, the higher the system's complexity. If one posits that the competitive survival of all systems vendors depends upon their ability to take regular advantage of new component technology, then the system architecture needs to accommodate this. But the more complex the system, the harder it is to go back into the system later on to dramatically improve it with new technology. Some functionality enhancements, or some cost reductions, can be done with almost all systems after they have been released, but it is very difficult to bring an integrated systems architecture back up to best-of-breed status. Rather, it usually makes more sense to start over again with a clean sheet of paper, which can be a competitive nightmare.

In general, the sheer pace of component technology advancement is forcing systems vendors into very short product life cycles and into making themselves as nimble as possible for the unpredicted technology that can offer it, or its competitors, a leapfrog advantage.

Integration Penalty #3: Application Breadth = System Size = Wasted Space (and Space Is a Precious Resource)

MSPPs cannot *do it all* in a traditional architecture without being large, even enormous, network elements. Today's breed of MSPPs fit two to four per standard 7' rack (and a couple, only 1). Space has a cost and has become a precious resource for the carrier in a deregulated world. And the worst part for a carrier is seeing a near-empty system occupying half a rack while waiting for its second or third, or fourth customer to show up. By their nature, MSPPs trade air and floorspace for application breadth. Yet this space can be as precious to carriers as dollars, and ideally, carriers shouldn't be paying for air.

Integration Penalty #4: MSPP = Complicated System = Long R&D Cycle (See Penalty #2)

MSPPs aren't easy or inexpensive to design and fully debug—even with a running start, MSPPs take at least two years just to get to Release 1.0. A lot can change in two years. Plus, it often happens that what carriers really end up wanting is the feature content of Release 2.0 or 3.0. So that means three or four years to reach a saleable product. Go back to Penalty #2. When the dust clears in three to four years, one can bank on a younger company that took advantage of the very latest component technology, producing a product with much better price/performance for those applications. And then the MSPP maker gets bound up in the following decision: Do I invest to make myself more competitive in the application, or do I cede that application to others and move on to some other opportunity (needing Release 4.0)? Eventually, the decision between reinvesting to reduce product cost for more competitiveness in today's applications, or investing to address future niches, has no other answer than starting over with a clean sheet of paper—long before the first MSPP development investment produces an ROI.

Integration Penalty #5: Long R&D Cycles + Short Market Windows = Low Probability of Decent ROI

MSPP development cycles are long because MSPPs are complicated. Market windows are short because component technologies and customer applications are changing so fast. The probability of traditional MSPPs earning decent ROIs is going down, not up. There are many reasons why start-ups and all companies can miss and/or not be competitive during a market window, but the most basic is product capability. A vendor's product strategy has to give it a chance to be nimble in order to hit, not miss, market windows. And the fewer times that a company needs to re-invent its product technology, the better the overall ROI.

Building-Block Architectures: Path to Application Breadth and Best-of-Breed?

Problem statement: How does one architect a systems product that can serve, in a best-of-breed fashion, the diversity of incumbent local-exchange carrier (ILEC), competitive local-exchange carrier (CLEC), and interexchange carrier (IXC) metro service-delivery applications in the face of component technology advances that change faster than the time it takes to finish a traditional integrated system design?

One possible answer that several companies are pursuing is to take a page from Lego, the company that popularized Lego Blocks. Can a *Lego-block family* of network elements be developed that doesn't suffer the penalties of an MSPP architecture and can provide the following?

- The same list of functions that MSPPs set out to provide
- Relatively short development cycles instead of long
- Best-of-breed manufacturing cost for most/all key metro transport applications
- The ability to significantly reduce the manufacturing cost multiple times over a product's lifetime
- A open-ended architecture with a legitimate chance to accommodate unexpected technology advances or application changes
- A means to maximize corporate ROI by stranding the least development dollars previously spent

The OSI Stack Hints at How to Break the Problem Down

The seven-layer open systems interconnection (OSI) functionality stack already hints at a building-block approach, and optical transport equipment is generally agreed to span the bottom three layers, i.e., the photonic layer, the transport layer, and the service layer as seen in *Figure 1*.

Whereas MSPPs are designed to integrate the marketing department's *optimal* mix of these three layers, a building-block family system would instead encompass multiple discrete product elements at *each* of the three layers. And these building blocks would be designed to hook together in a variety of configurations, much like Lego blocks if each was given the intelligence to provide *Lego-block glue*. In White Rock's case, this is a standards-based control plane.

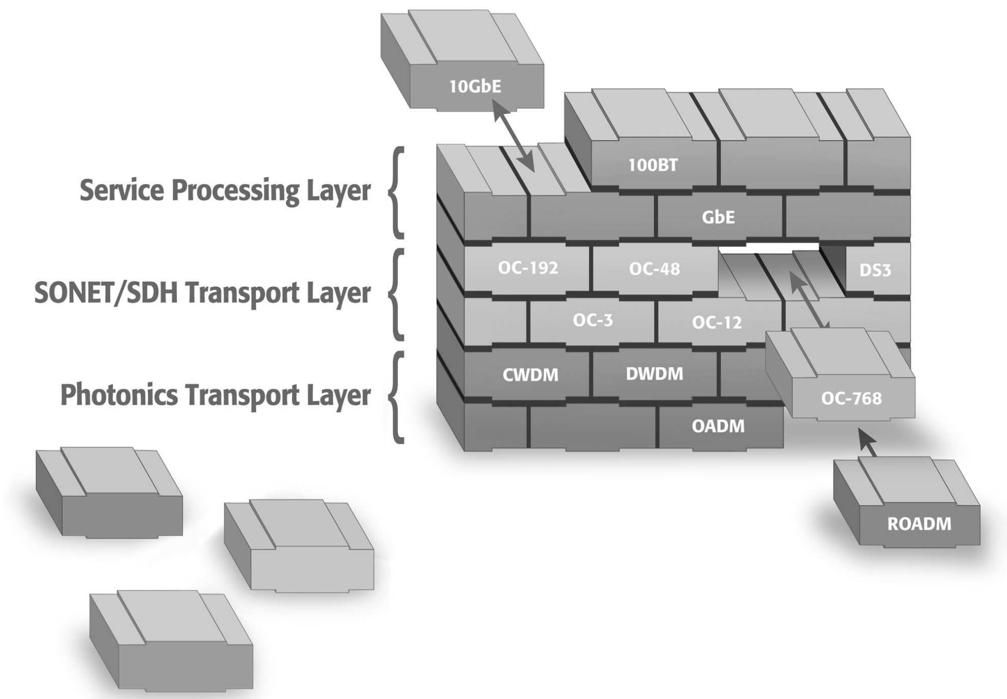
Building-Block Benefit #1: Application Breadth without Platform Compromise

We can imagine several discrete building-block element examples, and we can envision just from describing them how they change the development engineering problem compared to an MSPP architecture:

- An OC–48 system doesn't need to be designed to accommodate OC–192.
- An OC–192 system doesn't need to be designed to accommodate OC–768.
- A tributary element doesn't need to be designed for both optical OC–*n* tributaries and electrical tributaries (e.g., digital signal [DS]–1, DS–3, 10/100BT).
- A coarse wavelength division multiplexing (CWDM) element doesn't need to be designed for dense wavelength division multiplexing (DWDM).
- A synchronous transport signal (STS)–1 grooming switch doesn't need to be designed to groom virtual tributaries (VTs).
- Etc., etc.

In general, we can see and appreciate that the narrower the functionality, the better able an engineering department can be to achieve a best-of-breed result for any given building-block element. And the narrower the functionality list, the fewer trade-offs and compromises that need to be made in the design of that element. The most important compromises impact the product's cost to manufacture, and if the most important goal versus competitors is to have the lowest product costs, then minimizing the number of compromises in each part of the overall product family capability is crucially important in the competitive battle.

FIGURE 1



Building-Block Benefit #2: Narrower Functionality = Shorter Development Cycles = Latest Technology Benefit

While a building-block system does require several building-block elements to achieve the same overall functionality of a single MSPP, the development time required for any particular building-block element is much shorter than an MSPP. And if this development time can be reduced to nine to 15 months, then a building-block vendor has a chance to get full benefit from the latest component technologies—this is in contrast to the MSPP vendor, which is often forced into key component choices at the beginning of a three-year development.

Moreover, building-block elements represent separate developments that can be done in parallel with little conflict or interaction. By their nature, MSPP developments have numerous interdependencies between distinct parts of the system, and it is often the integration of these that is the most problematic and hardest to manage.

Provided that basic interfaces and communication links between building-block elements are architected up front, the building-block approach is showing signs of making the engineering job much easier in total.

Building-Block Benefit #3: Best-of-Breed Cost, Size, and Power

This can be a direct result of Benefit #1 if a vendor is committed to being best of breed. Anecdotally, White Rock was skeptical at first about whether a system built up from building blocks could be considerably cheaper, considerably smaller, and considerably more power efficient than the equivalent MSPP architecture. But so far the evidence supports the logic and our implementation of it, and this seems to be directly related to the compromises that must be made to develop a multifunction integrated system (see Penalty #1).

Building-Block Benefit #4: Readiness for the Unexpected Customer, Technology, or Application

Smart people try their best to predict the future, but usually fail to be perfect. The survival of a vendor in the metro optical equipment market may well depend upon its architectural and corporate ability to respond to the unexpected, and respond relatively quickly. A building-block family architecture is inherently open-ended, whereas an MSPP is too often a bounded system with hard limits that cannot be modified except by starting over. Although no vendor can react to all market events that occur, whether predicted or not, we believe that the company that is least fettered architecturally can react the fastest and can produce the best result.

The latest best example of this is the market importance of delivering Ethernet services in metro environments. One major carrier recently announced that fully 25 percent of their 2002 capital expenditure (CAPEX) budget would be spent to accomplish Ethernet service delivery. That same carrier not more than two years ago professed little interest in delivering such services. But the world has changed quickly, and now this carrier needs to change—and the vendors that supply them metro transport equipment need to react or miss out on this *sudden* opportunity. If a platform was architected two or three years ago and guessed wrong about this need, it is very likely that platform will not be able to be modified quickly, or if able to be modified, to be a best-of-breed contender.

Summary

Worldwide purchases by carriers of metro optical transport equipment will be large for a long time as the industry tries to fix the so-called metro bandwidth bottleneck. As a result, there will be heated competition from established companies and from start-up companies alike. Entering and then keeping up with the dynamism and rapid change of this market space is no simple feat for any metro equipment vendor.

The best way to serve this diverse application market from a product and technology perspective is clearly under a heated debate of sorts—otherwise, 50 new companies would not have been funded to compete with the 10 incumbent vendors that have been serving this same market for many years. Competitive advantages can be created via new technology or new product architecture, or both, and there are probably 60 opinions today on which approach may be best. Among the new architectures under development by a few of the newer companies is a building-block product family approach that shows the promise of having some important advantages over the industry's traditional integrated system approach. Time will tell whether transport equipment building blocks will catch on as well as Lego blocks have.

Meeting the Needs of Metropolitan Networks

Richard C. Notebaert
President and Chief Executive Officer
Tellabs

Abstract

The communications industry is changing, and as a communications equipment company, we must change our focus to reflect the new realities in the marketplace. Our service-provider customers have shifted their focus from investing in the newest technologies to investing in technology that manages bandwidth growth and speeds revenues. We can meet service providers' changing needs by solving the bottleneck issue in network links that are close to their customers. This article explains why metro optical networking can help service providers to lower costs, manage bandwidth, and speed revenues in metropolitan networks.

Introduction

Despite an economic downtown, end users continue to drive demand for communications services. This demand increases when companies relocate into new buildings in suburban locations, build data centers that require a large amount of bandwidth, and enhance their building with the latest technologies. Each one of these situations challenge service providers, because their customers will work with whichever company can turn up new services the quickest. And that means that service providers must devote the capital expenditures (CAPEX) needed to get high-speed services implemented and turned on faster than their competition.

Competition is strong among service providers in these situations. Some service providers go into a high-growth area early and place fiber long before companies move to these locations, giving them the advantage. In many cases, incumbent service providers need to invest new capital expenses into areas that may not produce new revenues. For example, an existing customer who relocates and needs new infrastructure may not require any more services than when at the old location. Nonetheless, the service provider is faced with making a network investment without the opportunity for increased revenue. That's why service providers need communications solutions that lower costs, manage bandwidth, and speed revenue fast enough for them to meet the needs of their customer.

Service providers are now turning their attention to ways to solve this bottleneck issue in the "last-miles" of their networks—the metropolitan network. This area of the network spans a region, such as Chicago or Memphis, or connects multiple locations in a geographical area. Service providers experience the highest and most unpredictable level of traffic in this part of the network, making it a primary focus, since it is also the area of the network with the highest growth potential. Industry experts forecast that overall traffic in the network will increase 50 percent to 60 percent annually until 2005. Aggregate voice, data, and Internet traffic in metropolitan areas will grow from \$15 billion in 2000 to \$50 billion in 2005. And, data center traffic alone is expected to grow at nearly a 100 percent compound annual growth rate (CAGR), consuming 40 percent of the total metro bandwidth by 2005.

Based on the current environment mix of increased network traffic, demand for bandwidth, and prevalent competition, service providers are challenged to meet the bandwidth needs of their customers, deliver services quickly, and with a profit in their metropolitan networks.

Delivering Revenue and Growth Opportunity

Service providers are looking for the best way to maximize their current network investment to get the most use out of their equipment. They also realize that their customers want high-speed data interconnections, which are difficult to provide without the right technology. They're confused about what is the best technology, and combination of technologies, for their company.

Technology that maximizes current network investment, integrates quickly, and delivers new services fast will win the business of these eager service providers.

At Tellabs, we believe metro optical networking will enable our customers to utilize their current network investment for traditional voice lines and upgrade to optical networking equipment to provide high-speed interconnections and services quickly. Metro optical networking will help service providers take advantage of the growth opportunity in metropolitan networks and provide valuable investment protection on legacy equipment.

Metro Optical Networking

Service providers are looking to solve the increase in bandwidth demand in metropolitan networks a couple of different ways. Some companies choose to invest in next-generation optical networking solutions, such as metro optical networking, or to focus on electronic sub-wavelength multiplexing. We believe our customers should be able to do both.

Metro optical networking enables service providers to keep signals in the optical domain, delivering new high-speed services with faster connections and increased bandwidth. It takes time to switch signals from optical to electrical, and back to optical. Metro optical networking enables service providers to send multiple signals over one lightwave using dense wavelength division multiplexing (DWDM) technology. In fact, DWDM technology allows service providers to send more than 80 different communications signals over a single optic fiber.

The lower costs that service providers realize from metro optical networking gives them room either to increase profitability or lower costs to remain competitive. In fact, next-generation technologies such as metro optical networking are 30 percent to 70 percent more cost-efficient than legacy networks.

While metro optical networking can be very beneficial, some service providers choose to focus on electrical sub-wavelength multiplexing as a way to send signals through their metropolitan networks. Sub-wavelength multiplexing keeps everything on the electronic level, enabling service providers to utilize existing network infrastructure. This saves companies money initially on network investment, but sooner than expected, the time will come when bandwidth demand exceeds available network capacity.

While most companies focus on either optical or electronic networking solutions, we believe service providers need to find the right combination of both technologies. Tellabs' metro optical networking solutions integrate easily with existing network equipment to enable companies to maximize their current network investment for traditional voice services and deliver new high-speed services quickly. These solutions also boost initial network capacity by as much as 32 times and offer the flexibility to handle today's network traffic and easily grow to manage tomorrow's optical networking needs.

Focus on Customers' Needs

Communications equipment companies can help service providers take advantage of the growth opportunities in metro optical networking by listening and respond to their needs. We need to deliver solutions that are flexible enough to allow service providers to find the right mix of electrical and optical networking that they need to deliver service and revenues quickly.

We can help service providers to speed installation, engineering, and provisioning by making fundamentally complex equipment simple. We need to develop simple engineering rules and easy design guidelines. The equipment should store the information needed to enable these rules and guidelines. An engineer that is working on the technology today needs to be able to pass the project along to new people without loosing information on how to make changes to the equipment. This effort will help service providers to integrate new technology into their existing network quicker and easier.

Conclusion

The realities of the communications industry have changed, and that means that all of us in the industry need to adjust. We need to develop solutions that address service providers' top business needs to manage bandwidth, lower costs, and speed revenues.

Service providers face their greatest challenge in metropolitan networks, where they are looking for new ways to stay competitive and generate revenues. Metro optical networking will enable service providers to integrate new high-speed optical networking equipment with existing equipment for traditional voice lines. Together, this combination of equipment enables new services to be turned up quickly and increase the capacity of existing fiber, which translates into revenue. Aside from meeting the needs service providers have today, metro optical networking also prepares networks for the future—protecting investment and lowering lifecycle costs over time.

Increasing Service Velocity in a Converged Network

Cüneyt Özveren

Chairman and Chief Executive Officer

Atoga Systems

Intelligent dense wavelength division multiplexing (DWDM) solutions are needed for the metro network so that service providers can increase service velocity and broaden their service offerings. This will enhance network performance and reduce operational costs through simplified provisioning of services. The purpose of this paper is to examine new methods for increasing service velocity and scaling in a converged network infrastructure, with specific focus on the challenges that service providers face when using this network architecture.

Network Architecture Trends

In the new market for convergence, fiber is becoming increasingly more available, and a number of drivers and applications exist that can generate profit for service providers. In 2000, the service-provider industry benefited from a competitive, capital-intensive market-share model, which increased revenue by attracting more customers. Initially, the return on investment for those companies with this type of business model was favorable. However, as bandwidth became a commodity, the market-share model resulted in an ever-extended timeline for positive return on investment and hence was no longer sustainable. Since profitability is driven by high margins, a value-based model has the best chance of driving service providers to profitability. For example, telecommunications companies have profited from the sale of relatively inexpensive local-access services. The model for cellular phones has also proved to work well for the telecommunications industry. In addition, converged network architectures are the trend, as they reduce the equipment and operations costs that arise in synchronous optical networks (SONET), DWDM, and Internet protocol (IP). Physical-network-layer convergence reduces the number of network elements, though tight integration among those layers is often difficult to achieve. Multiple protocols are still used for various purposes in converged networks, and applications have become particularly important.

Network Architecture Challenges

In order to shift to a value-based model that involves selling applications and high value-added services (VAS), companies must determine the limitations of an existing network and discover a way to migrate toward more effective network architectures. However, there are issues of time, cost, reason, and inertia to be considered in the migration to converged networks. It does not make sense to replace all existing equipment, for example. An integrated architecture can ultimately produce lower equipment costs, higher bandwidth delivery on demand, and the intelligence required to provision and deliver differentiated services (DiffServ). Some important issues include product and solution evolution, stability, standardization processes, and market acceptance. Migration also depends on the type of service provider and various economic factors. Network architecture challenges include pockets and segments with miscellaneous network architectures and overlays. Mappings and co-ordination among the layers and between networks are often quite cumbersome. Technology and protocol mappings, quality of service (QoS) mappings, and network management are potential challenges to network architectures.

End Result

The end result may lead to provisioning complications, such as a longer and more expensive provisioning cycle that requires truck rolls. Multiple network elements, increased operational costs, and complex traffic engineering complicate operations. There is also some strain on investors from the need for frequent equipment upgrades.

Service-Provider Challenges

It is often quite complicated for service providers to provide services in a converged network infrastructure. This can be accomplished, however, through protocols, tight integration between network layers, and network-resource optimization. Service requirements must be translated into the network parameters and protocol attributes. Service providers must be able to dynamically adapt to demand and network-topology changes. In the interest of QoS, it is essential to provide a wide spectrum of QoS with service-level agreements (SLA) to meet the needs of various services and applications. QoS objectives can be achieved by supporting connection-based QoS with a stringent end-to-end guarantee on loss ratio, transfer delay, and delay jitter. Connection-based QoS can be supported with a minimum of QoS requirements, allowing service providers to exploit additional network resources. Connectionless QoS meets the needs of specific services and applications through DiffServ with multiple levels of drop precedence and best-effort service. There are various access technologies in the current market, such as cable, digital subscriber line (DSL), Ethernet, and fiber. The access loop is connected to an aggregation loop that then gets connected to the backbone. The traffic must first pass through the access loop to the aggregation loop and then to a backbone, which creates too many router hops. In this architecture the multiple router hops create too much latency issues, making it impossible to provide applications to the end users.

The application service provider (ASP) model began with national service centers, though the model did not scale. With servers and services already present in regional colocation centers, service providers began to utilize local routing environments, which allowed end users to access application services directly on the optical metro network. Applications connected to an Ethernet switch within a data center can be delivered locally to the network. In this architecture, optical switching creates an incredibly fast and scalable core that pushes all intelligence to the edges. Decisions can be made at the periphery, and data can be applied to a wavelength in the optical network, assuring that the data will pass through the network quickly. The advantage lies in its exceptionally low latency. This type of architecture enables applications through high VAS, creating local environments that rely on high scalability and speed with intelligent edge devices. It is necessary to choose the right optical architecture and to build an edge device that can leverage that optical capacity to its maximum.

Provisioning

Overlay networks have a DWDM layer, a SONET layer, and an IP layer, and it is difficult to provision the various types of traffic and service offerings because there are no standards for signaling between IP, SONET, and DWDM devices. A customer who has DWDM and wants to set up an application often faces slow provisioning services that may take three to nine months, depending on whether an equipment change is needed. For example, a service provider might go out to a site and realize that there are no ports left. This situation would require the service provider to schedule another visit in order to install additional equipment that will increase capacity. This process could take six to nine months. *Figure 1* illustrates the traditional provisioning model.

Provisioning at the SONET layer often leaves responsibility to another party to make an application work within that pipe. Provisioning often works contrary to the problem that must be solved. The key issue regarding this model is that provisioning is not driven by higher-layer applications.

Application-Driven Provisioning

There are four issues to consider when driving provisioning with higher-layer applications. Overlays are separate and do not communicate with one another, which has led industry professionals to integrate those layers by collapsing them into one network element (see *Figure 2*).

Each layer is important and has a specific function. This network element combines the intelligence of the IP layer and the scaling capabilities of the DWDM layer with the reliability of the SONET layer to deliver voice, video, and data services. SONET is the best choice today for reliable transport of voice over the network without diminishing quality, and IP is a necessary component for delivering high VAS. Collapsing these layers into one box eliminates the need for carriers to manually configure three separate network layers. Information from one layer can now be used to provision the other layers. For a bandwidth-intensive application, such as videoconferencing, the ability to access that bandwidth instantly is critical. Leased optical carrier (OC)–3 is not an affordable alternative. However, since IP and SONET are in the same box, higher-layer IP intelligence can be used to trigger provisioning an OC–3 pipe instantly. This OC–3 pipe can be torn down just as quickly when the videoconference is terminated. The end customer is then charged for only the duration that the extra capacity is used. This can create significant revenue opportunity for the carrier, since such a flexible bandwidth can be charged at a premium. This is still affordable for the end user, since the capacity is paid for only when used.

FIGURE 1

Today's Provisioning Model

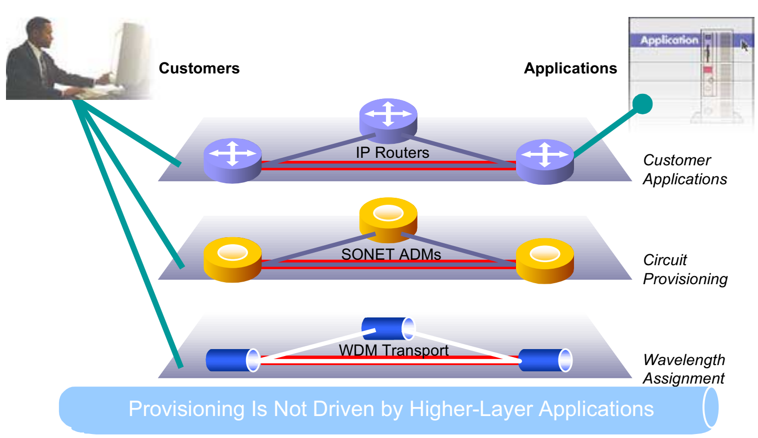

FIGURE 2

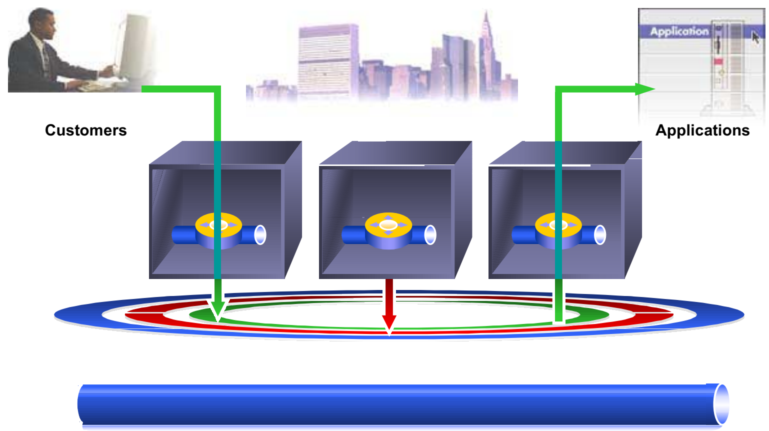
Signaling Mechanism



Optical Scaling

The second issue relates to the need to harness the scaling capabilities of the optical layers. SONET does not have sufficient capacity, and it is too expensive to strip out existing boxes and replace them with OC–192. Tunable lasers provide a solution to this problem, as they allow optical networks to be effectively managed and enable wavelengths to be taken from the optical backbone for data transfer. With tunable lasers, it is possible to add another card or box to the data center without performing truck rolls to other aggregation points. Instead, the lasers are retuned to create two groups (see *Figure 3*).

The network is split into two logical groups, and nodes are set to these groups, doubling the capacity. The network can be scaled to greater capacity by implementing add-in parts, and DWDM allows for greater scalability. If a request cannot be provisioned within the logical ring to which one subscribes, it is possible to look for more capacity in a different logical ring, which establishes access to the capacity available in that portion of the network (see *Figure 4*).

Figure 4 demonstrates the act of switching the node to the other logical group in order to achieve optical optimization.

Network Performance and Billing

The third issue relates to network performance and billing. Service providers who sell applications must guarantee their performance and be able to bill a customer for them. This requires SLAs on a per-user and per-application basis. Service providers must be able to monitor their applications and police the data traffic. It is possible for the architecture to assign wavelengths depending on the particular needs of applications, and performance is guaranteed precisely because data traffic is policed directly on the optical network. The act of policing traffic to a specific bandwidth

FIGURE 3

Optical Scaling

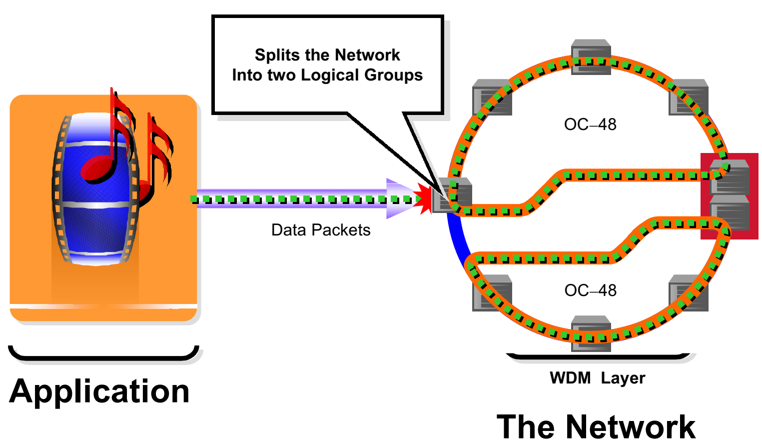


FIGURE 4

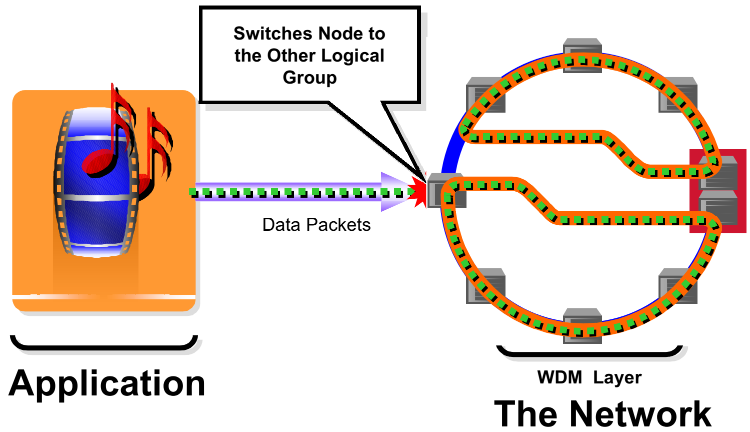
Optical Optimization



allows a service provider to provide separate billing for mission-critical applications. It is also possible to measure excess traffic that enables billing the user per usage.

Network Management

The fourth issue to be considered is network management, as it poses problems for carriers when they deal with provisioning. There are grades of service within each application, which causes database problems for carriers. Many carriers spend millions of dollars creating their own directories to solve network-management problems. Standard directories from multiple vendors are now available which perform network management. One can use a standard directory as an information repository and harness that information to manage the whole network. Directory-based product management includes good authentication features and contains applications in data sensors. Customers can access their portion of the directory in order to provision their own services instantly, add an application, or change the data service in an application. Traffic is metered and policed without delay, and there is no need to contact the service provider. This process can be activated in seconds, not months.

Protocols

Routing protocols for network reach and topology discovery are important. A Layer–2.x mechanism is employed for traffic engineering, QoS, and tunneling. Framing is possible using SONET and Ethernet, and a DWDM protocol is used for optical scaling. Converged networks offer diverse choices with regard to protection layers. The wavelength division multiplexing (WDM) layer has proprietary protection mechanisms. The SONET layer has a unidirectional path-switched ring (UPSR) or bidirectional line-switched ring. Two other protection layers include Layer 2, with a resilient packet ring (RPR), and the multiprotocol label switching (MPLS) layer. Traditional optical solutions at the metro edge usually only allow for the management of fixed transport services and typically contain Layer–1 switching intelligence. The current metro networks support applications through the use of multiple boxes and have the flexibility and efficiency to support rapidly evolving applications and services. IP has become the predominant network-layer protocol, and MPLS has allowed service providers to create IP networks that are highly scalable and capable of providing QoS.

Summary

New methods for increasing service velocity and scaling in a converged network are important, as they provide service guarantees for existing and new applications and make effective use of converged network architecture through tight integration between network layers. Service providers now have alternatives to expensive networks that require multiple devices. The combination of multiple network layers into one box reduces operational costs and simplifies network management.

Service-Provider Environment and IP Service Assurance

E. Sanders Partee
President and Chief Executive Officer
Viewgate Networks

Introduction

A primary concern of service providers today is the generation of new sources of revenue and preservation of existing revenue sources. For many of today's struggling service providers, the generation of new revenue sources often takes a back seat to preservation of existing revenue sources.

This narrow business focus results in continuation of traditional, connection-oriented data services, such as private lines, frame relay (FR), and asynchronous transfer mode (ATM). These static services are usually well managed with some level of service assurance specified within a service-level agreement (SLA). Typically, however, the assurances offered by the provider have been focused on performance of the network elements (NE) and not on the user experience of the service.

To counter this approach, corporate enterprises have implemented their own monitoring systems. Thus, they push service providers into offering service visibility and ensuring that they are actually getting the service at the contracted levels of performance. All too often, this dual approach to measuring the same service from differing perspectives produces results that do not match one another. Confusion and possibly contentious discussion erupt at quarterly provider-user account reviews, with each party defending the service performance indicated by their own set of reports.

This paper examines the area of Internet protocol (IP) service assurance from both the service-provider perspective and the customer perspective. Areas of discussion include the primary business drivers, the technical issues, actual service-delivery management (SDM) component issues, and why these topics have become increasingly important. Some business-model issues relating to service assurance are also explored.

New Service Trends

When service providers set the creation of new revenue opportunities as a top priority, they generally try to fulfill this goal by offering new services. These new services are likely to take a number of forms. For instance, there has been a shift today away from static services (connectivity-based models) characterized by monthly rentals and long-term contracts. Users are migrating towards service offerings based on episodic connectivity for use with emerging on-demand–type applications. When the nature of the application changes, so does the service. The profile of the person purchasing the service will move away from a fixed point within the enterprise, whose business is managing the telco, toward the actual business users of the service. Many of these users are scattered throughout the enterprise, not just in the information technology (IT) organization. One example could be a marketing manager who wants to do a Webcast at a particular time. Another example could be a chief financial officer (CFO), who may be renting a budgeting package over the Internetæa value-added service that would be most welcome.

These new services are changing the conceptions of what people are buying. IP virtual private networks (VPN), for example, are positioned as a replacement for connection-oriented services, such as FR and ATM. Offering additional flexibility, IP VPNs are connecting businesses and providing additional features, such as public Internet access as part of the service bundle.

The key issues then become concerns about delivery, security, and, most of all, performance. In this new environment of selling advanced services, the network is no longer the issueæthe service is. Assuring the quality of the service being purchased becomes a critical factor in the service user's buying decision and satisfaction. Assurance of these services requires measuring their quality from the user's perspective on a site-to-site basis for class of service (CoS) flow between different locations. The state of individual services need to take precedence over the state of the NEs themselves.

Technical Issues

A number of technical issues are involved in measuring these services. First, in an IP VPN scenario with the virtual router in the middle, there is a significant difference between managing the performance between different branches to each other on a single-provider network and managing performance out to another site that is not on the same network. Guaranteeing quality on off-Net participants is a difficult issue.

The second technical issue is the access network. If access to a building must go through the local phone company, managing the service quality will be limited to either the provider edge, or a reduced number of new services will be sold due to the pipe being the smallest link in the chain. From a technology point of view, the intelligent edge is both an issue and an opportunity. Currently, much of the diversity in provider edge devices, and even in customer-premises equipment (CPE) devices, has reached a manageable state. In the marketplace, however, there is an entirely new set of smarter routers and service agents that create opportunities. These new devices are able to support more differentiation for quality of service (QoS), more application awareness, and end-user–specific management systems.

These new service agents are able to deliver fine-grain QoS performance with less constraints than by traditional routers. At present, sophisticated accounting and performance measurement—for example, activating Net flow on a specific router—is difficult for carriers to do, especially on a wholesale basis. New service agents are being built to do the measurements and capture the data without slowing the router, without driving up the central processing unit (CPU) utilization, and so on. Where this measurement takes place and where these services are created—CPE versus point of presence (POP), for example—depends on what services are being built and on the size of the customer. Each has its advantages.

If the last mile to the customer is the most performance-constrained and the smallest piece of the pipe, the performance needs to be managed on both sides: both when leaving the enterprise (prioritizing that traffic and making sure the good traffic gets through first), and then from the service provider to the enterprise.

Finally, the technology is moving toward virtual private services with more on-demand services created in a dynamic environment rather than a traditional connection and security-focused VPN. Over time, IP VPNs will move to IP virtual private services, thus creating additional challenges. Traditional provisioning might be too heavyweight and unable to react quickly enough to provision a service that will last for 10 minutes or an hour and keep changing all the time. A more systematic approach may be needed to perform these on-demand services. As service-delivery speed increases, so will the requirements of service assurance.

Service Assurance Delivery

Carriers are facing several business issues in delivering service assurance. Most importantly, the customer must be kept informed. Because such services are invisible, the only way to help customers understand whether they are receiving what they purchased is to illuminate those services. A number of competitive advantages are being used in this service-assurance environment. For instance, the operations support system (OSS) can be leveraged. The typical fault, configuration, accounting, performance, and security (FCAPS) physical OSS model covers fault management, performance management, and so on. What is needed is a services OSS, which is a new breed of software.

Many larger carriers are concerned about their ability to do some of the high-touch, high–customer-focused type of tasks required with the services OSS, in which the focus is not managing devices, for example, but rather the service level and service performance. Customers are not buying the network; rather they are buying a service. And if that service begins to degrade, they will want the OSS to know about it. These customers clearly are seeking Web-based service illumination.

An environment is needed that can provide a tight loop between OSS system components, which provides active provisioning and injects low overhead. One possibility is to drive out to the customer base the ability to tune their VPNs and to tune their data services. The result is "do-it-yourself" customer service. Giving users the tools and the visibility—showing them what services they are buying and how they are performing—creates opportunities. For instance, a shared view between customer and carrier builds trust. Currently in the market of service assurance, the enterprise tool too often pushes out toward the carrier with complaints that service is not being delivered by the carrier. Bringing together a consultative tool and a collaborative problem-solving tool can build increased trust, customer loyalty, and retention. It also can provide an upselling tool for the service provider. In many cases customer unhappiness actually stems from changes in their requirements.

Customers may be trying to push too much traffic down the original circuits or the original VPN that they bought. In this case, the network is not performing poorly, and the intended service level is being met; but upgrades are needed to handle increased traffic. By discovering how well they are meeting the service needed, not just the contracted network transport, service providers may be able to generate more revenue and thus build situations that leverage the services OSS. The initial step is service design and provisioning for the first-time customers. Because a template is used—with some information from the customer about requirements—SDM and service assurance are needed to determine that delivery is meeting expectations and needs. This circles back into billing, and then the entire cycle starts again. Returning—to service the design, to redesign the system, to upsell the customer—can generate more revenue and customer retention.

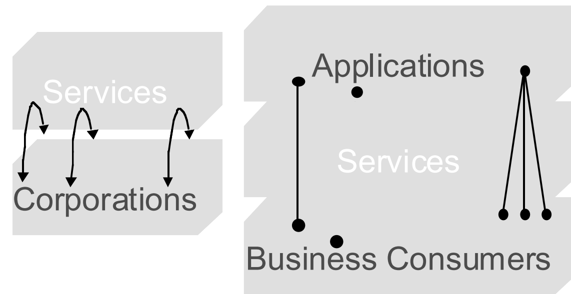
Business-Model Trends

The business-model issues surrounding the selling of new services and the providing of assurance that service needs are being met are changing within corporations. The existing model with IT managers purchasing services from a carrier to support user applications is evolving towards a tendency for end users in the various departments of the enterprise to buy applications directly from providers. Part of the application that is being purchased is this services transport. As a result, the entire business model is shifting, with changes in who buys service and how quickly, what the channels are for buying it, and the marketing implications.

There also are technical driver implications. Some research on connecting facilities together has shown that the IP services market is a roughly $40 billion business. If end users could be connected to applications in a more dynamic on-demand market, however, this business would increase six fold. While the IP manager may buy a facilities connection service, today it is end users that buy the application services. The buyer is shifting from IT manager to end-user (see *Figure 1*).

FIGURE 1

End-User Purchase of Service Applications



A movement from traditional implementation systems, such as traditional routers, toward more intelligent devices, such as an intelligent router called a service agent, has also been occurring. This change in the service-creation platform enables the capture of additional revenue. Consequently, the new business model has on-demand, service-appropriate bandwidth delivered in episodes. An episode in this sense might be, for example, the need for an on-demand, high-bandwidth videoconference one day a week for only 90 minutes, rather than a service purchased throughout the week. Episodes appear to be a growing trend for service delivery in the future. This trend will have relatively profound implications in the business model for service delivery.

Service retail carriers (see *Figure 2*) are emerging where organizations that are high touch can sell on-demand services, turn around and buy wholesale transport from carriers to deliver them, and be the middlemen to guarantee quality and actually put the services together. Some carriers are creating subsidiaries that can move quicker and attack this service retail market. Other carriers are creating service-creation platforms that can host these services. Still others are trying to ignore dealing with individual services.

Conclusion

The key to the new service-provider environment is to avoid becoming trapped in an outdated connectivity paradigm of simply providing facilities connection rather than actively pursuing the delivery of new services. To succeed, an OSS strategy must be developed that can provide fine-grain, customer-aware, and service-aware delivery to build and maintain leadership in the market. In addition, SDM and service assurance are critical to the new service market, which is based on charging more for delivering a value-added service.

The problem is that premium priced, value-added services cannot always be physically experienced. To overcome this, connectivity service must be illuminated so people are aware of the service's value. As the market moves on to deliver these new IP–based services, new business models and new opportunities will emerge for the forward thinking, nimble providers.

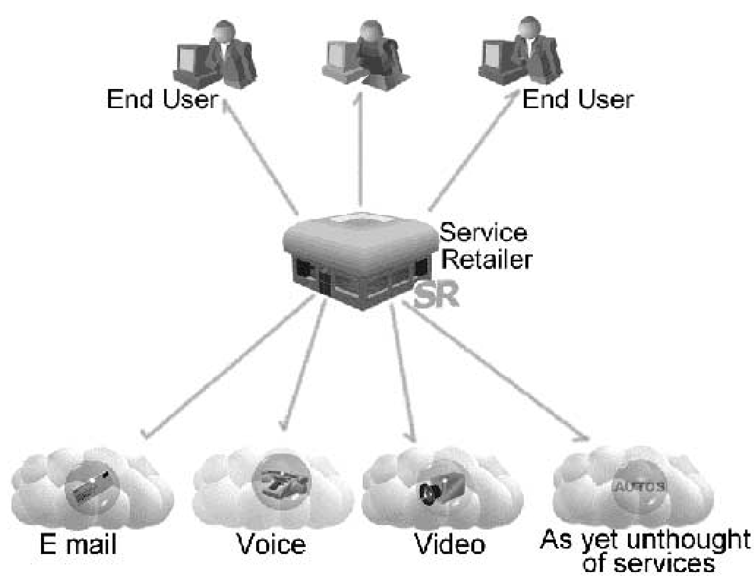
Rise of the Service Retailer



Configurable Processors Transform the System-on-Chip Platform

Chris Rowen
President and Chief Executive Officer
Tensilica Inc.

Introduction

The computer-system industry has evolved around the concept of the general-purpose computing platform: a slowly evolving instruction-set architecture, a family of hardware implementations scaling over time to higher performance levels, and a body of software packages spanning a broad range of computing applications. Starting in the late 1990s, electronics investment has shifted away from computing toward communications-centered applications, specifically to a new class of systems: high-bandwidth Internet infrastructure (data servers, integrated access controllers, core routers, Web switches) plus a vast array of focused-function end-user devices terminating the network (cell phones, personal digital assistants [PDAs], set-top boxes, digital cameras, Internet toys). The ongoing semiconductor revolution has abetted this shift and now makes it possible, and increasingly necessary, to build system-on-chip (SoC) devices that integrate all the processors, memories, peripherals, and interfaces of an entire system into a single integrated circuit (IC) platform narrowly dedicated to that application.

This article explores and illustrates the sweeping impact of this change in meaning of "platform" and highlights the potential leverage of automatic generation of application-specific hardware and software, using configurable microprocessor technology.

A Brief History of Platforms

The concept of a computing platform has powerful technical and economic motivations. Broad use of a common programming model, hardware implementation, and an applications portfolio has the potential to amortize the cost of initial development across a great volume of products and to reduce the cost and risk of new development. IBM's System 360, introduced in 1964, is considered the first major platform architecture, but each major generation of electronic systems has given birth to a dominant platform—for example, the Digital Equipment VAX introduced in 1976 and dominant into the 1980s, and the IBM/Intel/Microsoft PC, introduced in 1981 and dominant up to the present. Each of these platforms supported programming models supporting a wide range of applications (from payroll to mechanical design), and the core hardware implementation consisted of multiple chips (processors, memories, peripheral controllers), many of which were standard components intended for broad use outside the platform. In most cases, these platforms were designed or evolved over a period of years, accumulating hardware features and software infrastructure to support the broad set of target applications. Moreover, each platform gained flexibility by incorporating a general-purpose microprocessor architecture supporting a broad set of generic data-types—especially integers, character, Boolean and floating-point data.

The Design Paradox

Two fundamental shifts—one technical and one economic—are changing the design of platforms. First, continuing growth in silicon-chip capability—Moore's Law—is rapidly reducing the number of chips in the typical system and increasing benefits in cost, bandwidth, and power for the integration of multiple functions together on a single chip. Systems built from large collections of generic ICs, combined at the printed circuit-board level, are less and less able to compete technically with highly integrated systems that combine their processors, memories, peripherals, and other logic together on one or a small number of ICs. Second, growth in the value and importance of general-purpose computer systems (PCs, workstations, mainframes) has slowed significantly, in favor of a explosion of thousands of new types of electronic platforms aimed at communications and entertainment—network routers, MP3 players, cell phones, PDAs, and other focused functionality devices. Moreover, the global market for these devices is intensely competitive, so low manufacturing cost is key. These are highly flexible, yet very lean, new platforms.

This creates the central paradox of modern platform design: How do architects develop all of these new platforms that combine the key benefits—longevity, amortization of development costs over large volume, adaptability to changing market requirements—without taking too long or creating something so general-purpose that it fails to meet the brutal cost requirements of this new type of electronic platform. Without a sharp reduction in the cost of development of these new platforms, the variety and efficiency of new platforms will be significantly constrained.

How to Build a Platform

We could resolve the paradox if we could take all of the phases of normal platform design and compress them:

1. Compress the time and effort to develop, implement, and verify new microprocessors, including appropriate new instruction-set architectures, compilers, operating systems, and libraries optimized for the class of applications that will run on the new platform.
2. Compress the time and effort to develop, implement, and verify new system architectures that incorporate these processors and their surrounding interfaces and programming models.
3. Compress the physical implementation of the system—processors, memories, IO, and other logic into dense integrated circuits.

Compressed creation of new microprocessors for these lean platforms is, perhaps, the most daunting of these tasks. Traditionally, the time-scale for the development of substantially new processor architectures is years, especially when the development of new software development environments (compilers, debuggers, verification tools), and the porting of operating systems are included. Reducing the time and cost of development of a new processor accelerates the whole platform development and enables a much wider community of engineers to be platform architects. Configurable processor technology is the key.

Configurable Processors

Configurable processor technology focuses on the automatic generation of new platform-specific processor hardware design and software tools from a single high-level description. By automating hardware and software generation, the platform designer is guaranteed consistency among all of the representations of the processor definition—the hardware design, test benches, simulation models, compilers, assemblers, debuggers, and real-time operating systems (RTOSs) are all built for exactly the same architecture. This potentially eliminates the "Tower of Babel" that surrounds many embedded processor environments today, where subtle differences among members of a processor family—differences in instruction-set variations, memory system organization, debug facilities, and processor control structures—frustrate the system designer putting together the hardware, verification, and software tools. By generating the processor from a high-level description, the platform designer gets control over all of the relevant cost, performance, and function attributes of the processor subsystem, without having to become a microprocessor design expert. This effectively opens up processor design to a broad population of system and application architects, just as the proliferation of application-specific integrated circuit (ASIC) and logic synthesis tools democratized IC design during the past decade.

The four key questions for configurable processors are these:

1. What target characteristics of the processor can be configured?
2. How are the target characteristics captured by the platform designer?
3. What are the deliverables—the hardware and software components—to the platform designer?
4. What are typical results for building new platforms to address emerging "post–PC" communications and consumer platforms?

What's Configurable?

The notion of adapting the processor to fit the application is increasingly popular. A wealth of terms has appeared to describe the rich set of possibilities. The phrases "configurable processor," "extensible processor," "reconfigurable processor," and similar terms have only entered the electronics lexicon during the past three or four years, so it is useful to roughly define some of the terms.

Synthesizable Processor: A wide variety of processor architectures have been implemented in RTL to improve process portability and ease integration into standard ASIC design flows that include the generation of gate-level net lists from RTL by logic synthesis tools such as Synopsys's Design Compiler. However, synthesizability does not imply configurability. Moreover, architectures originally tuned for custom circuit implementation may require significant redesign to fit the stricter clocking, power management, and data-path design constraints of synthesis. Many popular architectures—including asynchronous response mode (ARM), millions of instructions per second (MIPS), Xtensa, and Motorola ColdFire—have been implemented as synthesizable cores.

Configurable Processor: A configurable processor is a design and tool environment that enables significant adaptation by changing major processor functions to tune the processor to specific application requirements. Typical forms of configurability include additions, deletions, and modifications to memories, to external interface widths and protocols, to commonly used processor peripherals, and, most importantly, to instruction-set functionality and execution pipelines. To be useful, configuration of the processor must meet two important criteria:

1. The configuration mechanism must accelerate and simplify the creation of legal and useful configurations.
2. The generated processor must include complete hardware descriptions (typically RTL descriptions such as Verilog or VHDL), software development tools (compilers, debuggers, assemblers, and RTOSs), and verification aids (simulation models, diagnostics, and test support).

Note that the concept of a configurable processor architecture is different from the idea of a reconfigurable processor IC described in a following section. Configurable processors may be implemented in many different hardware forms, ranging from ASICs with hardware implementation cycles of many weeks to field programmable gate arrays (FPGAs) with implementation cycles of just minutes. An important subset of configurable processors is extensible processors—processors whose functions, especially instruction-set, can be extended by the application developer to include features never considered by the original processor designer. Automated software support for extended features is especially challenging, however.

Application-Specific Processor: This is the broadest and most generic term for processors tuned for various embedded application classes. This may include both processors

FIGURE 1

Instruction Set	Memory System	Interface	Processor Peripherals
• Extensions to ALU functions on general registers (e.g., population count instruction) • Coprocessors supporting application-specific data types (e.g., network packets, pixel blocks) • High-performance arithmetic and DSP (e.g., compound DSP instructions, vector/SIMD, floating point) • Selection among function-unit implementations (e.g., small iterative multiplier versus pipelined array multiplier)	• Instruction cache size, associativity , and line size • Data cache size, associativity , line size, and write policy • Memory protection and translation (by segment, by page) • Instruction and data RAM/ROM size and address range	• External bus interface width, protocol, and address decoding • Direct connection of system control registers to internal register and data ports • Mapping of special purpose memories (queues, multiported memories) • State visibility trace ports and JTAG–based debug ports	• Timers • Interrupt controller: number, priority, type, fast switching registers • Exception vectors addresses • Remote debug and breakpoint controls

developed by traditional manual methods and automatically generated configurable processors. Examples of manually developed application-specific processors include the ARM9E (ARM with basic digital signal processor [DSP] extensions), MIPS's application-specific extension (ASE) for graphics, and Equator's MAP-CA general-purpose media. These designs are typified by multi-year development cycles and manual adaptation of software tools. The greater development cost and time for manual adaptation typically mean that these designs cannot afford to be narrowly application-specific and may not be able to achieve high application efficiency.

FPGA–Based Processor: As the capacity of FPGAs has grown, they are gradually changing their role from glue-logic and special-function block to full system implementation vehicle. Almost by definition, this means that processors are starting to appear within devices that contain lots of field programmable logic. Three categories have emerged:

- *Integration of Core Plus FPGA:* A standard fixed architecture core is incorporated on the same die as field programmable logic. Altera's Excalibur family and Triscend's products fall into this category. The processors are not field adaptable and the field programmable gates are used only for peripheral and interface functions.
- *Reconfigurable Processor:* An important subset of the reconfigurable processors synthesize parallel DSP architectures into specialized FPGA blocks controlled by reduced instruction-set computing (RISC) cores to create specialized field-configurable platforms often dedicated to complex communications infrastructure applications. Examples include the Chameleon CS2000 Reconfigurable Communications Processor (RCP) and MorphICs. Similar reconfigurable processors use small programmable engines or special DSP datapaths for executing parallel DSP algorithms, often in conjunction with RISC control cores. Examples include Broadcom's Calisto family (based on Xtensa) and the UC Berkeley Pleiades low-power heterogeneous reconfigurable multimedia processor project.
- *General Configurable Processors Implemented in FPGA:* Automatic generation of efficient processors of configurable architectures complements high-capacity FPGAs. In these cases, high-end FPGAs, such as Altera APEX and Xilinx Virtex devices, are used as synthesis targets. Tensilica's Xtensa and ARC's Tangent are both commonly used in this form. A variety of 8b and 16b processors are also available with some configurability features, including Atmel's AVR 8b RISC, Altera's NIOS, and several 8051 variants. There are no major differences between processors suitable for FPGA versus ASIC implementation—all designs want processors that are small, fast, and fully supported by tools. In practice, the processors in FPGA are among the smallest cores available and are used in applications that demand fast time to market but can tolerate the clock-frequency and unit-cost penalties of FPGA implementation.

Configurability of Processor Features

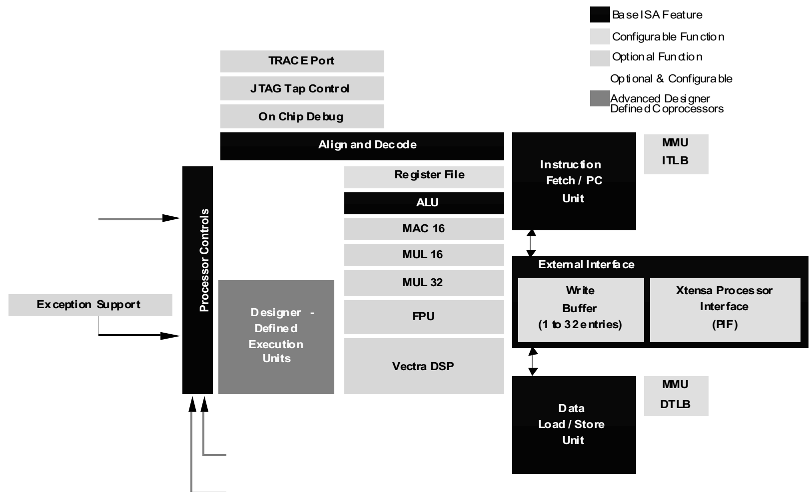
The goal for configuability is to allow features to be added or adapted in any form that optimizes the cost, power, and application performance of the processor. In practice, this can be broken into four categories (see *Figure 1*).

A color-coded block diagram for a configurable processor is shown in *Figure 2*, identifying baseline instruction-set architecture features, scaleable memories and interfaces, optional and configurable processor peripherals, selectable DSP coprocessors and facilities to integration user-defined instruction-set extensions.

The basic flow for generating a processor is shown in *Figure 3*.

The chip designer, the application expert, comes to the Web-based generator interface and selects or describes the instruction-set options, memory hierarchy, closely-coupled peripherals, and external interfaces required by the application. The generator produces both the complete synthesizable hardware design and the software environment in less than an hour. The hardware can be immediately integrated

FIGURE 2



into the balance of the SoC ASIC design. It is easily and legally portable to any process or fab, ensuring optimal performance and silicon leverage. The software development and tuning can also start immediately. With the integrated profiler and one-hour turn-around for software tools and RTOSs, the designer can, for the first time, realistically tune the processor to fit the application.

How Is a Processor Described?

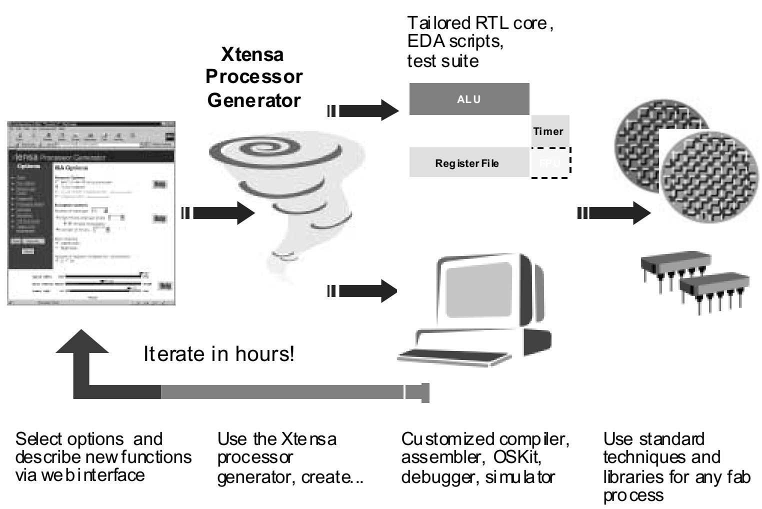
Fast and easy configuration depends on an appropriate means to describe and modify processor functions, especially instruction-set functions. Academic researchers have created instruction-set description languages, especially for the teaching, documentation, and generation of software tools and performance models, plus some limited automatic generation of hardware. The "Tensilica Instruction Extension" (TIE) language is the first widely used commercial instruction extension format and processor extension generator.

The TIE Language

A TIE description consists three basic parts:

- *State Declarations and Types:* Designers may add state registers and register files of any width and number. New C data-types can be associated with new register files.
- *Instruction Encodings and Formats:* Designers may specify new formats with up to six source and destination registers, including encoded immediate fields. Each new instruction gets a unique encoding.
- *Instruction Semantics:* For each group of instructions and data-type, designers specify the corresponding transformations from source registers to destinations registers. The designer may optionally specify pipeline latency, used by the compiler, simulator, and hardware

FIGURE 3



generator to automatically stretch complex functions across multiple clock cycles.

A Simple TIE Example

Here is a simple, but complete, TIE example of adding a set of instructions to the processor. It defines a new C data-type, "long128," and associates with it a 16-entry register file, where is each entry is 128b wide. The instructions that use the new register file include loads and stores, by default, plus one arithmetic instruction "add128." This instruction is pipelined so the 128b operation does not impact the clock frequency of the processor.

```
;use generator;
;generator::regfile   (name =>  "L",
;                      cname =>  "long128",
;                      sname =>  "s",
;                      width =>  128);
opcode add128 op2=0 CUST1
iclass ipv {add128} {out sr, in ss, in st}
reference add128 { assign sr = st + ss;}
schedule c2 {add128} { use ss 1; use st 1; def
sr 2;}
```

The software developer might directly use the new data-type and operations as follows:

```
main() {
int i;
long128[256] source1,source2,destination;
   for (i=0;i<256;i++} destination[i] =
add128(source1[i],source2[i]);
}
```

What Are the Deliverables?

TIE–based extensions are created by application experts, typically starting from the application kernel. They use Tensilica's baseline simulation tools to profile the application and identify hot spots in the original code, and then describe new data-types and operations that are more natural to the problem. All hardware, verification infrastructure, and software tools are created together from a single configuration file and delivered securely over the Web so that the designer can typically evolve an optimized configuration over a few days. A typical flow is shown schematically in *Figure 4*.

From that single configuration description, the processor generator produces the fast cycle-accurate instruction-set simulator and bus-functional model; complete C source libraries for the extensions; the full GNU–derived C/C++ compilers, including modified front-end, code-generator, code-scheduler, and intrinsic support; the OSKit, which is the support for kernel and debug extensions for third-party RTOSs; the hardware test-bench and complete diagnostics, including coverage of TIE extensions; the scripts for synthesis, place and route, test generation, and timing and power optimization and simulation; and, of course, complete source code in Verilog and VHDL.

What Is the Impact?

The promised benefits of automated processor generation are significant improvements in application efficiency (throughput, power, silicon cost) combined with simplification of full platform development (completeness and immediacy of compilers, simulators, RTOSs and hardware). To illustrate, it is useful to walk briefly through examples in multimedia, telecommunications, and network processing.

Consumer Multimedia

Video processing lies at the heart of consumer electronics—in digital video cameras, digital television, and games. Common tasks include color-space conversion, two-dimensional filters, and image compression. The industry-standard EEMBC "Consumermark" benchmarks

FIGURE 4

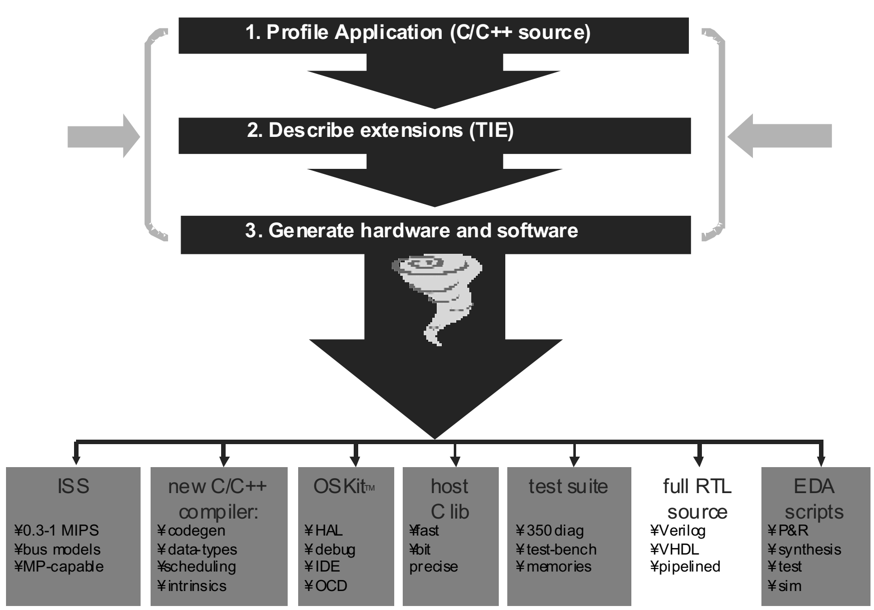


FIGURE 5

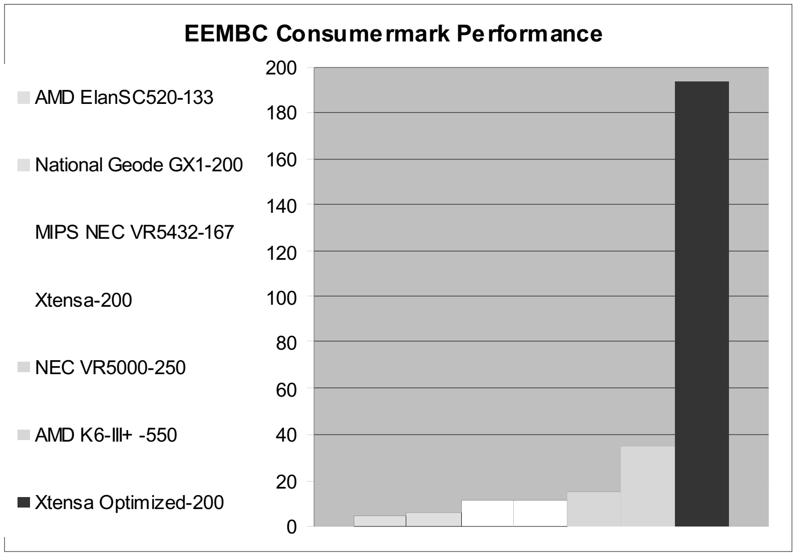
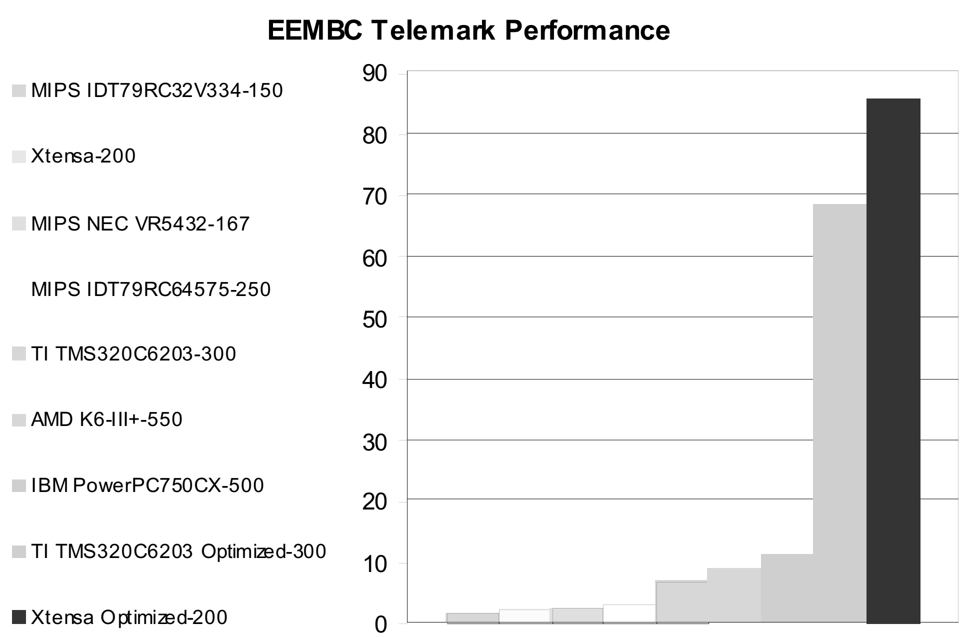


include a representative sample of all these applications. A standard configuration of Tensilica's Xtensa processor already includes many appropriate features for these tasks, and even this baseline configuration at 200 MHz (typical for 0.1µ complementary metal oxide semiconductor [CMOS] technology) delivers performance more than 11 times the performance reference, the ST20C2 at 50 MHz. However, when instructions for image filtering and color-space conversion are added using TIE, the average performance is increase by a further 17 times, resulting in a processor with almost 200 times the performance of the reference processor as shown in *Figure 5*.

These performance levels have previously only been achieved by specialized non-programmable logic blocks dedicated to a specific imaging function. The TIE add-ons include special instructions for gray-scale filtering and RGB-YIQ and RGB-CYMB color-space conversion.

FIGURE 6



DSP Acceleration in Telecommunications

Telecommunications applications present a different set of challenges. Here, the data is often represented as 16b fixed-point values, as densely compacted bit-streams, or as redundantly encoded data. During the past 10 years, standard DSPs have evolved to address many filtering, error-correction, and transform algorithms. The EEMBC "Telemark" benchmark includes many of these common tasks. In this case, the applications designer might start with an Xtensa with the Vectra DSP add-on—a family of vector (single instruction multiple data) coprocessors tuned to digital signal processing. This gives baseline performance on the EEMBC benchmarks that compares well with other leading 32b and 64b RISC processors. However, when some additional instructions are added using TIE and the code is re-optimized to exploit the configuration, the performance jumps another 37 times. The overall performance then exceeds that of the previous performance leader, a high-end Texas Instruments C62x VLIW DSP using hand-optimized code, as shown in *Figure 6*.

Conclusion

Innovation in embedded systems is almost frightening in its pace and diversity, particularly as product creators push to deliver both more flexibility and ease of use, as well as fundamental breakthroughs in bandwidth, battery life, and cost. On the surface, it would appear than ever-greater software functionality and flexibility stands in conflict to ever-greater hardware specialization. The conflict can be resolved by taking a fresh look at how these new SoC platforms are defined, designed, verified, and programmed so that a larger number of more application-specific platforms can be safely created by a wider population of engineers. Automated generation of application-specific platforms around configurable processors is one key to this impending explosion of new platforms.

Superconductor Systems for Wireless Networks

Randy Simon
Vice President and Chief Technical Officer
Conductus, Inc.

After more than a decade of materials and applications development of high-temperature superconductors for electronics, wireless communications has emerged as the market with the greatest potential. The explosive growth of the wireless industry coupled with the increasing technology demands of advanced wireless networks have created a significant opportunity for high-temperature superconducting technology.

The focus for using high-temperature superconductor (HTS) technology in wireless applications is in the form of front-end systems for base stations that exploit the properties of superconductors to create high-performance radio frequency (RF) filters coupled with the properties of cryocooled semiconductors to enhance pre-amplifier performance. The resultant receiver front ends simultaneously offer enhanced sensitivity to improve signal reception and exceptional selectivity to reject interfering signals. The underlying superconductive technology supporting wireless applications has been well enough in hand for several years to permit the intense product development required for widespread deployment. There have already been several generations of superconductor wireless systems that include a growing number of features and performance benefits. The evolving demands of high-performance digital wireless systems continue to drive efforts to further advance superconductor filter technology and enhance its ability to address the future needs of the wireless industry.

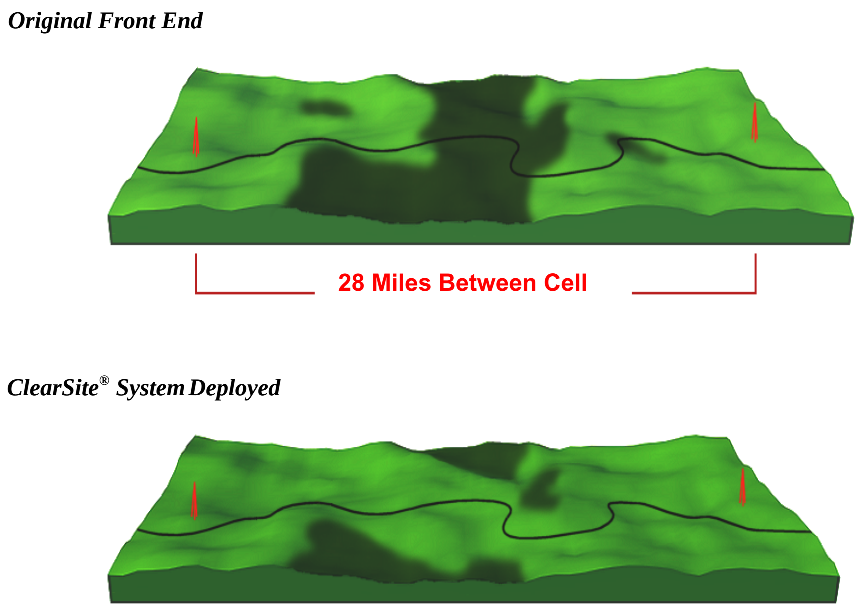
This technology has a unique role to play in wireless cell sites because the properties of superconductors make it possible to create filters that simultaneously deliver optimum performance with respect to adjacent band rejection and insertion loss. This is because superconductors are nearly lossless at microwave frequencies. As a result, extremely sharp filters—ones with a large number of poles or filter stages—can be built without incurring substantial insertion losses, whereas filters made from ordinary materials become increasingly lossy as they become more selective. Filters made using superconductors provide the closest approximation to a perfect filter—namely, one that allows 100% of the desired signals to pass through and rejects 100% of the unwanted signals. Hence, superconducting filters are ideally suited for rejecting out-of-band signals, particularly those that are very close in frequency to the desired band. This performance is exactly what is needed for preselect filters in wireless base-station receivers.

The ability to reject adjacent band interference is important in the base station because such signals can otherwise saturate the amplifier or introduce other nonlinearities in the receiver front end and introduce distortion into voice channels, reduce capacity in digital systems, and degrade data transmission. Superconducting filters can allow service providers to utilize their available spectrum without introducing guard bands or blocked channels at the band edge. By using extremely sharp adjacent-band rejection filters—commonly referred to as "brick-wall" filters—it is possible to maintain a greater number of channels in the band. In digital wireless systems, high selectivity against interference reduces the effective noise floor, thereby restoring lost capacity and reduced coverage as well as permitting lower mobile transmit power (see *Figure 1*).

The other major benefit of having superconductor and, more generally, cryoelectronic technology in base stations is the ability to increase the sensitivity of the receiver, thereby providing extended range and enhanced coverage. The sensitivity enhancement comes about by virtue of reduced noise in the receiver. The low noise results from two different effects: the nearly perfect efficiency of the superconducting filters plus the use of specially designed low-noise amplifiers (LNAs) whose own noise levels are reduced by operating at the same very low temperatures required for the superconducting filters. Like many other electronic components, properly designed semiconductor LNAs deliver enhanced noise performance when operated at reduced temperatures. Co-locating these LNAs with superconducting filters provides an ultra-low–noise receiver front end. Having a very low noise figure increases range and coverage, reduces mobile transmit power, increases capacity, and increases data throughput for 2.5G and 3G systems. By eliminating the conventional trade-off between sensitivity and selectivity, superconductor front ends give the service provider the ability to maximize coverage, capacity, quality, and data rate all at once.

FIGURE 1

By deploying a ClearSite superconductor system at each base station, cell-site coverage increases, eliminating the dead zone without adding a new cell site.



Source: Actual Carrier Field Data

The first field tests of superconductor front ends for wireless networks took place in the 1995–1996 time frame. For the first few years, when analog networks were dominant, the primary application for the technology was coverage expansion in rural networks primarily associated with the enhanced sensitivity of the front end. Over time, the application focus has shifted toward the more demanding requirements of digital networks in urban and suburban areas, and the opportunities for widespread deployment have expanded. Currently, three companies in the United States—Conductus, ISCO International, and Superconductor Technologies—are selling superconductor front-end systems to the wireless industry. As of mid-2001, several of the top-ten U.S. carriers have begun to deploy these front-end systems in their networks, and there are well over 1,000 of them in use across the country. These deployments have clearly demonstrated the ability of these products to increase minutes of use (MOU), reduce dropped call rates, and improve quality of service (QoS). For example, Dobson Communications has deployed ClearSite® systems from Conductus, and they have seen an increase in MOU by up to 30 percent in cell sites where the systems are installed.

More recently, extensive second-generation (2G) and third-generation (3G) urban field trials have clearly demonstrated the ability of superconductor systems to reduce the effects of interference on high-performance networks. In particular, the systems were able to restore capacity and coverage in cell sites that were dramatically degraded by the effects of interference. In addition, the systems significantly increased data rates and reduced bit error rates. From all indications, the benefits of these systems increase in higher-performance wireless networks (see *Figure 2*).

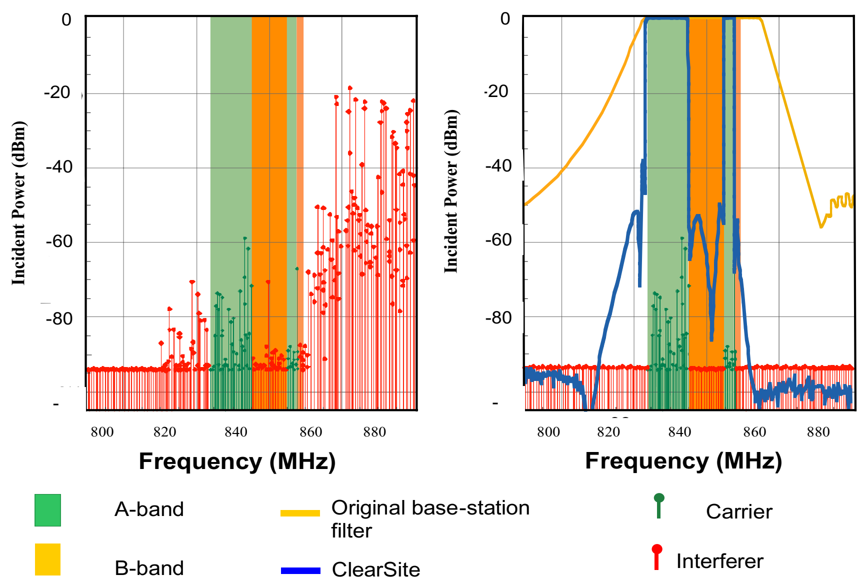
Urban cell sites operate in an increasingly hostile RF environment due to the proliferation of wireless service, the increases in wireless traffic, and the growing use of co-location. One particular source of interference that is increasingly prevalent in the United States is Enhanced Specialized Mobile Radio (ESMR) sites, as much as 50 percent of which are located within a kilometer of urban cellular sites. These sites produce strong interference signals very close to the cellular frequency bands.

While the effects of interference are increasingly evident in modern digital wireless networks, identifying and cataloguing the sources of interference is not a simple matter. In call division multiple access (CDMA) systems, for example, it is difficult for the switch to separate interferers from the desired CDMA carriers. The interference sources are typically variable and transient in nature. As a result, complex measurements and data reduction are required in order to accurately gauge the nature and impact of interference and to tie it to key performance metrics, such as system capacity and mobile transmit power. But despite these technical issues related to quantitatively understanding the nature of interference in wireless systems, there is a growing body of data demonstrating the impact of interference on digital networks.

CDMA systems are particularly vulnerable to interference by virtue of the unique power-control aspects of the technology. The power-control system causes all mobiles to increase power when interference signals are present in the band. These interferers can be in-band signals from numerous sources, or they can be intermodulation products caused by out-of-band signals—typically from either co-located or nearly co-located transmitters, or from competi-

FIGURE 2

The ClearSite superconductor system reduces interference at an urban TDMA cell site, resulting in an 80 percent capacity improvement.



Spectrum analyzer measurements at urban cell

tive mobiles far from their cell site and thus operating at maximum power. The effect of this power-control activity can go beyond the usual "cell breathing," which occurs as more and more subscribers use a carrier, and dramatically reduce coverage and capacity.

These effects and others have been studied extensively in field trials of superconductor systems. Conductus performed one such trial with a suburban CDMA B-band operator that was experiencing interference problems from a competing A-band operator. The goal of the trial was to quantify the capacity improvement that the HTS system could provide by diminishing the effects of the interference. Calibrated interference signals were applied at levels comparable to the measured interference at the site. These signals were observed to essentially collapse the coverage area of the site using only the existing front end. With the superconductor system in place, the full coverage and capacity of the cell site were restored (see *Figure 3*). Trials in time division multiple access (TDMA) systems have demonstrated results of comparable significance.

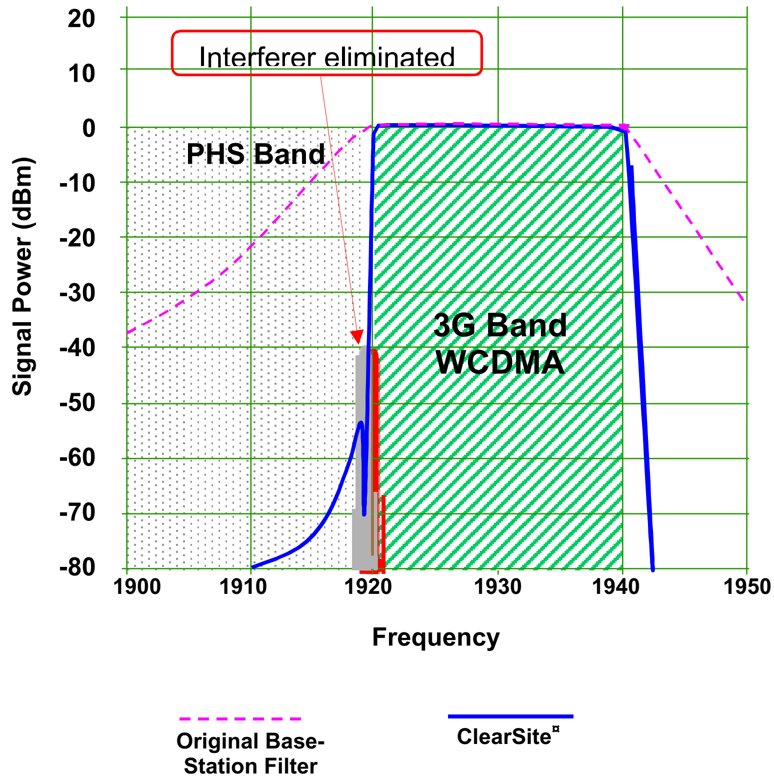
As wireless networks move toward increased utilization for data communications and 2.5G and 3G technologies are employed, the benefits of superconductor front-end technology will increase. The ability of wireless systems to support high data rates is directly related to the signal strength to interference ratio, as described by Shannon's Theorem. By reducing noise and diminishing interference, superconductor front ends are very effective in increasing the maximum data rate in wireless systems.

Field trials of 3G systems using the International Mobile Telecommunications (IMT)–2000 wideband CDMA (WCDMA) technology have demonstrated an even greater vulnerability to interference than was seen in standard CDMA systems. Conductus performed a field trial with KDDI and Hitachi in Japan that demonstrated the effects of interference caused by the Personal Handiphone System (PHS) and the ability of the superconductor system to counteract these effects. In this trial, the 3G cell site was again observed to essentially collapse in the presence of frequent but moderate-level interferers (See Figure 3). The superconductor front end fully restored capacity, coverage, and data rate, and improved bit error rate by three orders of magnitude.

The growing installed base of superconductor front-end systems in the wireless infrastructure as well as impressive results from a variety of field trials being conducted by all vendors provide an increasingly persuasive argument for widespread deployment of the technology. Alternative approaches to base-station enhancement, such as tower-mounted amplifiers and smart antennas, have distinct disadvantages when compared with the superconductor solution, including increased vulnerability to interference and cost, respectively. There are a number of criteria that superconductor systems must meet in order to gain widespread acceptance throughout the industry. From a performance perspective, of course, the products must provide a combination of unparalleled high selectivity as well as low noise (high sensitivity). These characteristics are the reason for using the technology in the first place. But beyond the electrical performance, the systems should be highly reliable, compact, and field-proven, as they are replacing existing technology that is very reliable and has generally not been a focus of much attention in the base station. Because the superconductor systems include a mechanical refrigeration

FIGURE 3

The ClearSite superconducting system reduces out-of-band interferers at a 3G site.



unit, operators have had to become comfortable with issues such as cooler reliability, the time required to achieve operational temperature, and the system response to various failure modes or degradation of performance. As more systems have been deployed and the track record of the technology has been established in the initial deployments, these issues have gradually diminished as major concerns for advanced operators.

Superconductor front-end systems are costlier than the conventional technology that they replace, but the economics of deploying them are increasingly favorable. When capital budgets were large, the answer to problems of coverage, capacity, and QoS was often to build more cell sites. In today's constrained economic environment, alternative solutions are more attractive. As an alternative to adding new cell sites, superconductor front ends are extremely cost-effective, with average selling prices being less than a tenth of the price of a new base station. Even when adding base stations is not a good alternative, but the technology is employed to combat the effects of interference, enhance QoS, and increase data rates, the economics are still very favorable. Based upon the increases in MOU and increased customer satisfaction, the payback period for the equipment can be very short—less than one or two years in many cases.

Superconductor front-end technology is an evolving technology in which new features and enhanced performance continue to be added to the products. The systems are getting more sophisticated, in many instances embodying capabilities for network optimization that are not available with conventional front ends. Some HTS systems are now combined with other base-station components such as duplexers, conventional front ends, and others. A goal of the superconductor industry is to eventually have the technology designed into the base station, which would be the path to the most widespread deployment. Superconductor filter technology itself continues to evolve. Recently, Conductus announced the development of a new filter architecture that provided the most selective wireless filter ever demonstrated—the equivalent of 50 poles. Such filters should be capable of countering the effects of interference in even the most demanding digital wireless networks.

In little more than a decade, high-temperature superconductors have gone from a novel discovery in the laboratory to a technology on the verge of being a mainstay in the wireless industry. Several companies offer a growing set of products that offer unique benefits to increasingly demanding wireless networks. In an age when multiple electronic technologies play a dominant role in our daily lives, superconductors are now joining their ranks.

Making DWDM Ready for Prime-Time

The Internet Is Here to Stay, and DWDM Is the Technology of Choice for Alleviating the Bandwidth Bottleneck

Moris Simson
President and Chief Executive Officer
Optenia, Inc.

Introduction

The rapid expansion of the Internet in recent years has inspired a series of new multimedia applications that require high-speed connectivity. These applications continue to demonstrate that the full utility of the Internet is far from having been delivered. E-mail was just the beginning; there are dozens of new "e-things" waiting to be developed into viable business models, all of which rely on the worldwide high-speed connectivity to the Internet. The latter requires broadband access and transmission networks that point to an exponential growth in demand for bandwidth as new users come on stream.

The unprecedented bandwidth demands have required the installation of extensive fiber-optic networks that connect major cities and geographical areas. During the last five years, there has been an increasing reliance on dense wavelength division multiplexing (DWDM) technology to multiply by 40 times or more the amount of information that can be carried on a single fiber. DWDM, which originally was used to provide capacity relief by reducing the need to install more fiber between major urban centers, has started to find new applications. Increasingly, the focus is to reach metropolitan centers and intra-city clusters with high-capacity optical links without having to add additional fiber cables, which can cost up to $60,000/km depending on the dig. Clearly, DWDM ring architectures with optical add/drop multiplexers (OADMs) hold the key to switched connectivity essential to support bandwidth needs in both metro and access networks. These will then feed large office buildings expecting to embrace Gigabit Ethernet and other bandwidth-hungry applications rapidly.

In parallel with this evolution, at the consumer level, broadband access, which today only reaches 3 percent of users, is expected to reach a global penetration of more than 10 percent in less than four years. Never in history has there been such a rapid build-up in bandwidth demand. The key to the surge will be the extremities of the networks or the access points: The more users come on stream and require bidirectional connectivity, the more the bandwidth demands on the backbones will escalate. These broadband applications, and the optical networks required to support them, will drive the knowledge and information-based economy and the way that people communicate and do business. As this transformation unfolds, though, an important question that needs an answer is that of economic viability—Will all of this infrastructure be affordable to build?

The answer is unequivocal: The only technology capable of economical broadband delivery is photonics. The next step in datacom is clearly Gigabit Ethernet for the last mile, representing the link between high-speed optical networks and the individual subscribers. And, DWDM is the technology of choice for transporting and distributing such bandwidth economically.

DWDM

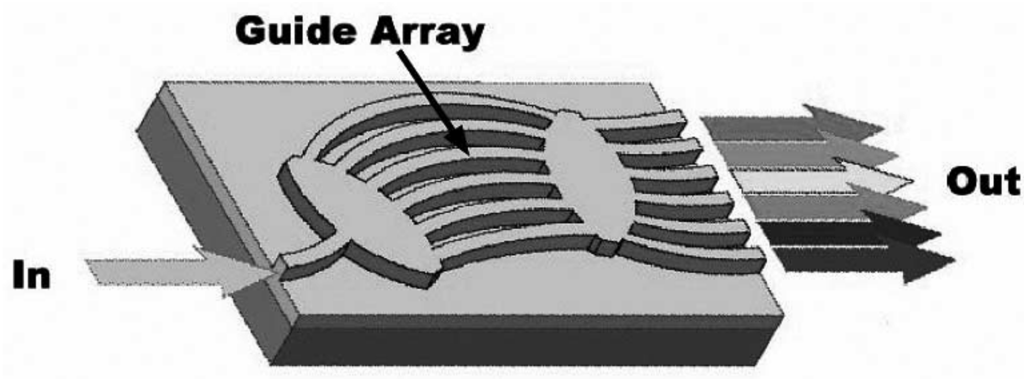
DWDM allows 40 wavelengths or more to be carried across a single fiber. The data from several sources is combined and transmitted optically by a laser of very specific wavelength. Several of these optical signals, each of a slightly different wavelength, can then be multiplexed and transmitted on a common fiber. At the opposite end, a demultiplexer splits these optical signals into individual detectors.

The technology used for multiplexing and demultiplexing narrowly spaced wavelengths has become a critical factor in the cost, and subsequent deployment, of optical networks. Traditionally, this has been accomplished using thin-film filters (TFFs). The assembly of these components is very labor intensive and extremely difficult to automate. Furthermore, TFFs do not offer acceptable performance for any more than 16 channels. Modern DWDM systems are now being designed with 80, 100, or even more channels, requiring much more economical and scalable technologies.

In recent years, there has been a significant interest (and over-abundance of investment) in arrayed waveguide grating (AWG) technology, shown in *Figure 1*. AWGs are manufactured using standard silicon wafer manufacturing techniques and offer better economics and performance than TFFs for more than 16 channels, due in part to the optical chip, which allows for automated assembly. However, beyond 40 channels, the manufacturing of AWGs becomes quite difficult. The chip size, or "die" size, of the AWG is

FIGURE 1

Basic Layout and Operation of an AWG Demultiplexer



quite large, and wafer non-uniformities result in extremely low yields and reduced performance. The economics are also somewhat compromised by the fact that maintaining the AWG at the required operating temperature requires significant amounts of power, which impacts operational costs and packing densities in the optical system.

The best means of reducing system cost is to integrate more component functionality into one module, which reduces the system complexity as well as the power requirements. The interest in planar waveguide technologies, such as AWGs, stems from the notion that increased functionality could be integrated on the same chip as the demultiplexer. However, with AWGs, the die size is already so large, and yields already so low, that integrating more components on-chip destroys the economic benefits that originally inspired the exercise. A new technology platform scalable to more than 100 channels is required and needs to offer the potential for integration, a very small form-factor, and economics superior to all competing alternatives.

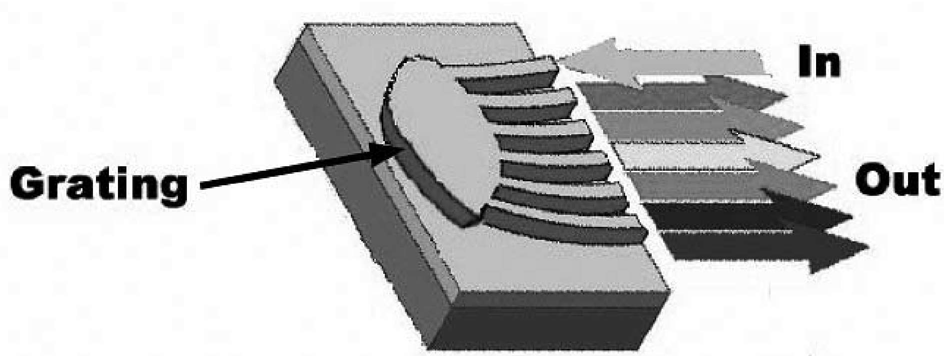
Echelle Grating Technology

Several years ago, there was an acceptance of AWG technology for high channel-count DWDM applications. At the time, the Echelle Grating (EG) approach was hindered by a requirement for very advanced processing techniques, especially in etching. The depth of the etch coupled with the requirements for verticality and smoothness made the fabrication of EGs very challenging. However, with recent advances in semiconductor manufacturing technology, the EG approach now outperforms AWGs and also offers scalability and manufacturability beyond what is attainable using existing technologies. The competitive advantages of the EG include performance, cost, power consumption, size, and scalability.

Although many similarities exist between the operating principles of EG and AWG devices, the layout of each is very different. Both rely on a high-quality grating to separate the narrowly spaced wavelengths. In the AWG, this is accomplished by the waveguide array; however, that section of the device becomes extremely difficult to manufacture at high channel counts or narrow channel spacings. Contrastingly, the EG relies on a traditional reflective grating, created by etching vertical facets into the waveguide core, shown in *Figure 2*. Scaling to high channel counts simply requires adding more "teeth" to that grating, and performance is not sacrificed. The die size, because of the reflective technology, is reduced by nearly a factor of four. That also benefits the power requirements, since the area requiring temperature control is much

FIGURE 2

Basic Layout and Operation of an Echelle Grating Demultiplexer



smaller. A typical 40 channel EG requires approximately one fifth the power of a comparable AWG.

For EG devices, the verticality and smoothness of the deeply etched grating facets are critical issues. An example of the type of etch required is shown in *Figure 3*. The reliability and reproducibility of the fabrication process for vertical facets continues to serve as the main challenge for those companies developing and commercializing EG technology. In recent years, these manufacturing issues have been overcome by some companies, and further developments, such as on-chip polarization compensation, have extended the EGs manufacturability beyond that of AWGs.

New Technology, New Opportunities

To be successful, integrated devices must provide greatly reduced cost per function without sacrificing the performance necessary for demanding telecom applications. The difference in the size between AWG and EG devices is illustrated in *Figures 4* and *5*, which compare six-inch wafers containing 40-channel demultiplexers. While only seven AWG DEMUXes can be patterned on a wafer, a total of 36 EG die can fit easily on the same wafer, representing a six-fold improvement in the die-level economics. Because of the small die size, the EG is a suitable platform for the on-chip integration of higher-level functionality.

The small size of the EG device transfers directly into a small package, a feature that is becoming increasingly important for today's complex optical networks that pack more and more capacity into the same size system. A fully packaged 40-channel demultiplexer with an integrated temperature controller is illustrated in *Figure 6*. This is roughly one quarter the size of most packaged AWGs *without* temperature controllers. The smaller EG form factor allows manufacturers to integrate more functionality on-chip or to hybridly integrate the device with an InGaAs detector array to produce very small optical channel monitors suitable for embedding directly in existing network elements. This type of functionality and integration has long been seen as the future of optical components; however, the execution of it has been hampered by the large size and low yields associated with AWGs.

The high performance of EGs results from the small die size, which minimizes the optical loss. The crosstalk is also inherently good because of the quality with which the grating can be defined (see *Figure 7*). Polarization sensitivity is minimized using proprietary compensation techniques, which remain the key to producing commercial EGs of the highest quality.

Die Size: 18 x 20 mm; Adjacent Channel Crosstalk: 35dB; Background Channel Crosstalk: 37dB

Scalability to high channel counts has led many systems manufacturers to shift from thin-film filters to planar waveguide components. However, modern DWDM systems require a large network fan-out to economically deliver

FIGURE 3

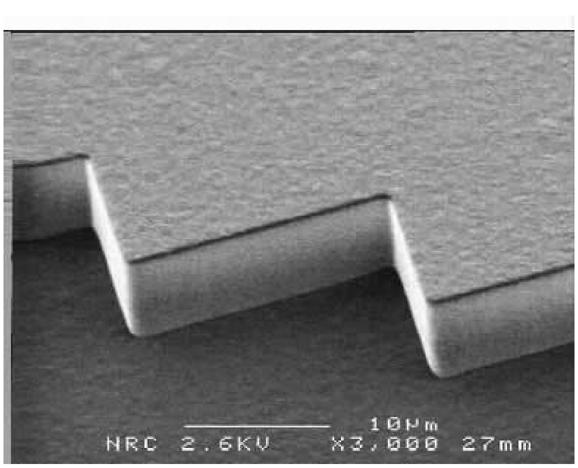

FIGURE 4

40-Channel Silica-on-Silicon AWG Demultiplexers

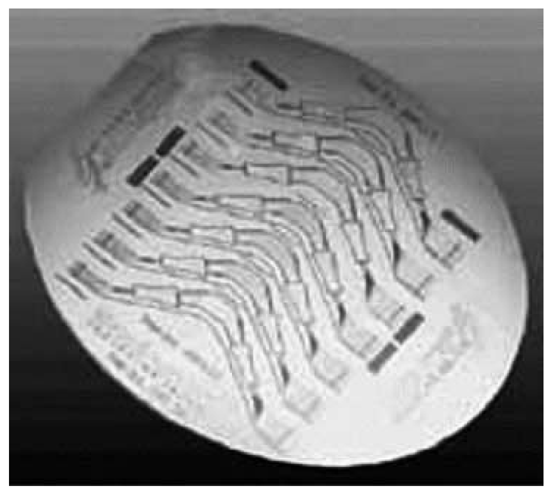

FIGURE 5

40-Channel Silica-on-Silicon EG Demultiplexers

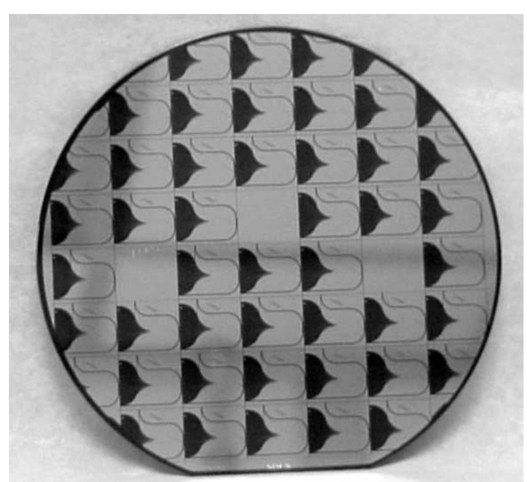

FIGURE 6

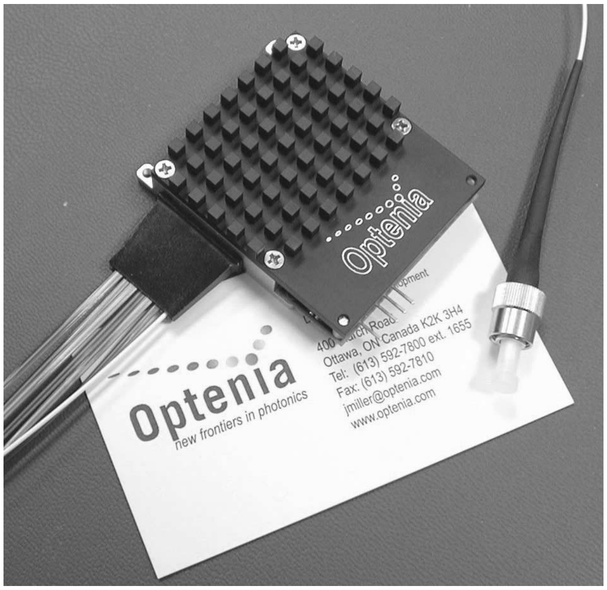
40-Channel EG Demultiplexer, Packaged with Integrated Temperature Controller



bandwidth to the edges of the network, and that requires scalability not available from TFFs or AWGs. EGs, in contrast, have recently been demonstrated with more than 250 channels on a single chip, and still over a dozen of these chips fit on a standard silicon wafer.

The performance of planar waveguide components, and the resulting signal quality in the optical network, relies on maintaining thermal stability to ensure optimum channel tuning. Both AWGs and EGs are packaged with thermoelectric coolers or heaters to control the devices temperature, but EG devices typically require one-fifth the power of AWGs. This translates directly into operational cost savings, and closer packing densities, which helps reduce the size of modern systems.

Photonic ASICs

Perhaps the most important benefit of EG technology is that it offers the ideal platform on which further functionality can be patterned on-chip. The restrictive size of other demultiplexer technologies makes this difficult, especially at high channel counts, where yields are already so low that adding further functionality results in significantly higher manufacturing costs. EG technology is being coupled with attenuator and switching functions to develop a new form of planar lightwave circuit: the readily customizable Photonic Application-Specific Integrated Circuit (ASIC).
In its most simple form, the Photonic ASIC would consist of a custom demultiplexer design that could be integrated with hybrid detector arrays to develop devices such as embeddable optical channel monitors. Variable optical attenuator (VOA) and switching technology will bring true customizability to this platform and be used to develop fully configurable optical add/drop modules (COADMs) and customer-specific designs for planar lightwave circuits. These modules significantly reduce the complexity and cost of the systems in which they are deployed and are truly the enabling technologies required for tomorrow's DWDM networks.

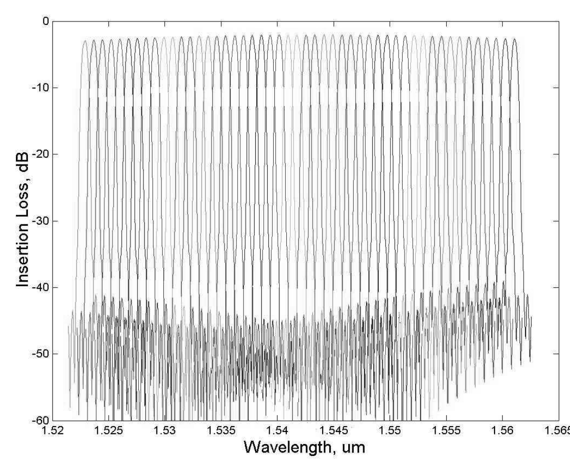
Conclusion

As the Internet expands and bandwidth requirements continue to grow, DWDM optical networks are being designed to transport staggering amounts of information. These large "pipes" will be fed by smaller metropolitan networks and access nodes, which require high-granularity fan-outs to effectively aggregate or disassemble that information.

As these networks evolve to higher channel counts at lower costs, the ability of today's TFF and AWG technologies to meet future system demands in terms of performance, cost, and manufacturability becomes questionable. The EG approach has quietly matured to a stage where, coupled with progress in silicon-based materials, it outperforms other competing technologies in nearly all respects. It does so at a fraction of the cost of competing technologies while using a fraction of the power. With scalability of up to 160 channels or more, in high volumes and small package sizes, EG technology is revolutionizing planar lightwave circuits and will be a critical enabler of tomorrow's high-functionality Photonic ASIC.

FIGURE 7

Insertion-Loss Characteristics of a 49-Channel EG DEMUX



Telco versus IP Service Creation and the Role of Softswitch

R. Paul Singh
Co-Founder and Vice President, Business Development
NexVerse

The outlook in the industry today is quite different from the outlook three months ago, when capital was readily available; every interexchange carrier (IXC) and incumbent local-exchange carrier (ILEC) was going to be under tremendous competitive pressure, and every Internet business model, including the new service-provider model, was expected to generate trillions and trillions of dollars. The recent NASDAQ downward slide on Wall Street has brought back some reality in terms of going back to the business fundamentals; profits (not only revenue) and paying customers (not only subscribers) are needed.

This paper will consider how the industry will evolve to meet the need for service providers to make money from the services they can offer. It will compare the service-creation models of today and tomorrow, the network and services of today and tomorrow, and the coexistence of the old and new models.

Service Creation Today

The basic tenets of service creation, whether based on Internet protocol (IP) or telco models, are the same. Service-creation tools, whether graphical or text based, are used to create services. Once created, services need to be verified and tested and then provisioned for the customers and billed for to be profitable. There is talk of services being created and provisioned by end users—something that will happen but that is not enabled today. However, customizing services through a Web browser with a limited set of predefined choices is already starting to happen.

The following steps apply to any basic service model:

- Service creation
- Service animation and validation
- Support-service deployments and customer scheduling
- Service provisioning
- Hooks to back-office systems (billing, provisioning, and network management)

The Network of Tomorrow

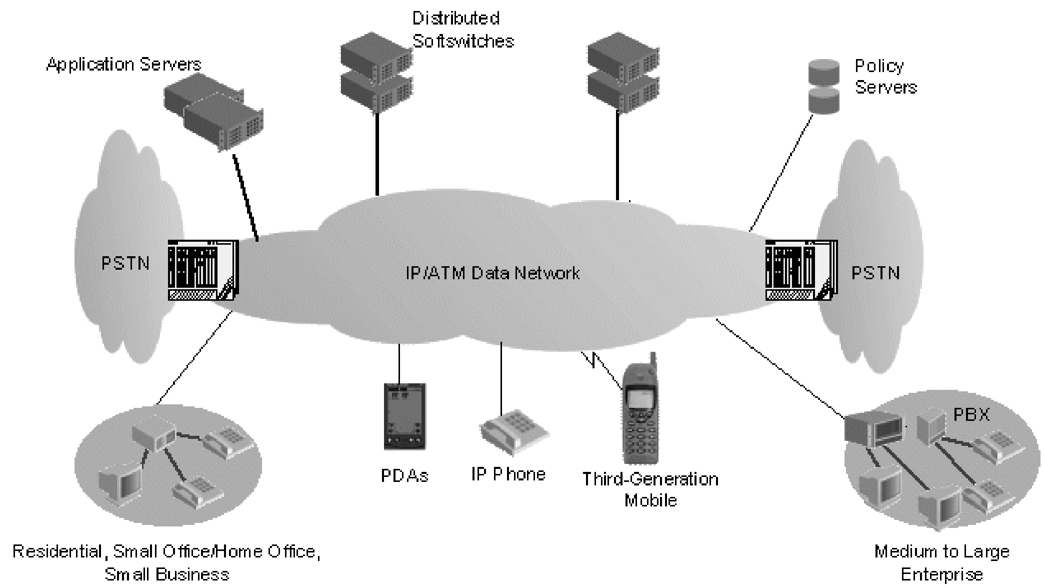
As everyone acknowledges, tomorrow's network will use pure IP or asynchronous transfer mode (ATM) or a mixture thereof. The bottom line is that people will get services off a data network. The intelligence will be distributed to the edges as well as the core (see *Figure 1*). At the corporate edges will be corporate gateways (also known as integrated access devices [IAD]) that will connect the private branch exchanges (PBX) and local-area network (LAN) traffic on one integrated data connection. If the corporation does not have the PBX and/or voice-mail systems, the voice services will be provided by an IP Centrex–type server off the network core while unified messaging may be provided by another server in the IP cloud. The same process is happening in the home with residential gateways or IADs proliferating with broadband cable and digital subscriber line (DSL) connections, wherein the personal computers (PC) are connected to the Ethernet port while black phones are connected to the analog ports on the gateway. Different application servers in the cloud offer different voice, data messaging, and streaming services. Then there are mobile IP phones and personal digital assistant (PDA) users who will also use the services enabled by this next-generation network (NGN).

In this new architecture, softswitches are needed in the network not only to provide the network intelligence to these edge devices so that calls can be sent to the appropriate devices but also to be able to terminate calls back to the existing billions of black phones connected directly to the time division multiplex (TDM) side of the public switched telephone network (PSTN). Softswitch architecture, done right, will enable the creation of true application servers in the telecom network and make the communications application service provider (ASP) model viable. Softswitch hides all the connectivity nuisances, be it with a signaling system 7 (SS7)–based network, or the primary rate interface (PRI) or T1 communicating applications specification (CAS), or simply via an IP/ATM access device and present industry-standard open interfaces to the application server, much like an operating system (OS) in the data world hides the nuisance of PCs, servers, and other peripherals from the applications.

There is a school of thought in the industry that everything will become end-to-end IP and replace the PSTN. The industry is not there yet. It cannot change to tomorrow's

FIGURE 1

Tomorrow's Network: Integrated Packet Network for Voice and Data



network with the flip of a switch because there is a hundred-year history with the PSTN. The PSTN will not be discarded because it is already established and it still works. Therefore, the gateways that bridge calls between PSTN and IP networks will continue to exist. There may not even be any reason to replace the good old black phone for a grandma who has only $2 on her phone bill every month. Instead, service providers target the digitally empowered users who have broadband access, PDAs, and cell phones; who are the early adopters of the new technology; who spend more than $100 per month on communication; and who want customization of the services. However, unless the new network achieves the same reliability as the PSTN, there will never be a complete transition into the new network.

In summary, tomorrow's network will be data based, highly scalable, and open. The new network will not appear in one day but will evolve over time, through transitional steps. Some predict it will take two to five years; others predict 10 to 20 years. As the services and networks are built, it is important to make sure that there will be a way for service providers to make money with them, because only then will new equipment be deployed. No new services will ever be created without a revenue model that satisfies the service providers that must deploy the equipment.

The Emerging Service Models

User-, Network-, and Application-Centric Providers

The current model of service providers in the telecom is born out of the Bell system, in which ILECs own the network, the customer, and the application. On the data communications side, this model did not work, as evidenced by the separation into the following three different kinds of service providers:

- User-centric service providers, such as America Online (AOL)
- ASPs, such as Coreo
- Network service providers (NSP), such as Sprint, Level 3, and others, that sell to such companies as AOL

Telecom service providers, over time, will also split into these segments. There is some evidence of that in the mobile space where Virgin Mobile, a user-centric service provider, is buying the network services from others. ASPs will offer specialized vertical applications that focus on particular niches. The user-centric service providers will buy services from the NSPs and ASPs and create a revenue model around that strategy.

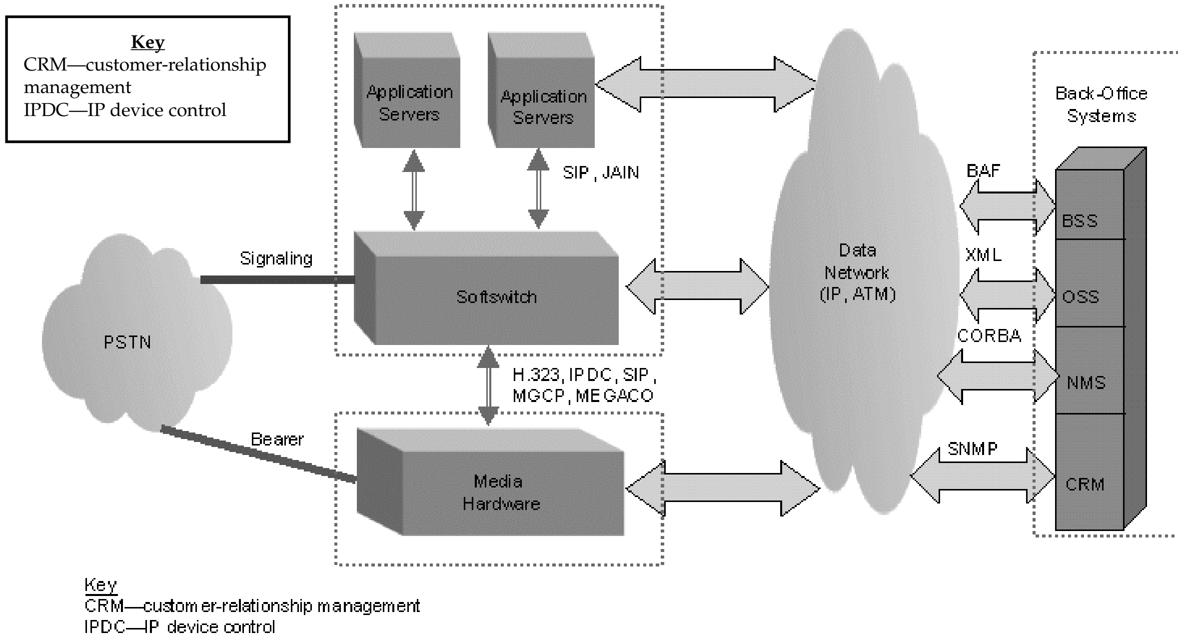
Vertical Services

The world is moving away from the "one size fits all" types of services that are offered by phone companies today. In the data world, users have a lot of control and capability to customize their services, and there are many vertical services—for example, for the manufacturing and services industry or for a doctor's or an attorney's office. In the converged world of voice and data, the users will demand the same level of control and customization, and service providers that offer these vertically integrated services will succeed and achieve faster profitability.

Also, the industry is going to move from a service-provider-control model to an end-user-control model, but it is unclear how much control will be transferred and when. However, service providers that offer levels of customization ahead of their competition will capture this highly profitable but demanding segment of digitally empowered users. In addition, there is a need for vertical services focused on individual professions, such as doctors, attorneys, and salespeople. So service providers that want to increase their profitability

FIGURE 2

Next-Generation Architecture and Interfaces



and achieve differentiation will need the new service-creation model and infrastructure technology that enables new levels of control and customization.

Billing Reforms

Today, a typical consumer deals with four different service providers: one for Internet access, one for local telephony, one for long distance, and yet another one for Internet access. Yes, people want choices, but they would prefer to write one check for all the services that are integrated into one bill. The billing models for wireline telephony will also undergo significant changes. The classical example is the cell phone, where the user pays for a set number of minutes and normally stays within that number, or the new long-distance models with phone service for seven cents per minute. Removing the billing effort that is spent by the existing phone companies and implementing a simplified billing structure would generate significant savings, exactly as a flat income tax would reduce administrative costs. Everybody would benefit, and economies of scale would be achieved. The bottom line is that the way services are billed and sold will undergo major changes in the next few years.

The Next-Generation Architecture and Interfaces

It is clear that the next-generation architecture will be a decomposed model, will be multivendor and multiprotocol, and will have industry-standard interfaces between these best-of-breed systems (see *Figure 2*).

Decomposed Model

The next-generation converged services will depend on a decomposed architecture for achieving flexibility. Exactly as in the data communications world, in which the mainframe was split into a distributed architecture, the "telecom mainframes"—i.e., the circuit switches—are undergoing the same transition to a three-layer model, in which the bottom layer is the hardware, the middle layer is the softswitch, and the top layer is the applications. Much like PCs and peripherals, the various types of devices that form the hardware layer in this new architecture include remote access servers (RAS), media gateways (MG), IADs, IP phones, and media servers.

The middle layer, the softswitch, is much like the OS and it controls the hardware and provides open interfaces to applications. With a scope as wide as this, it is clear that the new infrastructure will be multivendor.

Multiprotocol

The next-generation architecture, much like the current systems, will be multiprotocol. As seen in data communications, old protocols, once they work, continue to hang around the network while the new ones enter into the system. So it is important that the softswitch support multiple protocols to enable new and existing services to coexist. It is also important for the softswitch to be able to shield applications from the nuisances of different hardware and protocols they may be running.

Interfaces

There are many interfaces between these layers that are in different stages of standardization. PSTN interfaces—including SS7, PRI, CAS, and many others—need to be supported by both the hardware and softswitch. The International Softswitch Consortium (ISC), the Internet Engineering Task Force (IETF), and the International Telecommunications Union (ITU) are driving many of the new standards in the industry. Media interface protocol

H.323 still exists in many networks, while session initiation protocol (SIP) and MG control protocol (MGCP) are gaining ground. MG control (MEGACO) is right behind and will start to enter the networks in the next 12 to 18 months. As with any protocol, many of the interfaces are defined, but many of the implementation profiles exist and many new ones are being added to ensure smoother interoperability between different vendors.

The various application interfaces between softswitch and applications include SIP, Java application programming interfaces for integrated networks (JAIN), Parlay, and extensible markup language (XML). The ISC is working to make sure that the SIP interfaces between the application servers and the softswitches are defined. Many of the existing applications that use H.323 can also be interfaced by using H.323 standards.

In addition, the whole system has to be billed for, provisioned, and managed, and there are many interfaces that exist between softswitch and back-office systems that make up the business support system (BSS), operations support system (OSS), and network-management system (NMS) applications. In the billing area, the Bellcore automatic message accounting format (BAF) interface continues to be king, while Internet call detail record (ICDR) and other efforts are under way and will institute billing reforms. In the management area, simple network management protocol (SNMP) is the dominant system, although XML and common object request broker architecture (CORBA) are popular for integration with provisioning systems.

Next-Generation Services

Much talk about the new architecture is based on the premise that the applications will be completely IP based, providing services from anywhere to anywhere. Many communications ASPs have emerged in the market and were forced to build communications infrastructure because the next-generation architecture has not yet been deployed. Once deployed, the Web-hosting model will apply to the communications ASP, which will be able to offer services from anywhere to anyone with new IP communications applications.

Many of the applications that will be deployed first will IP–enable existing applications. For example, voice mail and e-mail combined with unified messaging will be deployed on the next-generation architecture on IP backbones such that users can get services from anywhere. Similarly, Centrex services will become IP enabled and hence will be offered not only by local-exchange carriers (LEC) but also by some service providers that will use a hosting model of Centrex services. The application list includes unified messaging, conferencing, unified call centers, communication portals, presence-based servers, and IP Centrex.

The New Service Model

The core services being built are very similar to what was on their old networks, but the new services are much more flexible and are based on a packet network. People are opening up to many different services and are enabling new service models to exist.

Three popular service-creation models are being discussed in the industry, and they each will play a particular role because their unique strengths and weaknesses fit with the service provider's business models. The three models are as follows:

- Edge-based service creation
- XML–based service creation
- JAIN/Parlay–type service creation

In the edge-based service-creation model, it is assumed that every application server will have its own service-creation model. It will provide a service-execution environment and will call upon the services from the softswitch as needed, using such protocols as SIP. This model is somewhat similar to the data communications model. However, much work is needed to unify these services and to offer a revenue model to the service providers.

In the XML–based service-creation model, the services may be created in an off-line world but will run on the softswitch or on some component of the softswitch. It may be more tightly integrated with the softswitch than the last model but will make it easier to manage and control the services.

In the JAIN/Parlay model, it is the interfacing with the application programming interfaces (API) supplied by these models that will be provided by the softswitch.

Which of these models is the best and will prevail? All these models will coexist, although one model will be better suited for one type of application/service, while another model will be used for a different service. Therefore, it is important that the softswitch be designed correctly to accommodate these different models.

Summary

In summary, packet networks are the future, but the transition to packet networks from TDM networks is an evolution—not a revolution. To make this transition smooth, an open architecture is needed with focus on software and applications with flexible service-creation environments (SCE). The network architecture will be decomposed, with vendors choosing their core strength in providing media hardware, the softswitch, or the application servers.

The applications deployed today in this architecture are the ones that are leveraging or offloading some of the existing switches. However, the growth of this new NGN architecture will occur only when there are broadband systems and new applications that existing circuit switches cannot create. It is a challenge for the whole industry, including the service providers and the vendors, to make the multivendor systems work, because failure would revert the industry to a single-vendor, proprietary system.

Second-Generation, Multi-Mode Wireless LAN Clients

Yoram Solomon

Vice President and General Manager, Advanced Communications Product Group

PCTEL, Inc.

Abstract

In this article, I am addressing the future of wireless local-area network (LAN) connectivity, referring to it as the second-generation (2G) wireless LAN. The four major issues that need to be addressed by wireless LAN product manufacturers are 1) the coexistence of physical-layer standards such as 802.11a, 802.11b, and 802.11g, 2) security, quality of service (QoS), and other "maturing" factors, 3) interference immunity, and 4) the user experience.

For every item, I am describing the current "state of the industry," as well as what will need to take place in order to have mature products ready for mass deployment. This article starts and concludes with a vision of the proliferation and mass-adoption of wireless LAN through the deployment of the 2G wireless LAN products beyond today's "early adopter" market.

Foreword

In the first quarter of 2001, the personal computer (PC) market continued its slowdown, as did the entire economy; however, the revenue from wireless LAN products was reported to grow 15 percent quarter over quarter. Has this market matured?

Today's wireless LAN market is in its "early adopter" stage. Today's products are not as simple to install and not as seamless to operate. The users of wireless LAN products are typically very technical and can overcome the hurdles associated with the installation and use of wireless LAN. However, the benefits of using wireless LAN are tremendous. Personally, I use only wireless LAN at the office, roaming from office to conference room. At home, I get connected to the Internet through my cable modem and wireless residential gateway, using my computer anywhere in the house. When I travel, I use my MobileStar subscription to connect to the Internet at booths located near almost every American Airlines' gate and make the most out of the downtime before my flight. Oh, and by the way, I also use it in the Starbucks near my house while I sip my "*grande coffee Frappuccino*®."

There is no doubt that wireless LAN is going to be adopted. However, there are several trends that must be observed and acted upon in order to deliver the right products for mass adoption. This article covers the four most important trends and issues around wireless networking. Addressing those correctly will promote wireless LAN adoption beyond our wildest dreams (Did anyone ever believe that there would be 400 million cellular telephones sold in one year?), introducing the 2G wireless LAN.

Frequency Bands, Modulations, 802.11g, and the PHY Layer

Wireless LAN products can use several frequency bands allocated by the Federal Communications Commission (FCC) and other regulatory agencies worldwide. The most common frequency bands are the Industrial-Scientific-Medical (ISM) frequencies of 902–928 megahertz (MHz) and 2.4–2.4835 (gigahertz) GHz, and the Unlicensed National Information Infrastructure (U–NII) frequencies of 5.15–5.25 GHz, 5.25–5.35 GHz, and 5.725–5.825 GHz.

Due to the lower bandwidth available in the 900 MHz band (only 26 MHz), the achievable data rates in that band are relatively lower, and with the increased use of cordless telephones in that band, it has never been widely used for high–data rate wireless networking.

The 2.4 GHz band was the first one adopted widely for wireless networking, mainly by the 802.11b standard (also known as Wi-Fi), by the wireless home networking standard (HomeRF), and by the wireless personal-area networking standard (Bluetooth), known as PAN. One of the leading reasons for such a wide proliferation of products and standards in this band is the availability and feasibility of silicon operating components. The resulting cost reductions, mostly through moving to low-cost complementary metal oxide semiconductor (CMOS) processes, increased the penetration and deployment of such products.

The 5.4 GHz band is not yet used for such products, as the availability and feasibility of silicon components in these frequencies are still being evaluated. The Institute of

Electrical and Electronics Engineers (IEEE) created a standard known as 802.11a that uses the 5.4 GHz band for high-speed networking, and several companies are developing components to support this standard and offer data rates higher than Wi-Fi in this band. It is expected that the first products will hit the market toward the end of 2001, followed soon by price reductions, causing this standard to then be widely adopted.

While the 802.11b standard offers a data rate of 11 megabits per second (Mbps) at the 2.4 GHz frequency band, the 802.11a standard offers a data rate of 54 Mbps at the 5.4 GHz band. Much like the migration from 10 Mbps to 100 Mbps (and then to Gigabit Ethernet and beyond) for wired LAN, there is a perceived need for higher data rates in the wireless LAN arena, beyond the 11 Mbps offered through Wi-Fi products. Texas Instruments (by acquiring Alantro) has offered a new modulation scheme called packet binary convolutional coding (PBCC), capable of delivering data rates of up to 22 Mbps still using the 2.4 GHz band. This technology was proposed to the IEEE for a working group called 802.11g. Shortly thereafter, Intersil offered a counter-proposal using orthogonal frequency division multiplexing (OFDM) capable of delivering 36 Mbps in the same frequency band. Initially, both proposals violated the FCC rules (15.247) for the use of that frequency band. However, the new FCC proposed ruling (Docket 99-231, discussed later in this paper) suggests modifying the rules such that neither proposal will be in violation. Meanwhile, in the IEEE 802.11g working group, the TI proposal was voted off, but the OFDM proposal still needs to get the support of 75 percent of the members to become the 802.11g standard.

What will the impact of 802.11g have on the use of 802.11b and 802.11a? The effect on the current 802.11b (Wi-Fi) standard is pretty predictable. Once a higher-data rate standard gets approved, the existing 802.11b will simply become a fallback data rate to the higher–data rate standard. This is similar to the original 802.11 (supporting 1 Mbps and 2 Mbps) that became the fallback data rate to the 802.11b (driving 11 Mbps or 5.5 Mbps). The main question is—What will the impact of a higher–data rate 2.4 GHz standard (802.11g) be on the higher frequency, higher–data rate 802.11a standard? I will assume two scenarios, depending on the first standard to hit the market with products.

Scenario 1: 802.11g Products Available before 802.11a Products

With the OFDM modulation for 802.11g being able to deliver as high as 36 Mbps, the main question is whether 802.11a will still be needed. I believe that there will still be a need for 802.11a for several reasons. One reason is the allocation of additional bandwidth that provides a higher aggregate data rate usable for wireless LAN. If 802.11g is used within a certain physical area, then only 36 Mbps becomes available in this area. If, however, both 802.11g and 802.11a services (or coverage) are offered in an area, then the aggregate data throughput offered at this area increases to 90 Mbps and therefore can support more users. Furthermore, the 2.4 GHz band sees more interference today from non-wireless LAN products, such as Bluetooth devices and cordless telephones. Adding the 5.4 GHz band for wireless LAN applications will help in avoiding some of that interference. The conclusion from this scenario is that the introduction of 802.11g will not delay or prevent the later deployment of the 802.11a-based products.

Scenario 2: 802.11g Products Available after 802.11a Products

As in Scenario 1, the introduction of 802.11a products before 802.11g products will not prevent 802.11g products from being deployed. While the 5.4 GHz band is limited to 54 Mbps, having 802.11g deployed will increase the aggregate data throughput by 36 Mbps to the total of 90 Mbps. Furthermore, with the 802.11a products suffering from a shorter range, there may be somewhat different applications for both standards. In any event, the conclusion remains the same: The deployment of 802.11a products before that of 802.11g products will not delay or prevent the later.

Given these conclusions, it seems that there is opportunity for the 5.4 GHz and 2.4 GHz standards to coexist.

Multi-Mode Access Points

The next question that comes to mind is—What will the migration path be for deploying the high–data rate standards?

One possibility is that all existing (installed) access points will either be upgraded to the high–data rate standard or become multi-mode. Most of the installed access points are not scalable or upgradeable to the new standards or do not support multiple standards. Therefore, the scope of this proposition is that the access points will be replaced in their entirety. This is a very expensive proposition and one that will probably never happen, much like the old analog cellular infrastructure was not replaced once personal communications services (PCS) and code division multiple access (CDMA) were introduced. I believe that we will continue to see multiple 802.11b access points, along with new multi-mode access points.

Another question is whether there will be new access points that support only the higher–data rate standards but not the existing 802.11b standard. With the current rate of 802.11b client product deployment, it has been estimated that by mid-2002 (when we expect to see some 802.11a or 802.11g products available), there will be some 20 million 802.11b-only client adapters installed in computers and other devices. Installing access points that do not support this 802.11b standard means that 20 million users will not be able to access them, and that is unimaginable.

Multi-Mode Client Devices

Now comes the question of whether the new clients are going to support only a high–data rate standard. Assuming that not all of the currently installed (802.11b) access points will be replaced by multistandard or high–data rate standards due to the required investment in infrastructure, there will still be many 802.11b-only access points installed. Therefore, installing wireless network cards in computers that support only the high–data rate standards would disable these computers from accessing the existing 802.11b access points. Wireless Internet service providers (W–ISPs)—such as MobileStar, WayPort, AirWave, and others—have already installed access points in public places such as airports, hotels, and even Starbucks' locations. They probably will not replace the existing 802.11b-based infrastructure, and users wanting to access the Internet or their corporate intranets in these locations will have to have equipment supporting the 802.11b standards. MobileStar, for example, offers its users both 802.11b cards and frequency-hopping (FH) cards to support the older infrastructure for the lower–data rate FH standard. However, the problem with that is much less acute than it might be if they had to provide all of their users with both a high–data rate card (supporting 802.11a and/or 802.11g) and an 802.11b card.

As new computers and other non–PC devices (such as personal digital assistants [PDAs]) become smaller, the amount of space allocated for extension accessories (such as wireless LAN cards) becomes more limited. Installing two cards (one to support 802.11b and one to support 802.11a) will be nearly impossible.

Moreover, wireless LAN is becoming an integral part of new PCs, as PC manufacturers such as Dell, Compaq, Toshiba, IBM, and others are shipping new computers with bundled wireless LAN cards in a mini–peripheral component interconnect (PCI) form factor. While PC–card (PCMCIA) accessories can be replaced during operation, the embedded mini–PCI cards cannot.

Therefore, the best solution for multistandard wireless LAN client support is multistandard wireless LAN cards, supporting more than one standard on the same card. These cards should support 802.11b, 802.11g, and 802.11a due to their coexistence in the marketplace.

Service Discovery, and 802.11b as the Negotiation Standard

With the aforementioned coexisting environment, products will need to implement "intelligent" service-discovery procedures, allowing them to identify the available networks and to select the best one to use.

The assumption is that beginning in 2002, there will be a mix of clients, some of which will have an 802.11b-only access card and some of which will have high-end multistandard cards capable of higher data rates. There must be a common way to communicate with them. I have proposed that this would be accomplished through the use of the 802.11b standard at its basic form. Since all client devices will be able to communicate through 802.11b, it can be used as the initial link between the client and establish the access point. Then, still using the 802.11b standard, the client and/or the access point will attempt to negotiate a higher level of communication, either using a higher–data rate standard (such as 802.11a or 802.11g) or enabling a higher level of security or QoS, or other enhanced features. If both ends (the access point and the client) can support a higher data rate or enhanced functionality, they will negotiate their link up to the highest common ground.

Security, QOS, and the Upgradeable MAC Layer

Security

In February 2001, the Internet, Security, Applications, Authentication and Cryptography (ISAAC) research group at the University of California, Berkeley, published an article attacking the level of security provided by the wired equivalence privacy (WEP) protocol supported by the Wi-Fi standard. Following this publication, the public perception of the security offered by wireless networking was that these networks are not to be trusted. A not-very-well-known fact is that most equipment vendors and W–ISPs recommended that WEP be disabled altogether "to simplify the installation and operation" of such equipment.

The IEEE formed a working group named 802.11i to address the security needs of the wireless LAN user community. Two future developments are certain: Some action will be taken, and it will render the existing wireless LAN cards obsolete. These changes will most likely affect the media access control (MAC) layer, which is implemented within the chipset that constitutes the core of the wireless LAN card. When a new security standard for wireless networking emerges, new chipsets will be developed, installed on new cards, and sold to end users.

Quality of Service

The basic 802.11b standard has one disadvantage when compared to HomeRF and Bluetooth: its inability to guarantee QoS. This disadvantage translates into an inability to deliver non-data services (such as voice and video) in a reliable, high-quality manner. Once again, the IEEE addressed the issue by forming a working group called 802.11e that proposed a QoS standard be implemented in the MAC layer. If approved, the next-generation wireless LAN products will support multimedia applications with a high level of quality. Once again, when QoS is implemented, it will render the existing wireless LAN products obsolete. They will be incapable of supporting the new standards and will force the end users to replace their hardware.

The Upgradeable MAC

The introduction of new standards that address QoS, security, and other issues will automatically make existing products obsolete. End users are typically reluctant to purchase products that might become obsolete and prefer to wait until the next generation is available. The way to reduce that risk is to offer a field-upgradeable MAC layer that is fully programmable in real time. When a new standard is released, the MAC can be upgraded by simply downloading a new driver.

This might appear to be a simple task, but the key to its successful execution is to correctly forecast the future standards that will be released and to incorporate a powerful-enough programmable platform that will be capable of supporting these standards. The trade-off can be in terms of flexibility versus cost and flexibility versus power consumption. A higher level of flexibility can be achieved when functions are implemented in software rather than in hardware; however, this typically involves a higher-cost platform (multiprocessor) and consumes more power due to the high-speed processors deployed. Moore's Law and the overall progress in semiconductor development will compensate for these trade-offs in the long run. The correct trend still needs to be a shift from hardware implementation to software implementation, offering the user the programmability and upgradeability that will reduce the risk of purchasing products before they fully mature.

FCC, IEEE 802.15.2, and Interference

On May 10, 2001, the FCC proposed changing the rules for the unlicensed 2.4 GHz ISM band. The commission proposed "to reduce the amount of spectrum that must be used for frequency hopping spread spectrum systems operating in the 2.4 GHz band (2400–2483.5 MHz), and to eliminate the processing gain requirement for direct sequence spread spectrum systems." This new proposed rule is known as "Docket 99-231." This ruling will allow both techniques proposed to the IEEE 802.11g committee (Texas Instruments' PBCC modulation and Intersil's OFDM modulation) to comply with the new FCC rules. This ruling will also allow FH systems (such as Bluetooth and HomeRF) to avoid frequencies used by a Direct Sequence 802.11b (or 802.11g) system, not having to hop throughout the entire frequency band.

While this ruling would seem to promote the adoption and deployment of wireless networking in this frequency band (through higher data rates and better mutual avoidance of the existing standards), it also allows for greater interference in this frequency band.

We must remember that this unlicensed band is open to use by other types of devices, such as cordless telephones. The FCC previously regulated all of the products using this band so that they had less interference with one another by spreading the signal over a wider band (whether through higher Direct Sequence processing gain or through a higher number of frequency hops in a FH system). With the proposed ruling, a device now operating in this band might generate a more "concentrated" interference with another device. Even before the ruling, devices operating in the 2.4 GHz band included cordless telephones, microwave ovens, and others. Now, with the new ruling, the expected interference from cordless telephones will increase.

The IEEE has addressed the mutual interference between Wi-Fi (802.11b) devices and Bluetooth devices through a newly formed working group named 802.15.2. This working group, however, is proposing to solve only the mutual interference created by Bluetooth and Wi-Fi products and does not address any interference to or from other devices using the same band.

Today, the deployment of products in the 2.4 GHz band is relatively low. However, we are expecting wireless LAN (mainly Wi-Fi), PAN (mainly Bluetooth), and even cordless telephones operating in this band (and thus offering longer range and multiple handsets) to proliferate. Once that happens, the level of man-made interference in this band will increase significantly. Devices incapable of avoiding such interference will suffer degradation of quality through lower throughput (or completely loose connection), range decrease, and noise. On the other hand, devices with intelligent interference-avoidance capabilities will outperform their competitors, offering superior range, throughput, and overall quality.

The User Experience

Microsofts announced that the Windows® XP operating system, launched in October 2001, will support wireless networking in a way that no other previous operating system has done before. This support addresses zero configuration, security, authentication, roaming, and service discovery. At the Wireless Ethernet Compatibility Alliance (WECA, the promoter of the Wi-Fi log and certification) annual member meeting in Helsinki in June 2001, Microsoft even promoted the idea of multi-mode wireless LAN client radios to simplify the user experience.

Where are we today? The installation of an 802.11b product is somewhat complicated. A one-hour installation can easily turn into a six-hour installation. Roaming between access points is not trivial, and extending this roaming to cover residential gateways and public "hot spots" (such as hotels, airports, and even Starbucks' locations) requires some "unnatural acts." Having to change configuration, release the current Internet protocol (IP) address, renew the IP address, and other tasks that need to be performed reduces the pleasure of experiencing a wireless LAN. To compare this experience to that of a cellular telephone, imagine what it would be like if, when you roam between cell sites (every 1–2 miles), you had to change your cell-phone configuration, release its telephone number, renew its telephone number, and do all of that so you could still accept phone calls. Unimaginable?

From this comparison, you can understand that in order for wireless LAN to be as widely adopted as cellular telephones, its operation must be as seamless as that of cellular telephones. While Microsoft® XP might offer a solution, the solution should be supported with existing operating systems that are still bundled with new computers.

Conclusion

In this article, I described 2G wireless LAN clients. The coexistence of the different frequency bands used for wireless LAN will lead to the adoption of multistandard (or multimode) products. The proliferation of protocols and functions (such as QoS and security) in an immature standard will lead to the development of software-programmable products that can be upgraded as the standard matures. The ability to avoid the growing in-band interference will differentiate good products from bad ones and give the manufacturers of the better products a competitive advantage. Last, but not least, the user experience will have to be as close as possible to that of a cellular telephone, with seamless operation that can leverage on the pervasiveness of wireless LAN in our lives.

Telecommunications Marketing Best Practices

David J. Sparks
Executive Vice President and Director of Client Services
Robinson & Maites Inc.

Marketing spending has dramatically increased in the telecommunications industry since deregulation in 1996. Spending has been driven by an increase in the number of competitors, greater geographic scope, a vast array of new services and products, and, of course, by open market competition. As a result of a slowing economy and general uncertainty in the consumer and business markets, we are currently experiencing a demand contraction and a reduction in aggressive spending by most major telecommunication competitors. In an effort to help guide telecommunications marketers in what may be a very difficult time ahead, we have reviewed marketing practices across all major firms over the last two years and identified what we consider to be telecommunications marketing "best practices."

Our firm has supported a range of telecommunications companies since the early 1980s. We have either worked with or competed against most of the major wireline, wireless, and data companies in the areas of strategic planning, new product introductions, and customer acquisition and retention. This article is based on research conducted in North America and on our experience and perspective in this rapidly changing marketplace.

Challenges Facing Telecommunications Marketers

Telecommunications marketers face a number of challenges in effectively and efficiently marketing their products and services. We believe these challenges are common throughout the industry:

- Difficulties with deregulation
- Rapid technological advancement/change
- Increased competition for customers
- Ponderous bureaucracy
- Industry consolidation
- Changing customer needs and expectations

Each of these challenges makes marketing a very complicated subject for all involved. In fact, many believe that telecommunications is the most complex marketing environment in the business world today.

The aforementioned challenges have created a common set of problems facing telecommunications marketers. We have utilized these problem areas to frame and identify best practices.

Best Practices: Marketing Solutions for the Most Common Problems Facing the Telecommunications Industry

1. ***"Learning Builds Earnings"***

   Problem: Because of severely limited customer knowledge, telecom customer marketing initiatives tend to rely on the most inefficient marketing tactics, namely mass advertising. Customer knowledge is limited because of regulatory constraints on information sharing and corporate silo infrastructures, which impede enterprise-wide understanding. Telecom marketers bang away at customer households and businesses as if they were single entities. In fact, increased knowledge would indicate that each has multiple individuals or groups with different needs. Discrete knowledge of individuals and internal corporate groups is needed to understand specific needs.

   Best Practice: **Increase customer knowledge continuously through the use of a closed-loop Learning Marketing Model to improve sales, upsell, and retention.** This is accomplished by making every tactical execution a learning experience. Relevant data is collected and reused to refine and enhance marketing efforts to better focus targeting, product offerings, and incentives. This leads very quickly to more effective and efficient marketing execution.

   Examples: The GTE Communications Corporation utilized this approach in launching their competitive local-exchange carrier (CLEC). They applied a Learning Model to all marketing activities, which better directed segmentation, messaging, product emphasis, incentives, and media mix. The Learning Model shifted their targeting efforts to specifically identified high-value customers. Targeting was based on behavioral data so that communications and marketing activity was triggered by calendar events or "moments of truth." GTE was able to use actual customer feedback to model anticipated behavior and/or lifestyle changes.

The results were vastly improved acquisition rates, lower cost of acquisition, reduced talk time at call centers, and dramatically increased close rates. It also enabled this CLEC to improve upsell and reduce churn.

2. "Minimize Customer Risk to Maximize Sales"

Problem: For telecommunication companies, existing products and services are often the most profitable to market to their embedded base. These products and services are available for immediate use and have broad penetration capability with few real costs other than marketing. The problem is that for customers, these products (e.g., vertical call-management services) may be the least appealing because of apathy, lack of benefit, or poor understanding of how they would be used. Because these products and services are not based on real or perceived customer need, telecom marketers are forced to spend heavily to generate sales. A subsequent problem is a high degree of churn as customers realize that they do not really need or understand how to use the product.

Best Practice: **Utilize special high-profile promotional offers to consistently overcome consumer intimidation/lack of understanding and stimulate trial.** Telecom marketers should use special promotional offers to allow customer to "try" at no risk. This reduces the cost of marketing and allows a greater number of people to try, thus enabling self-selection for those who really need the product or service.

Example: To motivate customers to try or buy additional services, Verizon Network Services built a "preferred pricing" model into their bundled array of product offerings. "Big Deal" customers got Verizon's best prices for buying into a very flexible bundled package. Options allowed customers the flexibility to choose other services at Verizon's best rates. By offering a "preferred" pricing model to customers, it reduced their hesitancy to try new products and services. Verizon had double-digit increases in the sale of add-on services and upgrades as a result of this effort.

3. "Less Is More"

Problem: Traditional telecom sales channels, such as call centers, do not maximize sales opportunities. While call centers handle both sales and service, the majority of the calls are for service. Call centers' ability to effectively sell is limited because of training and the high costs to initiate a selling process with inbound calls. When it does happen, product, pricing, and ordering are complicated affairs with multiple offers, system issues, and state variations. This results in low productivity and a less than satisfying customer experience.

Best Practice: **Simplifying call-center channel complexity makes it easier for agents to sell and easier for customers to buy. Products, services, and promotions should be constructed specifically for channel sales.**

Example: GTE Network Services accomplished this by focusing on a single offering that could be effectively supported at the channel level. They ran a vertical services program that allowed customers to choose any vertical service for a trial period of 30 days for $0.99. This was easy for customers to understand and much easier for call-center personnel to sell. Coordinated marketing and media tactics focused on making it a consumer self-selection. The results were a very efficient increase in vertical service penetration across the entire marketing area.

4. "Get It Together"

Problem: Consumers and businesses do not "shop" call centers regularly for telecom services. They have infrequent contact, primarily for moves, billing issues, and changing services.

Best Practice: **Telecom marketers can greatly increase sales by taking advantage of existing customer behavior, i.e., sell where they are already shopping**. By not trying to change behavior and leveraging existing behavior, telecom marketers can greatly increase exposure and real sales by extending distribution to traditional retail outlets.

Example: To gain top-of-mind awareness with consumers, Sprint formed alliances with retailers that carried products consumers shop for regularly. Radio Shack and mass-merchant electronic stores were utilized to sell Sprint products and services through a "store within a store" merchandising arrangement. Sprint services were offered as a natural compliment to consumer hardware purchases. While this tactic has now been widely emulated, Sprint was able to significantly grow its retail service at the expense of its major competitors. Inspired imitators included Bell Atlantic with Staples and Ameritech with Sears.

5. "Pour Old Wine into New Bottles"

Problem: For telecoms, developing and launching a new product can be a slow process with uncertain results. There are complex system-integration challenges—i.e., ordering, provisioning, billing, etc.—and lengthy regulatory and legal approvals required. In most cases, telecom marketers are selling what they have, not what customers need.

Best Practice: **Bundling/selling existing services in new packages helps telecoms to overcome new product-development challenges and provides a never-ending array of "new ideas."** The trick is how and what to bundle, and how to price it. Customer knowledge and research can provide the answers.

Example: Bell South was an early leader in bundle penetration to both consumers and businesses. They revised their call-center capabilities to emphasize "Complete Choice" bundles versus the traditional à la carte service approach. Another example is Sprint's B2B Long Distance Division. Their "business solution" is a simple package that makes it easy for small businesses to one-stop shop. Both companies have been successful at rebundling existing products to make them a better value, more convenient, and easier to acquire and change.

6. "Develop Firsts That Last"

Problem: Telecom product development is technology-oriented, not customer-focused. As a result, customer acceptance and adoption of new telecom products is slow. Products are created with features in mind instead of benefits. The "build it and they will buy it" mentality must change to improve effectiveness and efficiency.

Best Practice: **In the long term, successful new products and services must be based on addressing and anticipating real customer need, not just leveraging technology.** Again, this requires increased levels of customer knowledge and extensive research.

Example: AT&T developed "Family Packages" that addressed the different needs of multiple consumers in a single household. This increased penetration and revenue per month. Ameritech's "Call Privacy" service was a direct response to a high visibility, controversial concern with aggressive telemarketing to households. Sprint PCS anticipated the issue with wireless signal clarity when they created the "Digital Difference" through their state of the art digital system.

7. "Customer Relationships, Custom Made"

Problem: Telecommunications companies are not known for communicating and building relationships with their customers. High churn rates are based on the lack of, or inability to leverage, individualized customer knowledge. This makes customers feel like numbers, not individuals. Bureaucracy and fragmented company infrastructures contribute to this problem. Telecoms are also poor at post-sell communications. They have minimal dialogue with customers and offer almost no personalization in verbal and indirect communication with customers.

Best Practice: **Successful customer relationships are based on genuine content, true dialogue, and relevance to individual customer needs, not just on "customer appreciation" messaging.**

Example: Ameritech Small Business Services wanted to leverage relationships for upsell and retention purposes. They learned that their small-business customers were very interested and also concerned with technology. Ameritech leveraged this need by creating a magazine/catalog called *Small Business Solutions* to provide added value and information to their existing customers. They added value by customizing the magazine/editorial portion to small-business priorities such as how to get more out of technology and hardware, how to save money on technology and telecommunication needs, and how to finance these needs with flexible payment options through their telecommunications provider. This program generated increased levels of loyalty and added a new profit center vis à vis hardware/software financing.

The Benefits of Best Practices: Ongoing Improvement

While these best practices seem rather obvious, they are not widely practiced in the telecommunications industry. As we have shown, certain companies do certain things well. The key to improving marketing effectiveness and efficiency is utilizing these best practices in everyday marketing activity. Like any improvement endeavor, you can't be good at everything. We recommend that telecommunications marketers pick the ones that are right for their business situation and begin the process by scrutinizing all activities against them.

Getting Better Business Returns from Your MPLS Deployments

Adding Intelligence at the Customer Premises and Service-Provider Edge Is the Key to Making MPLS Efficient and Profitable

Manickam Sridhar

Chief Technology Officer

Sitara Networks

Good Technology, Bad Hype

One article says that multiprotocol label switching (MPLS) technology gives service providers increased control over their networks (*NetworkWorld Fusion*, 7/30/01). The next week, an article in the same publication says that experts are "raising red flags" about the technology (*NetworkWorld Fusion*, 8/6/01).

When any new technology with great promise comes along it is usually accompanied by so much hype that it becomes difficult for service providers to sort out truth from fiction. In truth, MPLS is an invaluable tool in the era of Internet protocol (IP) network convergence, but not if vendors oversell what the technology was designed to do.

To determine whether or not MPLS can contribute to the profitability and efficiency of existing network operations, there are two things to consider. First, what is the service provider's most pressing business requirement? Second, what was MPLS designed and optimized to do?

The answer to the first question is simple: increase revenue! Service providers are under tremendous pressure to move beyond commoditized Internet connectivity. On the surface, this should not be much of a challenge because business customers are clamoring for value-added services. This includes everything from managed services to IP–based virtual private networks (VPNs). The VPN market alone is projected to reach more than $35 billion by 2004 (Source: Infonetics).

MPLS, while it is an excellent technology for improving speed and efficiency in IP networks, is not—*by itself*—an enabling technology for offering value-added services. Here's what MPLS was designed and optimized to do:

MPLS is an Internet Engineering Task Force (IETF) standard designed to speed up IP traffic flow through a routed network. It is essentially a tunneling protocol that emulates an asynchronous transfer mode (ATM) permanent virtual circuit (PVC). Without MPLS, each router in the network has to look at the header of each packet and make routing decisions on a hop-by-hop basis for forwarding the packet. MPLS speeds up this process as follows: As packets enter the network, they are assigned labels that associate each packet to a forwarding equivalence class (FEC), as shown in *Figure 1*. All packets that belong to a particular FEC are mapped to the appropriate label-switched path (LSP) and typically follow the same path.

All subsequent routers use the label as an index to a table that specifies the next hop. The router may replace the old label with a new label identifying the next hop, and the packet is forwarded along. Because there is no further analysis of the packet's header after the initial labeling, the forwarding is much faster and more efficient. Routers equipped with MPLS create local switched paths by simply "swapping" labels throughout the network.

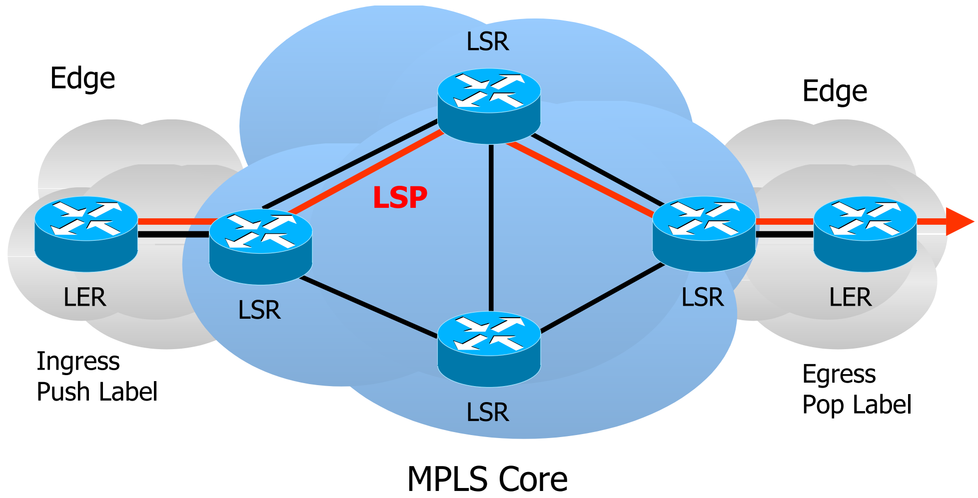
There are several options for marking packets, but the best tool (and the one most complementary to MPLS) is another IETF standard called differentiated services (DiffServ). The network equipment responsible for traffic classification and grooming would use DiffServ code points (DSCPs) to mark the packets so that the MPLS–equipped routers can look at the DSCP in the IP header and map the packet to the correct FEC.

In addition to speed, MPLS provides some of the traffic-engineering capabilities associated with the ATM world. For example, FECs can be established prior to data transmission or can be set up at flow time, which allows service providers to determine routes based on traffic flows rather than the shortest route possible (the way that IP routing protocols normally work).

MPLS labeling is also valuable because it creates a more consistent and uniform way of identifying packets across the

FIGURE 1

With MPLS, an IP Core Emulates an ATM Core—Efficient, Fast, and Manageable



network. Lastly, MPLS makes it easier to deploy larger-scale networks because the label-distribution algorithms learn new paths dynamically.

In fact, the real shortcoming of MPLS, given the service provider's business requirements, is that MPLS alone cannot create premium packages based on a customer's individual traffic requirements.

The Bottom Line Is Granularity

MPLS is designed and optimized to deal with aggregated traffic, rather than individual traffic flows. To maintain the forwarding speed it achieves, MPLS aggregates traffic into broad service categories, or Olympic services, such as Gold, Silver, and Bronze. Traffic can be assigned to one of these service classes and receive the priority associated with each class. However, there is no differentiation possible for individual users or flows once traffic has been aggregated into one of these broad categories.

This means that service providers lack the ability to do the following:

- Differentiate customers within an aggregate class
- Prioritize between a customer's high- and low-priority applications
- Guarantee bandwidth and quality of service (QoS) end to end for individual users and/or applications

Because service providers cannot get this level of granularity with MPLS alone, they cannot reliably offer premium services such as voice over IP (VoIP) and videoconferencing. They cannot guarantee that a customer's mission-critical applications, such as enterprise resource planning (ERP), will take precedence over e-mail or streaming audio. And they cannot guarantee that a burst of traffic from a customer's own users—or another customer sharing the same pipe—will not affect mission-critical traffic.

Granularity Has No Business in the Core

Can the routers at the core cope with the extra burden of more granular classification and provisioning? *Figure 2* illustrates how quickly granular classification and provisioning can cause a nightmarish processing burden at the core of the network as routers try to process millions of flows resulting in *billions* of operations associated with classifying individual flows. This much processing overhead would certainly decrease the throughput of a core router.

The First Touch

To create premium services in an MPLS routed network, traffic needs to be classified and groomed *before* it reaches the core. This "first touch" classification and grooming does the following:

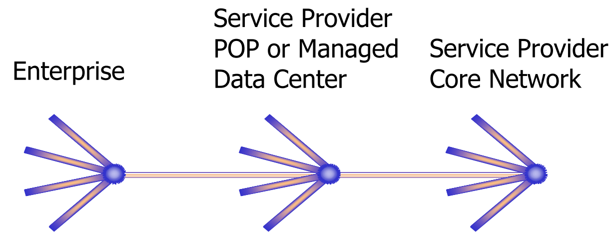
- Enables the core routers to maintain top forwarding speeds
- Provides the deep, granular classification that is needed to deliver value-added service packages based on each individual customer's needs
- Provides end-to-end QoS, which is necessary to offer customers bandwidth and service guarantees

This "first touch" is provided by specialized QoS appliance devices: QoSWorks at the customer premise and QoSArray and QoSDirector at the service provider's data center, as shown in *Figure 3*. This end-to-end QoS solution provides the following:

- Deep packet classification
- Grooming and managing all types of traffic so that service-level agreements (SLAs) can be constructed and traffic volume entering the core is predictable
- Accurate traffic statistics and usage for billing
- Packet marking with DSCP for mapping the traffic into the correct FEC

FIGURE 2

The Job of Doing Fine Grain Traffic Classification and Management Becomes More Computationally Intensive As Millions of Traffic Flows Aggregate at the Core of the Network. The Solution Is to Move This Task of Granular Classification and Management to the Edge of the Network, Where the Traffic Originates.



Location

Location			
Aggregation Point	1	2	3
Speed	64K – 100Mbps	10M – OC–3	OC–12 – OC–192
Number of Flows	100,000	10,000,000	1,000,000,000

- Policy management to distribute and track thousands of policies

Deep Packet Classification

By using a combination of the identifiers, shown in *Table 1*, at the edge of the network, QoSArray and QoSWorks provides the deep classification that can bog down edge routers and decrease their performance. QoSArray and QoSWorks automatically classify all IP and non–IP traffic in real time at wire speeds at Layers 2–7. The QoS devices can classify based on default and user-defined parameters and even distinguish between applications using the same protocol.

Traffic Management/Grooming

Core routers equipped with MPLS incorporate basic traffic-management capabilities; specifically, they offer a limited subset of queuing techniques (e.g., weighted fair queuing [WFQ] with weighted random early discard [WRED]). QoSWorks and QoSArray groom all transmission control protocol (TCP) and user datagram protocol (UDP) traffic using a far more sophisticated and complete set of traffic-management mechanisms than routers provide, as shown *Table 2*.

Each QoSWorks at the customer's network is responsible for traffic classification and marking of the DSCPs. In *Figure 4*, all videoconferencing traffic will be marked as higher priority over all other traffic. Videoconferencing packets are assigned to the appropriate MPLS path to deliver true end-to-end QoS.

Service providers are charging an additional 25 percent to 50 percent fee for their premium packages compared with the best-effort offering. A typical service provider could recoup its investment in less than 12 months while enjoying additional benefits:

- Improve customer satisfaction
- Control monthly operating costs
- More accurate billing

FIGURE 3

By Deploying Specialized QoS Devices at the Edge of the Network, Service Providers Can Deliver Precise End-to-End Service Guarantees for Each Customer and Each Customer's Applications, down to the Individual Flow.

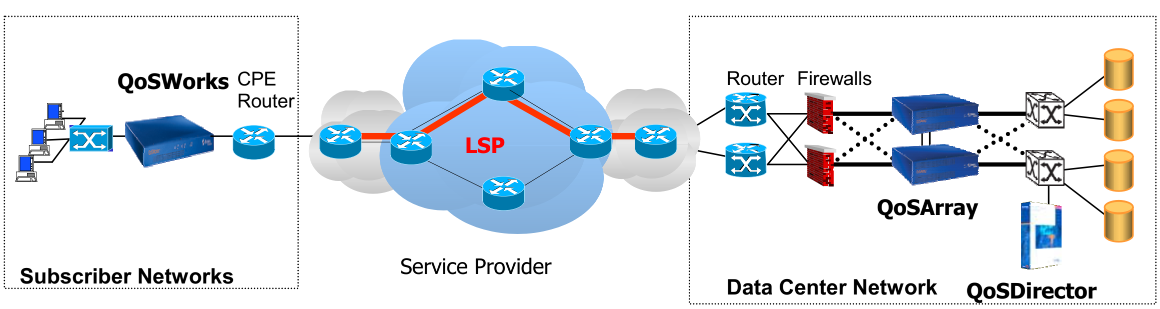


TABLE 1

MPLS Edge Routers Perform Gross Classification by the Following:	QoSWorks and QoSArray Perform Granular Classification by the Following:
Source IP address	Source IP address
Destination IP address	Destination IP address
DSCPs	Source port
	Destination port
	Transport protocol number
	Ethernet protocol type
	Layer-7 state information
	DSCPs

TABLE 2

QoS Mechanism	What It Does	Types of Traffic
Class-based queuing	Provides fine granularity of bandwidth sharing and traffic-priority control, including session level. Enables service-level guarantees for individual flows and aggregate traffic	Works equally well across all TCP and non—TCP protocols. Includes UDP, VoIP, IP, IPX, Appletalk, and SNA
TCP rate shaping	Improves wide-area network (WAN) link efficiency by reducing retransmissions. Provides end-to-end flow control, minimizes queuing delay; and controls bursts	TCP
Fair allocation of bandwidth by connection	Guarantees that all sessions in a policy have equal bandwidth. Important for networks incorporating large numbers of users of session-based applications, e.g., TN3270, CITRIX, etc.	TCP
Packet-size optimization	Reduces packet sizes at the traffic source to any specified size from a maximum of 1,500 bytes to a minimum of 64 bytes. Critical for mixing videoconferencing or VoIP with traffic characterized by larger packets. Minimizes the time packets wait in queues for transmission	TCP
Control bandwidth bursting	Allows traffic classes to borrow idle bandwidth from other specific classes, thus maximizing bandwidth utilization while guaranteeing that applications only use authorized resources	Works for all traffic classes
VoIP controls	Able to identify voice packets from other UDP streams, therefore providing higher voice quality by applying voice-specific QoS capabilities. Includes queue depth and call admission control (minimizes network jitter and packet delays), and prioritization (minimizes packet loss)	VoIP

TABLE 3

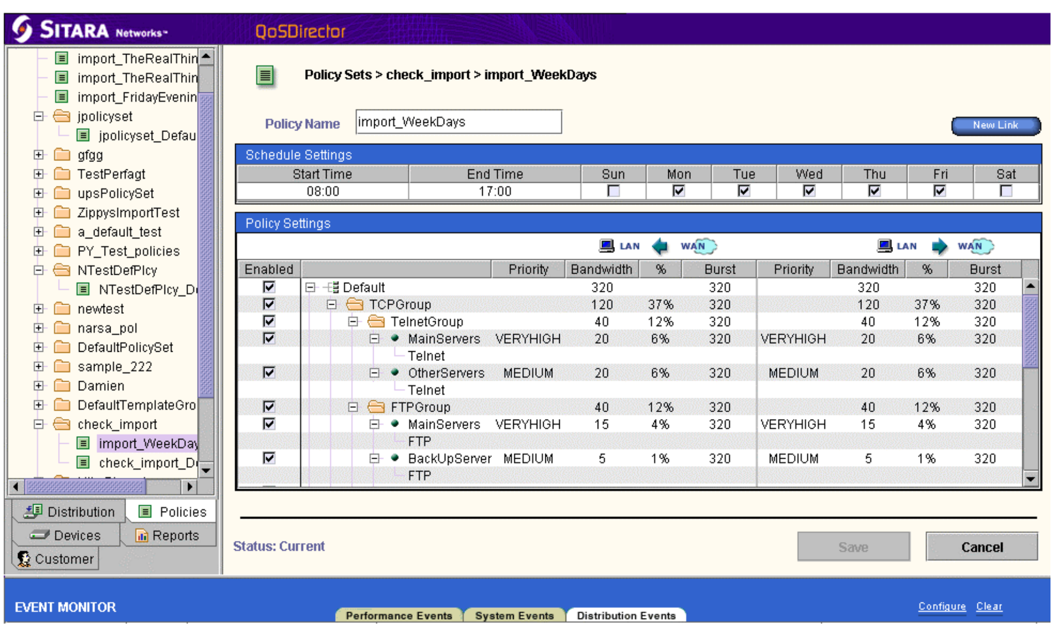
	Package 1 Protect CITRIX	Package 2 Deploy VoIP	Package 3 Best Effort
Committed Bandwidth	1 Mbps	750 kbps	384 kbps
Burst Bandwidth	5 Mbps	5 Mbps	None
Customer Priority	High	Medium	Low
Application 1	CITRIX = High Bandwidth = 512 kbps	VoIP = High Bandwidth = 384 kbps	WEB = High
Application 2	WEB = Medium	WEB = Medium	FTP= Medium
Application 3	FTP = Low	FTP = Low	E-MAIL = Medium

A wide range of SLAs can be created to fit a customer s unique requirements. For example, package 1 delivers 1 Mbps of committed bandwidth with the ability to burst to 5 Mbps. CITRIX has a guaranteed bandwidth of 512 kbps and high priority. With Package 3, the customer gets 384 kKbps of bandwidth with no bursting. They are a low-priority customer but can assign a high priority to Web traffic over their other applications.

Policy-Making and Reporting with QoSDirector

Setting policies and reporting on SLA conformance are essential tools for the service provider. Using QoSDirector at the service provider's data center makes it easy and efficient for service providers to create, distribute, and manage even the most complex policies (e.g., by application, time of day, etc.) for hundreds or thousands of customers and tens of thousands of flows. QoSDirector uses hierarchical policy setting, which makes it possible to apply controls at multiple levels of granularity. For example, service providers can structure polices by links, users, applications, or in any combination. Once the policies are applied, they can be monitored and fine-tuned based on real-time performance analysis from QoSDirector. The statistics collected can then be used for checking conformance to SLAs and generating accurate bills.

FIGURE 4



QoSDirector is a standards-based system that interoperates with other network-management systems and the service provider's existing operational support and billing systems.

Making MPLS Pay

When all the hype is over, everyone will get down to the serious business of evaluating MPLS and declaring it a success or failure. If service providers expect it to deliver revenue-generating services by itself, they will be disappointed, but if MPLS does what it does best—making an IP core as efficient and manageable as an ATM core—and service providers add QoS to the edge for classification and traffic management, then tomorrow's headlines will read: "MPLS and QoS Together Provide a Successful Formula for Service Providers to Increase Their Top-Line Revenue."

Appendix: Anatomy of an MPLS Network

A packet arrives at the ingress point of presence (POP) with a destination address marked 192.12.10.6. This packet would typically arrive at the Aggregator at the ingress POP through an access network, and the Aggregator then would forward this packet to the ingress label edge router (LER). The LER looks at a combination destination IP address, the incoming port, and IP packet markings, and then assigns a label to that packet.

This label assignment is based on the negotiations that happened previously between the ingress LER and the core label-switched routers (LSRs). These negotiations can be carried out using one of several techniques, including using the label distribution protocol (LDP), border gateway protocol (BGP) extensions, or resource reservation protocol (RSVP). The end result is a unique label that identifies each packet to a FEC.

For example, Label 5 identifies the unique port that connects this router with the core router. Label 5 is appended to this packet and sent to the core router. The core router ignores the packet's network layer header and simply forwards the packet using the label-swapping algorithm.

When a labeled packet arrives at the core router, the router uses the input port number and the incoming label to perform a match to an outgoing label that is stored in its forwarding table. When a match is found, it retrieves the outgoing label—e.g., Label 7—and replaces Label 5 with Label 7 and sends the packet to the appropriate outgoing interface that connects this router to the next hop in the LSP, which in this case is the egress router.

When the labeled packet arrives at the egress router, the forwarding component searches its forwarding table. If the next hop is not a LSR, the egress router pops the label and forwards the packet using conventional IP routing.

The Transformational Power of Future Wireless Technology

Carol Stephenson
President and Chief Executive Officer
Lucent Technologies Canada

Introduction

This paper provides my perspective on what the future holds in store. First, it will describe some of the major distinguishing characteristics of mobile communications and networking technology in the future. Second, it will take a look at the benefits and opportunities that this new technological frontier presents. And third, it will examine some of the potential dangers.

My message is this: we haven't seen anything yet. With the advent of broadband mobile communications, technology is becoming more personal, more portable, and more pervasive. It is now potentially within the reach—both physically and economically—of more people than ever before. This is where the real promise and the real power of future technologies lie. And it is up to us to realize that promise and leverage its power.

Personal, Portable, and Pervasive

What is meant by the phrase "personalization of technologies?" Personal communications is a term that has been around for a long time, especially in the mobile communications industry. However, we're not talking about PCS or simply putting a digital cell phone in every person's pocket. We're talking about developing wireless communications services that fit individuals like well-tailored clothes.

Increasingly, customers are asking for services that know them, that know what they want, and that know what device they are using. Customers want to be alerted if a danger exists or a new opportunity arises. They want the network to find them or to tell them where they are. Today's new services, such as location-based services, are beginning to meet these needs. But they pale in comparison to what's coming up in the future.

Some of the experts at Lucent's Bell Labs, for example, believe that each of us will soon have our own "cyber clones." These virtual agents will constantly anticipate our information needs, wants, and preferences. They will screen our messages and surf the Web, filtering out irrelevant data and presenting us with the information that we want in the format with which we are most comfortable.

We will also soon be able to customize the way in which we interface with the network in a highly personalized manner at any given time. Software advances—such as "servlets" or executable applications that will run on network servers—will allow us to tailor our interface to the network.

For instance, let's say you're in the car. You can then use your car's technology to interface with the network, or you can use your mobile phone or your personal digital assistant (PDA). At home, you could use your laptop, your gaming device, or your television. The choice would be entirely up to you, because the network would recognize you—no matter where you are or what device you are using.

Generally, network communication will also be more personal because it will be almost like talking with another person. You'll be able to ask the network questions and give it verbal commands. You could surf the Net with spoken words instead of clicking fingers. Voice portals are just beginning to proliferate, but many experts believe that voice will probably be the dominant form of on-line communications in the future. Voice recognition is already available. Voice commands can be used with cell phones to place calls.

In addition to the advent of highly personal communications, advances in microelectronics are shrinking technology—making communications devices, even networks and especially wireless networks, more portable. This technology, known as micro-electromechanical systems (MEMSs) or as systems on a chip (SoC) will likely revolutionize how we use technology. Already, scientists have developed microphones no thicker than a single strand of human hair, engines so small that thousands could fit on a Frisbee, and medical probes that can be threaded through veins.

The MEMS exchange—an umbrella group of MEMS manufacturers—projects that these micro machines will soon generate annual sales of nearly $100 billion in new industrial and medical products. With MEMS technology, scientists believe that we could build satellites the size of baseballs, yet with all the power of giant satellites. And these satellites could be launched with high-powered guns, instead of rockets or the space shuttle—saving hundreds of millions of dollars.

Back on the ground, experts at Bell Labs predict that wireless towers will eventually be so small that they will become part of the optical fiber that will be laid everywhere, bringing truly uninterrupted high-speed network coverage. MEMS will also dramatically shrink the size of communications devices. For example, Professor Clark Nguyen of the University of Michigan believes that MEMS could replace many of the traditional components in cell phones. As a result, mobile phones would become the size of wristwatches, require little in the way of battery power, and would possibly be cheaper. Combine these "Dick Tracy" tools with the new high-resolution monitors that you can clip on to your eyeglasses.

Jef Raskin, author and father of the original Macintosh computer project, tried one of these monitors recently and raved about it. It didn't look like the quarter inch display that it actually was, but rather appeared to be a full-size monitor. And he could sit back, lie down, and move from place to place without missing a Web site. How's that for portable?

MEMS technology promises to make our pockets and purses lighter in other ways as well. In just two years, for instance, watch out for cell phones with built-in bar-code scanners that will allow you to just swipe and buy.

In addition to becoming more personal and more portable, communications technology is also becoming infinitely more pervasive. It is being integrated into machines of all kinds. Bluetooth technology, Wi-Fi networks, and advanced sensors that interconnect machines are just some of the technologies enabling an increasing amount of machine-to-machine and object-to-object communications.

By 2010, Arun Netravali, president of Bell Labs and Lucent Tachnologies' chief technology officer, predicts that this "info-chatter" will surpass the communications volume generated by human beings. And he's not alone. Other experts speculate that by 2004 to 2005, as much as 60 percent of Internet communications will be devoid of human access.

Bell Labs experts at Lucent further predict that by 2025, the entire world will be encased in a communications skin. This skin, fed by a constant stream of information, will grow larger and more useful. This skin will consist of millions of electronic devices—from thermostats and pressure gauges to cameras and microphones—a myriad of SoCs. All of these will transmit data directly into the network, just as our skin transmits a constant stream of sensory data to our brains.

Such systems might be used for anything—constantly monitoring the traffic on a local road, the water level in a river to warn of floods, or even a person's vital signs. For example, a machine in a hospital or at a doctor's office could continually monitor a patient with a heart condition. When something is amiss, that device would automatically alert the doctor. A "pharmacy on a chip" is another possibility. Embedded under a patient's skin, this chip would allow medical personnel to automatically release medication into a patient's bloodstream—even if the patient is at home and not at the hospital.

The Good Things to Come

Personal, portable, and pervasive: these are the characteristics of wireless broadband Internet communications in the future. And at Lucent, it is believed that this new communications capability will rock our world, change our lives, and enable us to do and experience things that we never thought possible.

As Kenan Sahin of Bell Labs explains, "The Internet will evolve from being a complexity that we must spend time mastering to a behind-the-scenes tool that will improve the quality of our lives."

In a recent edition of Forbes ASAP magazine, editor Patrick Dillon is equally enthusiastic from a purely economic point of view. Speculating on the convergence of technologies now taking place, he writes that "looking over the horizon to 2004–2005, we think there really will be a new economy, and this time, we're going to get it right."

According to Forbes, all the signs of a massive turnaround are in place, including the bottoming out of the current high-tech business cycle and the return of money, new technology, and entrepreneurial fervour to markets. In short, the technological revolution will be rebooted. And if history holds true, Forbes predicts that the new mobile and broadband Internet could become a $20 trillion industry by 2020.

It would be nice to believe that some of this prosperity would be shared with the less developed countries of the world—for two very good reasons. First, the new satellite systems and small wireless tower technologies will enable us to build networks that are more cost-effective than any other previous networks. Furthermore, these networks will be easier to build—especially in the remote, geographically unfriendly places that land-based networks cannot reach. Second, the new mobile devices being developed today will not only be less expensive than current devices, they will be easier to use. The Internet will become a visually rich as opposed to text-laden medium. It will become intuitive and voice-based. As a result, mobile high-speed communications could bring the wonders of the Internet to a whole new group of people. It could significantly bridge the digital divide. It could give everyone a voice—a voice of unquestionable value.

Consider what happened in the Philippines last January. Hundreds of thousands of protesters massed in central Manila to oust Philippine president Joseph Estrada. Yet, they were not lured out of their homes and offices by megaphones or gunfire. Rather, they were enticed by millions of instant messages broadcast to their cell phones. Indeed, an estimated 100 million text messages clog the wireless networks in the Philippines every day—making the people of this island country the world's most avid fans of instant messaging.

Closer to home, consider the horrific events that occurred in New York, Washington, and Pennsylvania on September 11. Mobile communications and the Internet were crucial to all kinds of outreach and coping activities—from the cell phone dispatches of survivors to loved ones to the millions of dollars in relief assistance raised through on-line fundraising drives. Some people in or near lower Manhattan were surprised when they turned on their cell phones and were almost instantly contacted by their wireless carrier. The companies were monitoring cellular signals near the collapsed World Trade Center towers to try to find survivors who might have been trapped or unaccounted for. The ability to communicate in the face of such disastrous circumstances was invaluable to countless families, friends, and business colleagues. Their stories now linger in our collective experience. They have forever changed the value that we place on our communications tools.

The Dangers That Lie Ahead

However, the tremendous value of communications technology does not come without a cost. For example, by virtue of their very functionality, broadband mobile technologies will be far more effective in collecting personal information than any other previous technology. How will we strike the right balance between providing personalized service and not intruding on someone's personal business? How will companies protect the privacy of their customers? How will governments safeguard information about their citizens, especially in the face of increasingly porous borders? The new technology will also have the ability to find us wherever we are—perhaps even when we don't want to be found. The distinctions between work and home will further blur. For most of us, this will not be good. We will need to adopt a habit of finding the "off button" and using it.

Indeed, some observers argue that this could prove disastrous. In her new book called *White Collar Sweatshop*, Jill Andresky argues that portable computers, cell phones, pagers, and PDAs have served primarily to extend the workday, rather than radically reshape the nature of work. She further believes that people are working 10-plus hours a day, not because they want to, but because they have no choice. Many companies expect that kind of commitment. And despite that extra work and the fact that more and more families have become dual wage earners, many people are not gaining ground.

According to the Ottawa-based Vanier Institute of the Family, for example, the average Canadian family has not seen an improvement in their living standard for about 15 years. How can we ensure that broadband mobile Internet communications makes people's lives better? How do we make sure that it enriches work—that it makes work more rewarding and more creative—not just more productive? These are the hard questions that we must find answers to. If we do not, the broadband mobile Internet will never achieve its true promise.

Conclusion

To sum up, we are about to enter a new technological age—an age of personal, portable, and pervasive technology—the age of broadband, mobile Internet communications. This age will radically transform our lives. It will bring us services customized to our individual needs. It will make technology easy to use anytime, anywhere. It will allow technology to anticipate our every need and to truly make our lives easier.

This next wave of technology could kick-start the economy. It promises to bring everything the new economy was supposed to bring in the first place: new industries, profitable business models, and enduring innovation. Potentially, it could give everyone on this planet his or her own voice for the first time.

But, there are dangers inherent in this new age. The new technological order could jeopardize our privacy, erode our individual senses of identity, and create unforeseen personal and social pressures for people—both on and off the job. Like all great technological innovations of the past, the era of broadband Internet communications will create tremendous opportunities and equally daunting challenges. And, in the end, its success or its failure will come down to the decisions that we make today.

The biggest and most difficult of these decisions may concern the type of legacy that we would like to leave behind. Throughout history, the great business people have always done more with their good fortune than simply build a business and make a profit. During the mid-1500s, for example, Cosimo de' Medici of Florence, Italy, built and nurtured the greatest banking dynasty that the world has ever seen. Yet at the same time, he cultivated an enduring legacy of patronage to the arts—a legacy that ignited the Renaissance.

Andrew Carnegie made his great fortune in steel, railroads, and steamships and, in 1901, pocketed $240 million when J.P. Morgan bought him out. But Carnegie then set out to distribute his wealth, most notably by providing public libraries throughout the United States and Great Britain.

Henry Ford's dream was to make an automobile that everyone could afford and in the process of achieving his vision, he became history's first billionaire. He also paid his workers more than any other American manufacturer. He introduced the eight-hour workday and instituted a profit-sharing plan that would distribute up to $30 million annually among his employees.

How will we, as business leaders, make sure that the world we create through broadband, mobile communications will be a better one? How will we work to ensure that this new technology not only improves our bottom lines, but also brings the wonder of Internet communications to people who might never have the opportunity without our help? How will we make sure that the broadband, mobile Internet improves the quality of life for our employees and their families?

These are some of the difficult questions that we should ponder. These questions are difficult, but we must ask them. Our answers to these questions today will be our legacies tomorrow.

Standardization in Fixed Broadband Wireless Access

Paul Struhsaker
Chief Technology Officer
Raze Technologies Inc.

Since 1995, consumers' demand for high-speed Internet access and data-intensive broadband communications has grown exponentially, both at home and in the work place. Clearly, we are still in the early stages of deployment of broadband access. There are more than 100 million households in the United States, and, by the end of 2001, the rollout of both cable modems and digital subscriber line (DSL) will have provided access to less than 10% of the market. The Federal Communications Commission (FCC) in a 134-page study predicts that by 2004 nearly half of all Internet connections in the United States will be high-speed broadband.

Until last year, it had been expected that cable modems and DSL could provide service to as much as 90% of these households. That projection is being significantly reduced due to impairments and limitations in both the cable and voice physical line plant and due to accompanied deployment issues that have surfaced in the last year. We increasingly hear about a growing "digital divide" that exists between larger metropolitan areas that are seeing deployment and infrastructure upgrades and smaller cites, towns, and rural areas. The digital divide is significant and affects from 35% to 50% of the available market.

Fixed wireless broadband access and rural service using satellite broadband services are increasingly seen as the solution to address these markets. With the continued spectrum reallocation efforts by the FCC, nearly 300 megahertz (MHz) of licensed spectrum and 100 MHz of unlicensed spectrum will be available by 2002 to 2003. Cost-effective broadband wireless has the ability to be a viable solution to address this underserved market.

The key issue for the fledgling fixed wireless industry is the development of interoperable standards so that fixed wireless can achieve the economies of scale that DSL and cable modems have achieved through the respective standardization efforts of their industries.

It is beyond the scope of this paper to address all standards efforts in broadband access. The remainder of this article will examine both the benefits of standards and the efforts under way to achieve interoperable fixed wireless standards and concerns that stem from these issues.

Standards allow equipment from multiple vendors to interwork seamlessly. They also promote competition and, in general, reduce the operating costs for all. Once a standard is established, everyone in the supply chain can streamline production and reduce expenses. The chip/component manufacturers can reduce costs by mass-producing their products. Equipment manufacturers can reduce expenses and product prices by purchasing from multiple sources, knowing that each component is built to a standard. Similarly, carriers reduce their costs by integrating equipment from competitive, standards-based products that have predictable interfaces and functionality. This chain of cost-efficiency results in reduced prices, higher-quality products, and significantly increased competition and choice for the consumer.

Some classic examples of this can be seen in the wireless industry. When cellular wireless was first introduced, there were a few proprietary technologies. The early deployments of these technologies resulted in disparate networks, inefficient equipment, and high consumer prices. As the industry developed common standards (e.g., code division multiple access [CDMA] and the Global System for Mobile Communications [GSM]), the prices dropped and the use of cellular phones increased to the point where today cellular phones are almost ubiquitous. Another example is wireless local-area networks (WLANs). In 1993, WLAN was a limited market due to the high cost of non-standard, proprietary equipment with products costing well over $500 and providing less than 128 kilobits per second (Kbps) data throughput. In collaboration with the equipment suppliers and silicon vendors, the Institute of Electronic and Electrical Engineers (IEEE) established the 802.11 standard for WLAN technology. Today, standardized WLAN products have been reduced to ~$75 and deliver ~11 Mbps data throughput. Enhancements to 802.11 will result in ~50 Mbps products reaching the market in 2002.

The penetration for broadband access to the residential and small office/home office (SOHO) is highly price sensitive. There are more than 70 million Internet users in the United States. Of these 70 million users, more than 52 million are dial-up users whose access charges are on average $25 per month. Several studies of the cost sensitivity of consumer interest in broadband Internet service directly relate penetration to pricing. As *Table 1* indicates, the price must fall to $25 per month (the same price that people currently pay for dial-up service) for broad market penetration.

Without standardization and the associated cost-reduction factors that will result, service providers will not be able to meet consumers' pricing expectations.

Clearly, service providers in fixed broadband wireless access (FBWA) want three basic issues solved by their equipment vendors: subscriber cost, radio frequency (RF) link performances (e.g., the non-line of site problem), and standards to allow the use of multiple vendors. The current generation of proprietary FBWA solutions fail at all three of these critical measures.

If standards are so important and are a requirement to reduce cost, why are the fixed broadband wireless standards efforts so fragmented?

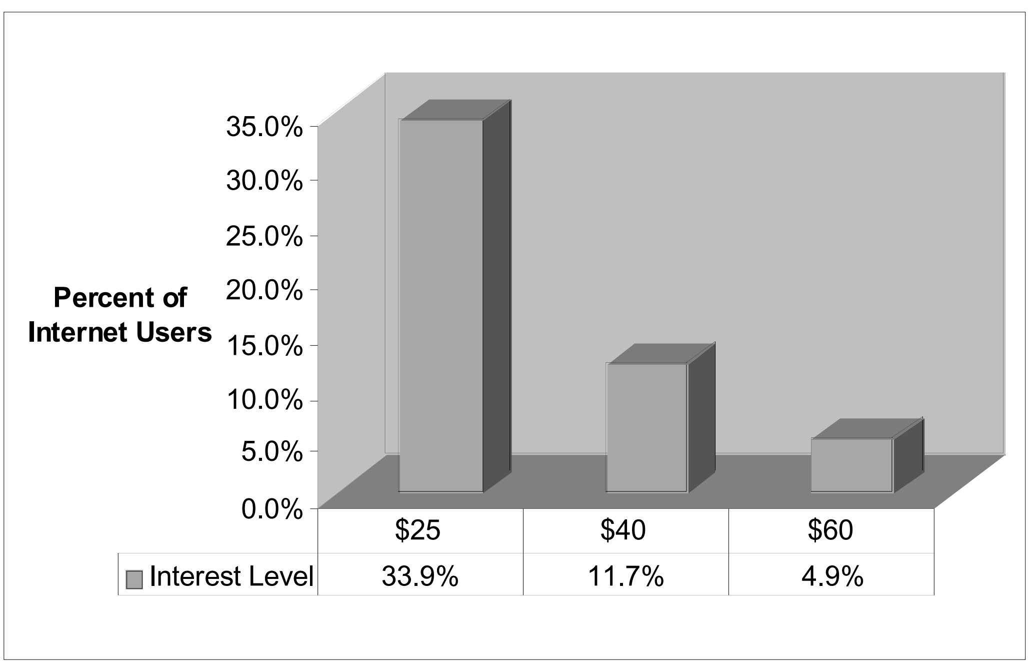
One aspect is economic self-interest. Early market entrants and/or major corporations would like to make a de-facto standard using their technology. The success of Qualcomm in the establishment of CDMA cell-phone technology is the best model. Qualcomm was successful due to the demonstrated superiority of their technology. Where Qualcomm's introduction of CDMA for civilian use was a revolution (even though it had been used for decades in the military), FBWA technology is an evolution. FBWA is based on the synthesis of a number of existing technologies such as optical frequency division multiplexing (OFDM), block frequency equalization, adaptive modulation, block adaptive error correction, adaptive beam forming, and multiple channel processing. All these technologies have been field-proven and are decades old. It is their low-cost integration to create the next generation of FBWA products that is unique.

The second aspect is the wider set of requirements that FBWA systems must address. Spectrum for FBWA that is applicable to low-cost home and SOHO deployment will be in four separate bands between 2.5 gigahertz (GHz) and 6 GHz in the United States. One of these bands can support isolated uplink and downlink channels such as the cellular technology frequency division duplex (FDD). The other bands provide uplink and downlink on a single channel similar to WLAN products (e.g., time division duplex [TDD]). Some service providers need support for data and voice (primary voice in some instances), while others require only data. FBWA must be able to evolve its level of service in the future to provide value-added products that provide incremental revenue to service providers. Toll-quality voice continues to be the single most important value-added revenue for any operator. As data revenues erode, voice, streaming media, and other quality of service (QoS) capabilities will be required for operator and service providers to generate healthy revenue and profits.

The efforts to create a fixed wireless broadband standard can be divided into two types of organizations: open and closed.

Open standards groups are accredited by national and/or international standards organizations. Representation is based on individual attendance and participation by written submission. These organizations use due process and voting to achieve consensus in development of the standard. Group/block voting by a single corporation is prohibited.

TABLE 1



Most important is that the open standards provide a right of appeal inherent in the standards letter ballot process (More information on the IEEE Project 802 is provided in Appendix A.).

The two principle open standards groups in FBWA are as follows:

- IEEE 802.16 Broadband Wireless Metropolitan Networks @ www.ieee802.org/16/, which consists of four task groups:
  - TG1 frequencies greater than 11 GHz
  - TG2 coexistence/RF planning (a function lacking in all other standards bodies)
  - TG3 frequencies from 2 to 11 GHz
  - TG4 unlicensed frequencies (UNII 5.8 GHz band in the United States)
- ETSI BRAN (Broadband Radio Access Networks) @ www.etsi.org

Closed standards forums are corporate based. Voting is at a corporate level and members have unequal voting rights. Furthermore, these groups have executive power that has a concentrated vote and can force the direction of the group. In some cases, assignment of intellectual property rights is a requirement to become a member.

The three principle closed standards groups in FBWA are as follows:

- BWIF (Broadband Wireless Internet Forum) @ www.bwif.org, chartered by Cisco Systems to promote their current FDD–OFDM product as a standard
- WDSL (Wireless DSL) Consortium @ www.wdslconsortium.com, which is more of an industry group that is actively participating in the open IEEE 802.16 standards process
- OFDM Forum @ www.ofdm-forum.com, which is promoting a patented technology for OFDM from Wi-LAN, is also participating in the IEEE 802.16 standards process

There is, today, a great deal of criticism of the progress made in open standards bodies. That criticism is unwarranted. In the latest 802.16 session, the IEEE 802.16 TG1 is completing the ballot stage of the process and will soon (Q4 2001) be an approved standard. At the same meeting, TG3 completed the basic draft standard, and that draft is currently undergoing a formal comment process. Making extensive use of the TG1 media access control (MAC)–layer standard has accelerated the TG3 efforts.

Both the WDSL and OFDM Forum industry groups are active participants in these IEEE 802.16 TG3 efforts. To further accelerate the standards process, IEEE 802.16 is holding six meetings a year, as opposed to the standard three meetings, to increase progress. In addition, e-mail reflectors are being used to reach consensus on technical issues between sessions.

TG3 is expected to have a draft ballot specification in the fourth quarter of 2001 and ballot to begin in the first quarter of 2002. Demands on service providers and actions by the FCC are also helping to drive standards to move faster.

Compared to closed standards, IEEE 802.16 is making a series of technical and technology cost trade-offs to ensure that the long-term cost structure of products will remain low. In particular, the subscriber costs and complexity are being reviewed. 802.16 is also addressing a common MAC and basic physical-layer (PHY) structure that will support all TDD and FDD bands in the 2 GHz to 11 GHz band. Like IEEE 802.11, we can expect a series of standards enhancements from IEEE 802.16 to address this issue.

Which leaves us to reconsider our question: Why do standards activities appear to be fragmented in broadband wireless?

In fact, they are not fragmented. Consensus is being rapidly built on a much wider set of standards issues that address a world market—not just a U.S. domestic market. Consensus will be reached at a more rapid pace, as the standard will leverage high frequency standards efforts that are completing the ballot process.

In spite of the consensus being built, why is BWIF the only forum that is not participating in the open standards process? The answer is simple: Because they want to be considered a de-facto standard. Unfortunately, the current BWIF architecture can address only less than half of the available domestic frequencies that will be available in 2002. Modification of their baseline architecture will result in the same issues internationally.

In the end, the open standards process produces a broader standard that will see continued enhancement and acceptance. The worldwide success of projects 802.3 and 802.11 have proven that, in the end, open standards provide the key to better services, broader support, and continued product improvement.

Appendix A

IEEE 802

The IEEE project 802 local-area network (LAN)/metropolitan-area network (MAN) standards committee (LMSC) held its initial meeting in February 1980. It was sponsored by the IEEE computer society to create a single 1 Mbps to 20 Mbps LAN standard. This and subsequent meetings divided the task of creating a standard into three distinct layers:

- The physical layer (PHY)
- The media access layer (MAC)
- Higher-level interface (HILI)

In practice, project 802 develops standards for the lowest two layers (PHY and MAC) of the open systems interconnection (OSI) reference model. A guiding principle of the group has been to have a common interface at the logical link control (LLC) sub-layer. This ensures that standards efforts at higher layers in the OSI model will have common support by all the supported standards.

During the 21 years of operation, project 802 has provided project authorization (PAR) for a number of working groups and their subordinate technical advisory groups (TAGs). The following is a list of the current active working groups:

- 802.0 Sponsor Executive Committee (SEC)
- 802.1 High Level Interface (HILI)
- 802.3 CSMA/CD for 10/100/1000/10000 based LANs
- 802.11 Wireless LAN (WLAN)
- 802.15 Wireless Personal Area Networks (WPAN) [Bluetooth and derivative]
- 802.16 Broadband Wireless Access (BBWA)
- 802.17 Resilient Packet Ring (just authorized)

IEEE standards are coordinated with both U.S. and international standards groups and a majority of IEEE standards are submitted to, and approved by, the International Standards Organization (ISO). Once a project has been authorized (an approved PAR), the working group goes through a series of technical submissions, discussions, and votes to develop a draft standard. Once the initial draft standard is written, a series of technical and editorial evaluations and changes are conducted. This culminates in a letter ballot where the voting members formally approve or provide specific written amendments to the letter ballots.

After the letter ballot has passed and the amendments have been addressed, the draft standard is provided to the IEEE Standards Board Review Committee. Upon approval of the IEEE, the standard can be published as an official IEEE standard. It is now common practice to have a parallel submission to the ISO JTC1/SC6 (Joint Technical Committee 1, Sub-Committee 6, responsible for LANs).

IEEE 802.16 is seeking to leverage approval of 802.16 TG1 (frequencies greater than 11 GHz of operation), which is entering letter ballot to greatly accelerate TG3 (frequencies from 2 GHz to 11 GHz of operation).

Project 802 holds plenary meetings three times a year. For more information, please refer to the IEEE project 802 Web site at www.ieee802.org.

Next-Generation Services: A Service Developer's Perspective

Arshad Syed
President
Integrated Telecom Solutions

This paper offers an overview, primarily from the service-developer perspective, of next-generation services, user solutions, and convergent solutions. Although the opportunity is tremendous, consideration must be given to cost constraints, especially for companies with strict budget guidelines and for smaller companies that cannot afford a great deal of speculative development. In the United States alone the number of wireless subscribers is estimated at more than 100 million, with an estimate of nearly 120 million by the end of 2001. Enormous growth potential exists in North America alone with even greater potential worldwide. The market demand definitely exists. With regard to the speculative opportunities, the time-to-market drivers must be balanced against the fact that, when a service is developed, probably only a very small segment of the marketplace is available because international ubiquitous services do not exist today, although, hopefully, they will in the future. If a service is developed for the United States, for example, it will be applicable only to North America for the most part and not worldwide. The return on investment (ROI) always must be balanced against this other business driver to the realistic short- and mid-term business case.

Service Drivers

In the past few years many services that were called next-generation services had very disappointing take rates for the carrier, the big vendor, and the smaller companies. Service providers and network operators want the best possible service and the most reliable system, and, of course, they want it at a reasonable cost. Significant pricing pressures exist. Future technology and the next generation, however, hold the promise to make these things possible because the volume will drive all these services and the revenue. Consequently, consideration must be given not only to the estimated 120 million U.S. wireless subscribers but also to the worldwide market, which is the true mass market. One of the technology drivers that will have a direct impact on profits and services is broadband wireless. Some of the advance-enhanced technology, such as wireless handsets with nice visual displays and the bandwidth that will be in the network to support it, is very attractive from a service-provider perspective. Mere proliferation of the Internet and the wireless Web will not improve the take rate or the usage, but services that offer greater value and increased productivity will be a key factor to better penetration.

Service Solutions

Presence and actual location—which will soon be available in North America—coupled with the Internet, some of the bandwidth that will be in the network, and basic wireless intelligent network (WIN)–type standards could lead to valuable solutions. Some will perhaps be a retooling of existing solutions and others will be brand-new solutions. Parlay and some other standard application programming interfaces (API) may allow providers to develop one platform that then can run on different types of infrastructures and networks.

Global network interoperability, of course, has been both positive and negative depending on the perspective taken. Progress has been made on standards, but in today's world there is a duality of networks and a duality of standards. Roughly half the world is Global System for Mobile Communications (GSM). North America and most of South America are American National Standards Institute (ANSI)–41 compliant. The same is true for advanced intelligent network (AIN), capability set (CS)–1, and the International Telecommunications Union (ITU) standards. There is a lack of interworking gateways even though these standards have been out for a long time. No major service provider really has installed gateways that would interwork within, for example, the United States and the United Kingdom, or the United States and Japan, or Brazil and Germany. Significant traffic flows exist among all these countries, and those gateways could be valuable, but most carriers currently are so focused on data that this is being overlooked. Those gateways could allow international ubiquity of service rather than only roaming. The national and international variances do cause problems occasionally. While service solution providers often are expected to do speculative software development, more leverage, especially with some of the new technologies and some of the initiatives, would expand solutions development.

The convergence of network standards, the third generation (3G), and other developments are very promising, as is the set of new standards from the Internet protocol (IP) side. For example, a traditional AIN or WIN, when coupled with IP, generates some very interesting possibilities. Some of the standards that are being adopted quickly on the IP side are worldwide and global. The Java and the hypertext markup language (HTML) or wireless markup language (WML) are the same in the United States or in an Asian country. For instance, the secure sockets layer (SSL), Java, enterprise Java, and common object request broker architecture (CORBA) are all the same, which is encouraging. Standards make it possible to think about solutions and develop them. In general the industry's move toward one worldwide standard is very positive, facilitating innovation, creation, and competition.

Regulations

Regulations, although often perceived as negative, actually can be positive on occasion. For example, the enhanced 911 (E911) mandate issued several years ago will open new location services and enhanced location services because, once location-finding equipment and the infrastructure are deployed, operators will want more mileage beyond E911. Local number portability (LNP) is another example of a regulation leading to innovation and new service deployments. Recently, the Federal Communications Commission (FCC) issued more regulation in wireless caller name and number portability which will likely result in more service deployments and increased value for the consumer. Thus, regulations actually are sometimes very helpful and positive.

Evolution versus Revolution

In terms of the infrastructure challenges and opportunities, for some operators with significant sums invested in infrastructure, it will be difficult to abandon those systems and go to wireless or broadband wireless quickly. Thus, new services must be able to exist within the current infrastructure and evolve with it for a period of time. Some of the capabilities, such as broadband and the Internet, are interworking and eventually will drive mass usage that can result in lower user costs and lower operating costs. There is potential for many millions of wireless users, even billions of wireless users. The existing technologies have to be leveraged, and a strategy must be in place to bridge to the next-generation networks (NGN). There will be a gradual evolution, rather than a revolution, to the NGN and to next-generation services.

With regard to infrastructure, some of the current services are very popular and will remain in demand. Those services will continue to exist for a while. Therefore, new services must coexist and interwork with the old services. What will be needed is a means of taking some of the old solutions and retooling them to use the Internet and some of the more available bandwidth. As a result, global access in a seamless manner definitely will drive the usage.

Next-Generation Architecture

Convergent architecture will need support for new and traditional interfaces as well as support for IP, best-price performance, and ease of use from a subscriber's point of view. In addition, support for these must be built into the infrastructure and platform—neither as an afterthought nor only as the responsibility of the service or the solution that will run on it. There also will be demand for high reliability and high availability along with flexible characteristics based on the applications. Running an application that is mission critical, for example, will demand higher reliability, and a greater price/performance ratio will be acceptable for that. Running an enhanced service that does not need to be available continuously must be able to take the same platform but with a lower reliability and availability, thus a lower price/performance ratio. These flexibilities must be available.

Migration to next-generation architecture should be driven by services rather than by technology. This is a key differentiator. It is possible to implement the technology and deploy it without knowing how it will be used. At the same time, knowing the kind of services desired could interest subscribers and drive costs down while increasing access. The global 3G migration, for instance, is very important. Ubiquitous services should be driven by content and by personalization. Personalization in this sense means knowing the user, the user location, and the user profile and preferences so that this profile can be applied in real time to increase productivity and add value.

Service Evolution

Evolution on the services currently available—caller name, caller identification, virtual private network (VPN) on the wireless side, mobility, and so on—requires that these services be opened to the Internet. All the services that are deployed today will continue for some time, and the life of those services needs to be extended by opening the access to the service data for subscribers using the fixed Internet or the wireless Internet. This is one way of bridging, or moving toward, the next-generation services. Another strategy is retooling of services for better value by leveraging IP technology. IP can be used to retool many services and cut the cost of deploying and operating services for the network operator. Opening service data for everyone to use on the Internet, in a secure and simple manner, and retooling some of the services, would lead the way to fully convergent services.

Future Scenarios

A number of services might be seen as next-generation services, or even convergent services, because they use aspects of telephony, wireless, location, and the Internet. For instance, location can be coupled with incoming call treatment. A user's only number will then be the wireless number. Depending on the user's location, calls are automatically sent there—home, office, or elsewhere—because the presence of the user's handset is recognized there. Calls automatically will go to voice mail if the user is at a place where it is indicated the user does not want the phone to ring. Similarly, when the user is not close to any locations that the service knows about, it will ring the wireless telephone. Location can be used in this way by coupling existing wireless networks and the fixed network to offer a service that is attractive and valuable for subscribers.

Caller identification or caller name also can reach improved value by applying new technologies to it. Instead of a user having to call voice mail to check messages, the termination attempt trigger, which contains all the information that will be displayed in a caller identification box at home or office, can be used to provide a notification on a wireless telephone in real time when a call is made to home or office. In addition, a personalized and secure Internet portal will exist that shows what happened and who called. While checking e-mail on the Internet, for example, a user could see a screen pop up that would indicate someone is calling. If this service was implemented on a softswitch, that call could potentially be taken as voice over IP (VoIP) from a laptop or on a wireless telephone because those capabilities may exist to connect those calls. This portable caller identification also will have the capability to show a call in progress. For instance, if a user misses the screen pop, the call will go through because it is in real time, and perhaps someone will answer the phone. After the fact, because it is the softswitch service, it will show an updated line of text indicating that the call is in progress, and the user could elect to join in on that call as a reverse of three-way calling. This is an example of the possibilities once IP, wireless, location, and other elements are brought together.

Front-End Communications Processors: Their Place in an IP World

Angus Telfer
Chief Technology Officer
INETCO Systems Limited

Introduction

Communications front-end processors (FEPs) are responsible for linking client applications and their associated networks to host computer-based applications. With the advent of the Internet and of Internet protocol (IP) as a universal protocol, it is often assumed that there is no longer any need for FEPs as "everything is IP." This may well be true where FEPs provide only straight connectivity (and assuming IP never changes). However, FEPs also perform a number of other vital communications-related functions that are closely linked to transaction applications, including message and transaction switching, multiplexing, transaction security, quality of service (QoS) guarantors, and end-to-end transaction management and reporting. The need for these functions is especially important in mission-critical transaction environments, such as point-of-sale, security, and health-care applications. In these environments, FEP functionality is more necessary than ever before.

This paper examines the functions performed by FEPs in relation to IP network environments. It also outlines different approaches that may be used to implement this functionality and discusses the advantages and disadvantages of each.

FEP Functionality

FEP functionality is primarily at the communications level. In terms of the open system interconnection (OSI) model, this means the transport, network, protocol, link, and physical layers. Functionality provided can be broken down into the following categories:

- *Connectivity:* Involves the connection of networks, devices, and servers
- *Switching:* Involves the switching of packets and messages based on network addresses and message contents
- *Multiplexing:* Involves the multiplexing and demultiplexing of data streams, such as the aggregation of transactions in retail point-of-sale applications
- *Reliability:* Involves issues such as end-to-end delivery confirmation, maintaining a necessary QoS, load sharing, and appropriately pacing transactions so as to not overload any device or server
- *Security:* Involves data-security issues such as encryption, firewall type issues such as the examination of data address information before routing packets, and device-security issues such as ensuring that there is no way to penetrate and take control of a device remotely
- *Network Management:* Involves network monitoring and network control
- *Reporting:* Involves the reporting of network and communications activities for analysis. These reports may be used for customer billing, network planning, or for proactively finding and eliminating network problems.

Each of these categories, and how it pertains to the IP world, is explained in the following sections.

Connectivity

A traditional use of FEPs is to act as a multiple protocol gateway for connecting diverse equipment. This is how it got the name "FEP" in the first place. It "front ended" the mainframe computer.

At first glance, this function is no longer needed in an IP environment, as all devices appear to be converging to a single communications infrastructure. However, things are not that simple in reality. New IP–based protocols such as wireless application protocol (WAP) and short message service (SMS) are required to support wireless "always-on" applications. Other new IP protocols, such as test transmission control protocol (TTCP) and QTP, are required to properly support transaction-based services. Finally, even existing protocols, such as IP, hypertext transfer protocol (HTTP), etc., are being evolved to meet increased requirements for security, addressing, reliability, priority traffic, etc. The result is that the IP infrastructure is steadily moving to having as many (or more) different protocol implementations than there were in the "bad old days," where each equipment manufacturer supported their own suite of protocols.

Integration of these new IP protocols and protocol variants over time could presumably be done by upgrading all equipment simultaneously. However, this is not practical. This is especially true in these days of network appliances where each appliance performs specific, well-defined functions. Even if it were possible within a particular enterprise, connection to the network outside the enterprise would necessitate a multiple protocol gateway of some sort.

Switching

Another important traditional use of FEPs involves the switching of packets and messages based on network addresses. In modern implementations, this may also be based on message contents. One message may be sent to one server while another message may be sent to another server based on such items as the "terminal identifier" or "bank identifier" field within the message.

With the Internet, switching is accomplished at the client (e.g., PC) end of the network. Control of all communications, including making simultaneous connections to several destinations, is clearly left with the client (e.g., Internet browser, e-mail, etc.). While this approach works quite well in client-centric systems, it is potentially disastrous architecture for mission-critical applications where the enterprise must maintain constant control over the device. With a client-centric architecture, there is no reliable way to manage, monitor, or audit the device in real time, as it may be communicating with several remote servers simultaneously. As well, such an approach provides a large opening for hackers to steal control of the device.

The answer is to have a communications processor (e.g., an FEP) through which all the device's communications goes and through which it can be monitored, audited, and controlled. This device can then route the messages appropriately and can also be interrogated at any time with respect to the status of any device, as well as being able to report any abnormal events that occur.

Multiplexing (Aggregation)

One particular type of FEP that is used within many financial networks is a network access controller (NAC). As well as the other functions described in this paper, a NAC is capable of concentrating multiple data streams onto a single data stream by acting as a gateway between circuit-switched data and message-switched data. This multiplexing (or aggregation) of data allows there to be fewer circuits on the host side of the NAC than there is on the device side. It also means that the host side circuits can be static as opposed to the device side, where, in the transaction world, circuits are often transient and generally last only a few seconds each.

This function is less important in the IP world than it is in the legacy world, where circuit management traditionally placed a large load on the mainframe. However, it is still important in large networks, as transmission control protocol (TCP) connections are still relatively expensive and the maximum number of connections into a server is generally much less than the number of concurrent transactions that could otherwise be handled by that server.

Reliability

Reliability involves issues such as end-to-end delivery confirmation, maintaining a necessary QoS, load sharing and transaction pacing so as to not overload any device or server, and alternate routing in case of server failure.

Traditionally, the FEP would be responsible for these functions and would handle them as follows:

- Message delivery would be acknowledged end-to-end. That is, a message would not be acknowledged back to the application until confirmation was received from the remote device either by a direct acknowledgement or a delivery-confirmation message.
- QoS information would be maintained on an end-to-end (e.g., client device to server application) basis by measuring the time before a confirmation was received, by noting retransmissions and other recovery actions, and, if necessary, by alerting the network operator.
- Load sharing and transaction pacing was done by the FEP holding onto transactions and spreading them over available circuits (e.g., via rotary hunt groups, etc.) so as to not overload any device. Channels to the host could be "paced" by allowing transactions through at only a specified rate. Alternatively, channels could also be configured as half duplex (i.e., one-way only) to prevent the turn-around delays encountered in many hosts.
- Failure recovery was done by the FEP transparently routing transactions to an alternate host should the primary host fail. Note that it is generally important in these scenarios that all transactions be routed to either one host or the other in order to maintain the operational integrity of the application and its database. If the client device controls the switching between hosts, it is invariable that some devices will be connected to the primary server and that some (due to purely transient issues) will end up connected to the secondary server. At this point, the enterprise is, whether it wants to or not, running a distributed database.

In pure Internet-based IP networks, some of these functions are provided by the router network, while many are not done at all. This results in a poor (and generally unknown) QoS. In addition, the host must be thoroughly tested in advance to ensure that it can always take the simultaneous, worst-case transaction hit, as there is nothing in the network to spread load or to pace the rate of incoming transactions.

Security

Security in IP networks is primarily accomplished by the use of firewalls and virtual private networks (VPNs). These approaches provide a level of security but do not eliminate the possibility of insider attacks on the network. For example, a client device could be being taken over by hackers, or an attack could be mounted on the server.

Traditional FEPs do not provide much in this area other than the examination of addressing information before packets are sent on. However, FEP–like functionality is increasingly needed that would allow the client to be blind to all incoming requests except those from the FEP. While this is not strictly in tune with the concept that everything should be simple network management protocol (SNMP) manageable, should respond to pings, should allow downloads by file transfer protocol (FTP), etc., it is much more secure than the approaches used in most current IP networks.

Another instance in which FEP–like functionality is required is the filtering out of messages that do not conform strictly with expected transaction types before they get to the host. Firewalls currently do this to some extent. As mission-critical applications expand on IP networks, it will become increasingly necessary to expand this capability to the actual transaction message itself.

Network Management

One of the areas in which traditional FEPs excel is in their ability to monitor the health of all network elements, including that of the client devices themselves. The FEP is in the middle of every message and so always knows the state of the device without the need to poll it.

In most current Internet-based IP implementations, there is no central network entity. Instead, network-management functions are generally placed off to the side, where an SNMP server such as HP OpenView polls devices, receives alarms, and notifies the operator as it deems appropriate. Putting network management off to the side like this is, at best, a very poor substitute for providing in-line network management. It eliminates the possibility of using network management as part of a dynamic feedback system where corrective action can be taken automatically in real time. It also increases the bandwidth required due to the management requests that must be made over the network.

Reporting

Reporting on communications activities is important, as it generally affects core business operations, such as network planning, billing for network use, auditing (for security), and the interception of data as required by some governments for digital wire tapping.

Centrally located FEPs are an ideal place to collect the data required for such reports with minimal network load or changes to server applications. The alternatives are to collect the information from the devices themselves (impractical for large networks and for places where the devices are owned by third parties) or to collect the information from the server (impractical where multiple server applications are involved or where the servers are owned by third parties).

FEP Implementations

As can be seen, FEP functionality is very important in IP networks used for mission-critical transaction processing. As our dependency on real-time transaction systems grows, it will become increasingly vital. Given this, how can such functionality be achieved? Following are some of the methods that have been used.

Client as FEP

One way that has been promoted is to move the responsibility to the client as is done with Web browsing over the Internet. In this model, the client, such as an automatic teller machine, connects to each server application directly. That is, it connects to one server for financial transactions, another server for device management, another server for network management, another server for providing local advertising, and may even connect to other servers for such things as requesting cash replenishments, etc. In the case of network or server failure, the client simply finds another server to connect to independently of any central control.

The primary advantages of this solution are in favor of the client manufacturers. It is simple to implement, and it moves the control of the device from the central server application to the client. This reduces the reliance of the client manufacturers on the producers of the central servers and allows them to make their client application more proprietary.

Key disadvantages of this approach are as follows:

- The client is operating essentially independently of any central application. This makes it very difficult to control or monitor. If security breaches do occur, they can be difficult to detect, and it can be very difficult to regain control in order to limit the damage or correct the problem. This lack of a central control or audit point can be disastrous in mission-critical environments.
- As the clients operate independently, there is no good way to switch them from one server to another server in any synchronized manner. In normal operation, clients will tend toward being distributed over all available servers due to variable loading conditions on the network. This is not a problem if servers are identical and meant to be operated in this fashion. However, in the case of most enterprise servers, there is the concept of primary and secondary servers (if for no other reason, then to provide a method of updating server software). Distribution over these servers without appropriate operator control can result in problems maintaining consistency within the database, with encryption keys, etc.
- As all clients are operating independently, they must all be individually managed. In large systems, this results in a requirement for extensive network-management bandwidth for querying and otherwise managing all of the devices. With a centralized FEP approach, this would be accomplished simply by management of the FEP itself.
- The need for multiple communications connections from the device using the client-centric approach opens it up for attacks from outside. This is especially a problem because most client devices use either Microsoft Windows™ or other well-known IP stacks that have been extensively "hacked."

Given these problems, why is a client approach to providing FEP functionality considered at all? The answer is simple. It allows terminal manufacturers—be they manufacturers of client software, automatic teller machines, or terminal adapters—to quickly put a product out with minimal or no interaction with the producers of the central server application.

Server as FEP

The direct opposite to having the FEP functionality in the client is to put it all in the server. This approach is similar to that used by Tandem in the legacy world.

The primary advantage of this embedded approach is that the server application is tightly coupled to the networking functionality, simplifying management and control as well as increasing security.

The primary disadvantage of this approach is that most current applications involve multiple disciplines, each with sophisticated software applications. For example, even a simple point-of-sale terminal may use biometrics for identifying the customer as well as for doing the financial transaction. There may also be loyalty card programs, checks regarding card usage for security reasons, inventory information regarding what is purchased, management of the point-of-sale terminal itself, and, of course, management of the network links. Putting all of this in one server is, realistically, impossible. Even if achievable at some point in time, it forces enterprises to accept inferior (or no) solutions in one area in order to get superior solutions in another area. Adding new capabilities outside the server vendor's product range becomes expensive or impossible. Any attempt to move to another vendor in the future also becomes extremely expensive. Such lock-in to a single supplier is not in anyone's interests even if it is possible.

Network-Based FEP

This is the approach generally promoted by the network-equipment providers and telcos. With it, there would be a large network box at the central site that would control communications between the servers and the different network access points to which the clients would be connected.

When fully developed, this approach has the possibility of solving many of the communications problems inherent in using today's IP networks for mission-critical applications. It can provide centralized network management, a centralized audit point, separation between the network and server protocol stacks, flow control of data into the servers, and server fail-over and load balancing.

The primary disadvantages of this approach are that 1) it is not yet fully implemented in terms of the features required for large enterprises, 2) it requires all network devices (including terminal adapters) to come from a single vendor if they are to be properly managed end to end, and 3) it is purely a network device with no knowledge of either the client or server application whatsoever.

Most of the disadvantages of this approach may be resolved over time should the manufacturers see sufficient revenue from such an integrated solution to warrant the work necessary and should they also open up the management interfaces to third-party device manufacturers. However, current network boxes sold for this application are very limited and manage only the vendor's own equipment. This often leaves third-party devices operating in the "client FEP" model, the worst of all models from a mission-critical transaction application perspective.

Transaction FEP

In this approach, a box is inserted between the network and the application servers that knows of the different types of transactions that will pass through it. This box acts both as a network management and control point, and also as a message switch.

The advantages of this approach from a network perspective are the same as for the "network-based FEP." In short, it provides centralized network management, a centralized audit point, separation between the network and server protocol stacks, flow control of data into the servers, and server fail-over and load balancing. In addition, as it is transaction knowledgeable, it can also provide concentration of transactions on few communications channels to the servers, content-based message switching, and even message conversion. Finally, as it is aware of the end devices, it can provide management on a true end-to-end basis, as well as providing guarantees of message delivery not otherwise possible.

The primary disadvantage of this type of solution is that transaction FEPs are very specific to different verticals. That is, a transaction FEP for point-of-sale terminals is of little use in security, automatic teller machine, or other applications. For this reason, the spread of transaction FEPs has been slow, and most have been created by system integrators for particular customers, as opposed to being created as products for particular markets.

Summary

As can be seen, FEP functionality is vital within the IP world and will become even more important as the Internet evolves and as our commerce and personal interactions become increasingly reliant on IP technologies. Without FEPs, it will be difficult to guarantee the QoS, the scalability, or the evolution of network standards and applications that will be necessary to provide true mission-critical enterprise solutions.

The conventional approach for providing FEP functionality in the IP world is the most prone to problems, as it is based on a client-centric architecture that places the client clearly in control of all communications. Likewise, the approach of putting the functionality in the server application is not advisable, as it is based on a mainframe architecture whereby all services and applications on the mainframe were purchased from a single supplier. A network-based architecture whereby the network is managed as a single point is better but suffers from the weaknesses of being closed to third-party vendors, being incomplete, and being ignorant of the transactions that pass over it. Transaction-based FEP architectures are clearly preferable to the other approaches; however, they are not always available, as this field is just emerging.

The functionality that FEPs provide may come in a variety of guises under a variety of names (none of which are "FEP"). It is up to the purchaser to do the research and weigh the pros and cons of each approach before deciding the best approach for their mission-critical application at this point in time. This is a new era that is evolving quickly.

The Future of Communications

Brough Turner

Senior Vice President and Chief Technology Officer

NMS Communications

If the 1990s were the decade of the Web, the 2000s will be the decade of Internet-telephony communications. The industry can expect not a $10 billion change, but a $1 trillion change over the decade, with innumerable ways of marketing new voice services. But the landscape is going to be radically different from that of communications today. The key to this change is the imaginations of 10 million Web designers.

Talk about new network services dominates the industry today. Within the past 12 months, long-distance carriers have begun to admit that long-distance revenues are threatened and may no longer provide the base for company growth. The crux of the problem is that for three to four years, data bits have been overtaking traditional voice bits, but most of the revenues come from voice. The question is, what new services will generate the necessary revenues?

Recruiting Web Developers

Today, even teenagers have Web sites—a radical change from five or six years ago. And with new developments, the world of communications services is ready to open to Web developers. Imagine the possibilities if a teenager were managing communication services on a family's second phone line. There is no reason why a Web developer, even a teenager, could not come up with specialized answering treatments, download scripts, and create whatever sorts of communication services are interesting in a given week. Imagine what sounds a teenager might use for personalized alerting, with alternate sounds depending upon who is calling. For a teenager, special triggers might place a phone call to a pager or a mobile phone to announce that tickets to an event are available. Voice chat could be automatically available as part of a multiple-player game. A teen's circle of friends could have a custom find-me, follow-me intercom.

Such a scenario is not inconceivable. Remember, in five years the Web evolved from the point where most people had never heard of the Internet to where even teenagers have Web sites. With a corresponding change in the communications industry, teenagers will be able to produce their own services. No one is thinking in these terms today.

Capturing Revenues

The Internet has spawned a variety of interesting ways to market products and services. Carriers will be able to make money by capturing transactions but, in a fully evolved market, the traditional carriers may only be selling quality of service (QoS) bits. The services themselves may come from multiple diverse sources. And there will be an enormous number of new software products—some of them free.

Subscribers are still likely to contract with one company for the 7x24 execution of a session initiation protocol (SIP) script, thereby ensuring that their Internet telephone is still answered even if the power fails. That is one example of a service likely to come from traditional carriers.

There are opportunities to survive the coming commoditization of both 19th-century services—basic voice—and 20th-century custom local-area signaling services (CLASS). However, these opportunities are different from what the industry is discussing today. The voice portal business is expected to grow from literally nothing in 1999 to a more than $10 billion market in 2003. Although that is exciting growth, $10 billion is not much in terms of the telephone industry. Worldwide voice revenues are measured in the trillions of dollars.

Current Industry Focus

Today's industry focus is on softswitches and on a gradual evolution from the existing intelligent network (IN) to a "decomposed" network, which is a decomposed copy of the existing IN. In this model, there is a network operations center (NOC) or point of presence (POP) that incorporates softswitches, application servers, and media servers. There are gateways between the Internet protocol (IP) network and the public switched telephone network (PSTN), but they are all centrally located in the new equivalent of the central office (CO). Who actually develops and deploys the new applications in this environment? Traditional carriers do, exactly as in today's IN. The new application development environments are useful in that, for example, selective call forwarding can be made dramatically easier to use. However, it is still the service provider that creates the selective call-forwarding service. All the user can do is slightly modify the way the application works. The applications are still being written by the service provider or by a small group of companies that provides solutions to the service provider. The code is not available for a Web developer to play with, let alone a teenager.

Typical application programming interfaces (API), such as Java APIs for integrated networks (JAIN) and Parlay, allow third-party developers to personalize services, but most of the functionality is controlled under JAIN or Parlay. And, in this model, subscribers remain committed to a specific service provider that supplies everything. The decomposed softswitch architecture continues the model of the IN developed over the past 20 years. Although the industry is comfortable with this architecture, it is not the ultimate model.

Growth of the Internet Model

A break will occur, probably beginning within two to five years, creating the conditions for explosive growth based on an Internet model. In the Internet model, everything is wide open; nobody controls who can create a new Web site. Some of the underlying structure, such as the domain name server (DNS) and domain name ownership, is controlled, but at the application and the Web server level. No one is truly in control. That lack of central control has been very interesting in terms of the five-year transition that happened in the 1990s to the point where anyone can have a Web site.

Most of the pieces needed to build a distributed communications infrastructure that could support a transition similar to that of the Internet are in place now through the SIP family of protocols. But questions remain regarding software-development tools and adequate QoS.

The SIP family of protocols provides the foundation for distributed call control, exactly as hypertext markup language (HTML) provided everything necessary for Web sites and Web browsing. SIP does not directly cover the scripting of prompts and address other factors, but the addition of voice extensible markup language (VXML) moves the industry closer to the turning point. The SIP model supports completely distributed applications. SIP services are becoming available from major carriers around the world.

QoS Issues

Of course, the explosive growth of distributed communications services following an Internet model requires an Internet that provides "adequate" QoS for interactive voice communications. This is not available in today's public Internet. But the cost (recurring cost, not capital cost) of providing "gold" bits—i.e., two levels of service—is effectively zero when the percentage of gold bits is less than 15 percent of the total bits.

Today, data bits are growing at roughly 100 percent per year, while voice bits are growing 8 or 9 percent per year. The crossover point has already occurred, suggesting that voice will represent less than 10 percent of the bits by 2004. With zero costs and a competitive marketplace, subscribers can expect within three years to purchase Internet service for a flat monthly rate that provides today's services, plus the ability to send up to 10 percent "gold" bits for the same flat monthly fee or for an incremental flat monthly fee.

The Internet backbone already has QoS that is adequate for voice telephony. Multiple carriers offer service-level agreements (SLA) that guarantee sufficiently low latency and packet loss to support IP trunks between private branch exchanges (PBX) at different business centers, if those business centers are each connected to the same backbone provider via T1 lines. The bottleneck today is in the access network, but cable modems (CM) and digital subscriber lines (DSL) are expected to provide broadband access for 24–28 million subscribers by 2004.

A CM, today's backbone, and SIP telephones could deliver toll-quality speech service over today's Internet. QoS is an issue but not an obstacle.

Software Issues

A bigger question is that of service-creation software. For more than 20 years, service-creation environments (SCE) were dominated by high-end specialty software. The 1990s saw Microsoft's telephony application programming interface (TAPI), Java TAPI (JTAPI), S100, and a series of other APIs and environments for creating applications that had a mixture of call control and interactive voice response (IVR), with or without speech recognition. None of these really gained traction. Tens of thousands of programmers are writing applications for the communications industry, but there are three million Windows programmers and untold millions of Web programmers. The question is how to harness 10 million Web programmers and get them to write communications applications.

SIP is an early attempt to make communications call control available to Web programmers, and VXML—which has been developed in the Web portal industry and standardized by the World Wide Web Consortium—is the first step toward integrating IVR with call control. The pieces needed to make the process easy are probably less than two years away. Between SIP and various extensible markup language (XML) derivatives, over the next 12 to 24 months, everything necessary for Web developers—even teenagers—to feel comfortable creating applications will likely fall into place.

A New, Creative Approach

There is a market for services created by individuals, and when 10 million people begin thinking of services, the result will be very different from anything happening today. Such creativity will make the world of communications dramatically different.

Of course, the IN and softswitch model has years of life left because there are billions of existing phones and captive customers. The entire mobile network is built around captive services, and even third generation (3G) wireless will not change that situation in the next three to five years. On the other hand, the Internet model is set to explode, probably within the next two to five years. The transition in communications will be as dramatic as the Web transition was between 1994 and 1999.

Crossing the "Telechasm": Who Will Make It to the Other Side?

Terry Unter
Chief Operating Officer
Corvis Corporation

The telecommunications industry has reached a defining point even more profound than the digital revolution of two decades ago. The decisions carriers make today will determine whether or not they'll be in business next year.

The explosive growth of data traffic, fueled largely by the Internet, is stretching the limits of transport and processing capabilities in today's core networks. Carriers are asking how they can satisfy burgeoning and hard-to-forecast capacity demands without pricing themselves out of an intensely competitive market. If they're looking beyond mere survival, they're also wondering how to create new revenue opportunities and be first to capture them.

Data already makes up a more than half of the traffic in communications networks. Data communications continues to grow, even in a challenging business climate, doubling almost every year. These realities lead us to the conclusion that data is now the single greatest consideration in transport design. The inadvisability of applying established technologies to networks carrying traffic that is inherently changed in nature and composition seems self-evident. In the late 1990s, during the first wave of transition from voice-centric to data-centric networks, most changes in network design and technology occurred in the service-switching layer. The movement then was from circuit switching to packet switching. Now, the transition is expanding to the transport layer. The architecture and the physical building blocks for the transport layer now need to match the economics of what has become a data network. The two most significant differences between data and voice communications are the average distance of a data flow and the revenue per bit.

As carriers' traffic is increasingly dominated by data, network capacity must expand. The problem is how to expand. To continue the legacy architecture optimized for voice traffic, where the majority of calls occur within 600 to 700 kilometers, is to miss important opportunities to improve the profitability and overall performance of a carrier's business. Data communications typically span 2,500 to 3,000 kilometers. Carrier income is still primarily realized through voice services. Data services have not proved as plentiful or profitable as traditional voice. If communications growth were the result of voice traffic, the conventional design and technology of the transport layer would do nicely. But it is not, and to optimize a carrier's performance and profitability, a different kind of network is required.

So here's the turning point. Legacy wavelength division multiplexing (WDM) networks—which can carry tens or hundreds of gigabits per second per fiber—have met soaring capacity requirements, but at a price. Interim quick-fix strategies have introduced the benefits of optical-to-electrical-to-optical (O–E–O) regeneration/switching and optical add/drop multiplexers (OADMs)—technologies that enhance carrier performance up to certain capacity and service levels.

The survivors of this decade will be the ones that acknowledge that if they are successful, their networks will inevitably grow to require a new network paradigm. Ultimately, they will have to cross the "telechasm" from lost-generation to next-generation, and exploit the performance and cost advantages of optical networking.

The intelligent interim strategy, therefore, is to simultaneously position the network for today's requirements and tomorrow's realities. For any carrier that intends to prosper, the answer is to embrace *optically optimized* networks.

What Is An "Optically Optimized Network?"

The optically optimized network is one in which breakthrough optical technologies are strategically deployed where they offer the greatest return on investment (ROI) and lowest cost of ownership. The transport layer has been traditionally viewed as static capacity built to growth forecasts. As we move to a data-centric world, this transport layer becomes part of the services platform. This requires network flexibility and speed of provisioning and reconfiguration. An optically optimized network can shorten provisioning and reconfiguration intervals to days or even hours, as opposed to weeks or months. Furthermore, this flexibility allows carriers to expand their addressable markets and deliver valued services that command a price premium. Through the optically optimized network, time-of-day and day-of-week bandwidth services can be extended to customers that could not afford this capability under the old transport model.

Carriers need to be able to capitalize on the benefits of optical technologies in a way that best suits their unique network traffic, installed equipment base, service requirements, and business case. That means the specific architecture of the "optically optimized network" will be unique for each carrier:

- For many carriers, the optically optimized network is largely based on legacy equipment, complemented with hybrid electronic/optical technologies that stage for the future—with a migration path toward all-optical core networking available whenever it is required.
- As carrier traffic is increasingly dominated by data communications, the optically optimized network exploits the legacy network for local/regional grooming and transports long-distance traffic on an efficient, all-optical mesh overlay core—analogous to an express highway system

There's no question that for networks overwhelmed with data traffic, all-optical core networking is the way to go. However, judiciously applied optical innovations can optimize the performance, responsiveness, and profitability of carrier networks with lesser reach and traffic requirements—if growing their business is part of their plan.

New Network Challenges Call for New Optical Core Strategies

Internet protocol (IP)–based intranets and the Internet—and the customer demands they have spawned—have fundamentally redefined the way carrier core networks are used in two key ways.

1. Internet users demand plentiful and ever-increasing bandwidth but are reluctant to pay much for it.
2. They refuse to pay for it in any way that scales with distance.

As a result, carriers have to reconsider their strategies for handling long-haul and ultra-long-haul traffic, increasing capacity requirements and the need for flexibility in service offerings.

Unfortunately, with the type of equipment in today's networks, bandwidth is expensive and difficult to deploy, and the cost of a connection increases with transmission distance. While transport costs continue to climb, transport revenues are taking a back seat to the new revenue focus: services and content.

Some carriers have responded to this challenge with an old-world mindset: throw more legacy bandwidth and equipment at the problem. Scale instead of transform. Take what was used in the past, and install more of it. Relieve congestion in the core, and never mind that you have to manually provision multiple cross-connects and regenerators to furnish the long-haul and ultra-long-haul circuits that are increasingly in demand.

That's hardly the prescription for a networking world in which profit margins are shrinking, carriers are being called upon to provision circuits of 1,000 km or more, and profitability requires being able to offer more revenue value than simple commodity bandwidth.

"The folly of attempting to expand networks with existing SONET/SDH technologies has resulted in tremendous capital expenditures that carriers have not been able to recover with marginal revenues," states a 2001 Aberdeen Group report. "Such expenditures have led to a softening in the financial markets for carriers, and in at least one case... to outright bankruptcy."

So what *is* the prescription, if legacy optical transport isn't up to the challenge? What is the most cost-effective way to transport traffic across hundreds or thousands of kilometers? What is the most effective way to maintain signal strength over long distances and multiple nodes in the typical fiber network? How can a carrier differentiate itself in a challenging economic climate?

Available technologies offer vast differences in implementation cost, provisioning interval, performance characteristics, and total cost of ownership (TCO). Traditional network architectures can be a deck of cards poised to collapse under the weight of all their electronics. Consider a typical terabit national network, for example:

- With legacy WDM equipment, that network could occupy 700 racks of equipment at a capital cost of more than $400 million—about twice that in operating expense.
- An interim solution that introduces optical regeneration and add/drop capabilities (say, configured with optical amplifiers every 80 kilometers and O–E–O regeneration every 400 to 500 kilometers) could reasonably trim 200 racks of equipment and $8 million from the capital budget, compared to the legacy approach.
- An *optically optimized* architecture, which exploits the merits of all-optical networking where it proves in, redefines the economics altogether, as shown in *Figure 1*.

Judicious application of all-optical capabilities in the network core can completely redefine the business case for a typical terabit national network.

Is Your Network Positioned to Bridge the "Telechasm?"

How much of current network expenditure is actively returning revenues and how much is simply sustaining the network? How quickly can the network respond to changing customer requirements and new business opportunities? Can the network cost-effectively offer "liquid bandwidth," that is, poured into the network at will and served up on demand?

What is the true cost of the network—and the cost of lost opportunity? What is the cost-per-bit under the current architecture, compared to the cost-per-bit that can be achieved with forward-thinking deployment of optical innovations? That metric—comparing current to achievable efficiencies—reveals the degree to which the network is optically optimized.

How do you improve your network's score on that critical survival metric?

FIGURE 1

The Cost of Complexity

Typical 1Tbps Nationwide / Countrywide Network

	Legacy DWDM	OEO & OADM	Optically Optimized
Line Cards	4800	1600	600
Power	1982KW	800KW	304KW
Space/Racks	980	610	330
CapEx	$420M	$340M	$230M
Edge O-E-O switch ports	$90M	$90M	$90M
Core switch ports	$190M	$190M	$40M
Regens	$100M	$0M	$20M
OpEx	$800M	$600M	$85M

For Networks Not Yet Dominated by Data Traffic...
An optically optimized architecture could be achieved by implementing a hybrid "convergence switch" in the core. The Corvis optical convergence switch integrates both electronic and photonic switch fabrics for synchronous transport signal (STS)–1 and virtual channel (VC)–4 grooming and wavelength switching. In fact, it is the only product available today that combines electrical grooming for synchronous optical network (SONET) termination and optical switching in a single platform.

With this converged technology, carriers can integrate existing voice-based access, metro, regional, and national networks as well as all-optical express networks onto a single network element, with seamless network management across multiple network topologies, such as point-to-point, ring, and mesh architectures.

The carrier can then migrate traffic from SONET rings to a more efficient and cost-effective optical mesh overlay network as needed. There's no need to migrate the *network*—just migrate the *traffic* for which the business case says, "Go optical." When/if all traffic has migrated to an all-optical tier, this hybrid switch can be used in a grooming function.

This optically optimized architecture starts moving the networking away from the inherent constraints of SONET rings, particularly the requirement to reserve so much bandwidth for protection/restoration. Unlike rings, an optical mesh can be organized into many logical architectures, permitting flexible configurations that can support various traffic and protection requirements across large networks.

Multiple routes exist between network points, so traffic can be easily re-routed to an alternate path in the event of a fault or fiber cut. In contrast, ring networks would have to provide significantly more bandwidth (and support dual-ring interworking or matched nodes) in order to offer comparable protection.

For Networks Dominated by Data Traffic…
An optically optimized architecture provides an all-optical mesh overlay that serves as a high-speed core layer for express traffic (see *Figure 2*). Where legacy SONET rings are exhausting their capacity (or have proven inefficient), the carrier can migrate express traffic to the new optical mesh tier, and use freed legacy resources for collecting, multiplexing, and grooming voice and private-line traffic. The new express layer would carry the aggregated traffic delivered by electronics-based networks in addition to directly carrying the fast-growing IP traffic.

In making the decision to introduce an all-optical tier, the nature of the traffic and the growth of data communications is the primary consideration. A good rule of thumb to consider is when your network approaches 300-gigabit capacity, it is probably used heavily for data communications.

"Large long-haul carriers wishing to stay in business have no choice other than to create next-generation, overlay, all-optical express networks between NFL cities," states a November 2001 report from CIBC World Markets.

This all-optical mesh overlay network provides essential survival needs:

- Ultra-long-haul transport and all-optical capabilities reduce or eliminate the need for costly regeneration equipment.
- Open gateway interfaces accept high-speed traffic from any type of network device.
- Optical switching capability and selective add/drop functionality makes a highly flexible solution designed to drop any service at any point.
- Remote, integrated, network-management, and provisioning capabilities increase service velocity and provide for a high level of service differentiation.
- Hierarchical optical restoration greatly increases the reliability and availability of the combined network.

An effective way to deploy optical mesh backbone networks in conjunction with existing networks is to use a hierarchical, or two-tiered, architecture, where the all-optical overlay acts as the high-speed core layer for express traffic.

A Phased Migration Strategy

The good news is that it's not a leap of faith to cross the telechasm from legacy to next-generation, optically optimized architectures. A sensible migration path is available today. Carriers can start making their networks future-ready while minimizing capital expenditures.

Carriers can deploy next-generation optical transmission and switching incrementally in their existing networks and scale/upgrade as needed. With the Corvis optical network suite, optical network gateways and optical amplifiers can become OADMs. Add/drop multiplexers (ADMs) can become optical networking switches. Optical networking switches can support smooth migration from SONET rings to intelligent optical mesh architectures. New fiber routes can be added to optical switches at any point. All of it can be protected at the optical layer and managed from a unified network-management system.

For example, a carrier might do the following:

- Take the first step across the telechasm by deploying point-to-point links with optical network gateways—jumping-off points from the legacy network to the all-optical express highway
- Upgrade sites that have back-to-back optical network gateways into OADMs when optical bypass is required
- Upgrade optical ADMs to optical switches as needed

In a phased process, carriers can make forward-looking investments that 1) meet today's requirements with minimum capital expenditure, 2) position their networks for emerging demands and opportunities, and 3) enable them to upgrade whenever the business case dictates, without premature or stranded investment.

When "Optically Optimized" Means "All-Optical Mesh Core"

For carriers with capacities beyond 300 gigabits per second (Gbps) and circuits exceeding several hundred kilometers, the optically optimized architecture naturally exploits the advantages of an all-optical overlay mesh core. This architecture dramatically reduces costs, opens up new service opportunities that couldn't previously be supported, and enables the carrier to gain first-mover advantage to capture new business.

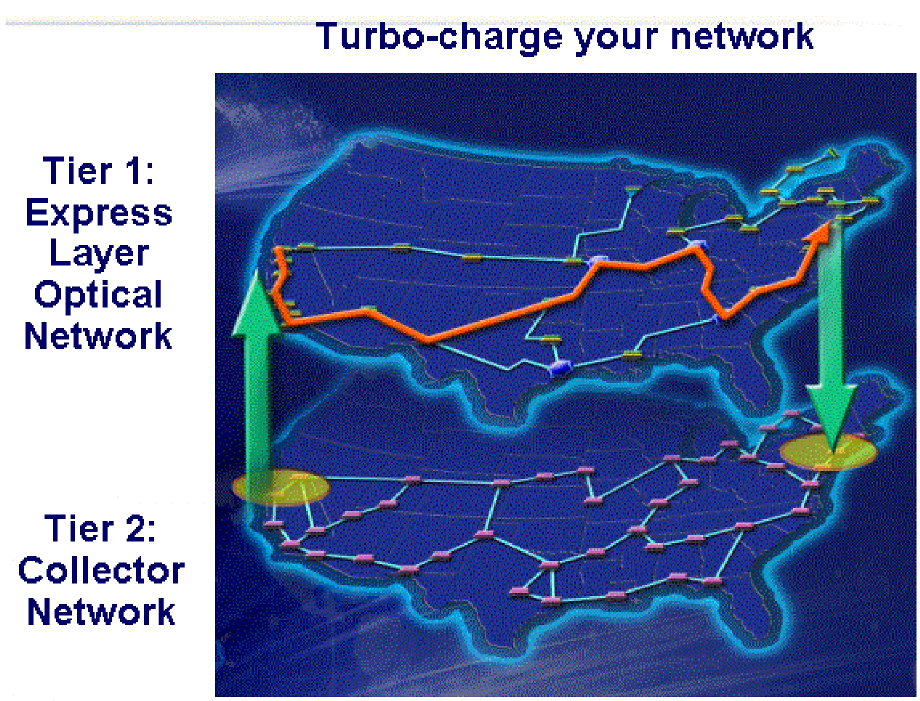
Slash the Cost of Supporting Network Traffic

"In an era when service providers, particularly competitive local exchange carriers, CLECs... are collapsing under the burden of network costs, the importance of cost containment cannot be overemphasized," states a 2001 Aberdeen Group report on the development of optical mesh architectures in the network backbone.

The capital and operating expenses of conventional point-to-point WDM systems are quite high, mainly due to the large number of regenerators required in a national-scale network. Yet in a typical backbone network, 70 percent of

FIGURE 2

A Different Approach



the traffic at any node is just passing through. Subjecting this traffic to unnecessary opto-electronic conversion and regeneration is a costly proposition.

"Once a carrier surpasses 500 Gbps long-haul capacity, the math proves it's time for a new long-haul architecture where the scalability of optics wins," says a November 2001 CIBC research report. If optical links of 3000 kilometers or more can be achieved without opto-electronic regeneration, some 80 percent of the circuits in typical U.S. backbone networks could do without electronic regenerators. Imagine the savings in capital expense, power, provisioning interval, operating expense, line-card inventory, and more.

Corvis systems reach more than double that distance. Its optical networking products have transmitted data more than 6,400 kilometers without electronic regeneration on a live carrier network, proving the viability of coast-to-coast express networks. A customer's "optically optimized" network may use Corvis optical products to create an overlay optical mesh core—analogous to an express highway—that minimizes or eliminates these significant cost factors:

- Number of switch ports and line cards required
- O–E–O conversions at switching points and between endpoints
- Number of discrete network-element management systems

Optical switching and transport rests on a self-evident business case: If you reduce the number of O–E–O conversion points in the network, you reduce implementation cost, network latency and complexity, provisioning interval, space and power requirements, and upgrade cost.

In fact, reducing requirements for regenerators, amplifiers, and their associated cost elements can potentially save carriers 20 to 40 percent on capital costs and 50 to 60 percent on operational cost of long-haul platforms. An all-optical overlay network takes this self-evident principle to its ultimate limit—eliminating O–E–O conversion for express traffic except at source and destination points.

Open Up New Revenue Opportunities Never before Possible

Traditionally, carriers have assessed equipment purchases from the perspective of network segments: switching, transport, budget categories, line items, engineering requirements to fulfill, etc. Viewed in that perspective, the optical express architecture is an impressive cost-saving framework, but that's only half of the picture.

Carriers need to factor in the gains that come with new service opportunities, or, conversely, the opportunities they would forfeit to competitors whose architectures enabled them to respond faster and win the business. Viewed in this perspective, the all-optical network (AON) rewrites the rulebook with instantaneous provisioning.

When you don't have to manually provision numerous regenerator sites en route, suddenly you change the economics of setting up "express" circuits (those that traverse a node without drop or regeneration), wholesaling bandwidth, and providing bandwidth on demand with point-and-click availability.

Ease of provisioning opens up the network to a whole new market segment for short-term, high-bandwidth users who cannot economically use the backbone networks as they are configured today. An all-optical mesh core creates opportunities to offer dynamic wavelength services that more closely mirror the dynamic requirements of carriers and their customers.

"This first-of-its-kind network gives us the ability to offer bandwidth that is so flexible that it can best be described as 'liquid;' which for customers means bandwidth that can be poured anywhere, anytime, in any amount," said Rick Ellenberger, Chairman of Broadwing Inc.

Rising to Opportunity Faster Than Anyone

In an intensely competitive environment with so many players, a carrier's ability to respond quickly to opportunity is a huge differentiator. It may well define which carriers survive current economic conditions in the industry.

"First mover" carriers—the ones that can turn up service in hours rather than weeks or months—will gain strategic competitive advantages in commodity bandwidth markets. Carriers that can respond this fast will do more than steal market-share; they will also uncover new customers and markets by addressing dynamic opportunities.

"The flexibility of Corvis next-generation solutions enables us to offer and deliver optical innovation to our customers in record speed."

—Matt Bross
Chief Technology Officer
Williams Communications

Optically optimized networks enable carriers to deliver revenue-generating wavelength services essentially on demand. For example, Corvis optically optimized networks support on-demand provisioning and reconfiguration. Just turn up TxRx cards at circuit endpoints; the network-management system auto-configures the rest.

As a result, carriers with optically optimized networks are setting new speed records. For example, Williams Communications provisioned an optical carrier (OC)–192 circuit within 48 hours of receiving the equipment. Broadwing Communications installed and turned up 38 OC–192 (10 Gbps) circuits in less than 60 days.

A key to this rapid delivery interval is remote point-and-click provisioning of wave services. The optically optimized network is inherently bandwidth-ready, with no requirement to preprovision expensive 10 Gbps electronics and optics at regeneration and switching sites. That means no stranded capital and no delays turning up bandwidth when and where it is needed.

"Provisioning a circuit is a keyboard exercise rather than a labor intensive, hardware driven event," said Chairman Ellenberger of Broadwing Inc. "For example, visualize having the bandwidth you need in minutes rather than months, by clicking a mouse instead of waiting for a technician."

Speed and flexibility open the door to a new world of capabilities that expand a carrier's addressable market. Carriers can now cost-effectively offer unique, short-term revenue services, such wavelength-based services by time-of-day, day-of-week, and, eventually, bandwidth on demand with tailored service-level agreements (SLAs).

Summary

As telecommunication networks are pressured to meet changing and unfavorable economic conditions, carriers are being forced to reconsider their strategies for handling traffic and services. With the type of equipment in today's networks, bandwidth is expensive and difficult to deploy, and the cost of a connection increases with transmission distance, whereas revenues do not. Legacy SONET/synchronous digital hierarchy (SDH)–based WDM networks have met soaring capacity requirements, but at high cost and with inherent constraints on scalability and efficiency.

The survivors of the next decade will be the ones that cross the "telechasm" from legacy networks to *optically optimized* networks—in which optical technologies are strategically deployed where they offer the greatest ROI and lowest cost of ownership.

For many carriers, the optically optimized network is largely based on legacy equipment for now, complemented with hybrid electronic/optical technologies that stage for the future with a clear migration path toward all-optical core networking whenever it is required.

As carriers' traffic is increasingly dominated by data, network capacity must expand. The problem is how to expand. To continue the legacy architecture optimized for voice traffic, where the majority of calls occur within 600 to 700 kilometers, is to miss important opportunities to improve the profitability and overall performance of your business. Data communications typically span 2,500 to 3,000 kilometers. To optimize performance and profitability, a different kind of network is required: an optically optimized network. The optically optimized architecture exploits the legacy network for local/regional grooming and transports long-distance traffic on an efficient, all-optical mesh overlay core—analogous to an express highway system.

With judicious implementation of optical innovations, carriers can start migrating traffic from legacy SONET/SDH networks to optically optimized core overlays and reap the benefits of optical in the time frame that suits their requirements and business case.

Carriers that adopt optically optimized networks will be able to do the following:

- Grow their businesses while controlling capital and operating expenses
- Differentiate themselves with record speed and flexibility—primarily the ability to provision new services in minutes or hours instead of months
- Expand their addressable market by offering unique, short-term revenue services and "liquid bandwidth"
- Operate with efficiencies that allow for profits despite intense competition

Enabling Multiservice Carrier Networks Using MPLS

Steve Vogelsang
Vice President and Co-Founder
Laurel Networks, Inc.

Introduction

The past several years have witnessed dramatic growth in demand for bandwidth and Internet protocol (IP) services. Service providers responded with equally dramatic investments in their core IP network infrastructure to add capacity and support IP–based services such as Internet access, transport, and Web hosting. As a result, the following has occurred:

- Service providers' IP backbone capacity exceeds that of their frame-relay and asynchronous transfer mode (ATM) service backbones, and in many cases contains unused excess capacity.
- Equipment vendors have built terabit routers that dwarf the capacity of ATM switches.

Today's economic climate is forcing service providers to slow their investment in core network capacity and instead focus on profitability. The unused excess capacity on IP backbones, along with the need to achieve profitability from their IP network investment, are causing many service providers to seek ways to derive additional service revenues from their IP network.

Service providers are now at a critical crossroad in the development of their data networks. While ATM and frame-relay networks are a key source of current revenue, their IP infrastructure represents future revenue streams and new service opportunities.

What if the excess capacity in service-provider IP networks could be used to deliver existing Layer-2 services such as frame relay and ATM? Service providers could achieve increased profitability through the following:

- Reduced infrastructure cost by deploying frame relay and ATM service over a single IP backbone.
- Increased revenue by using their IP network to support new, revenue-generating IP services.

Enter multiprotocol label switching (MPLS). Once viewed only as a traffic-engineering technology, service providers have begun to see MPLS as the missing link that can turn their IP backbone into a true multiservice infrastructure. And for good reason: Today's IP–based core routers have backplane capacity and interface speeds that surpass their ATM and frame-relay switch counterparts. MPLS brings the connection-oriented forwarding necessary for private data transport services to the IP network, while also offering the quality of service (QoS) and bandwidth-management functionality of traditional frame-relay and ATM networks.

MPLS technology combined with service edge routing enables service providers to offer existing, profitable Layer-2 private data services such as frame relay and ATM, as well as new services, such as Ethernet private line, over their IP backbone.

Multiservice over MPLS enables service providers to offer switched services as well as IP services on a common edge routing platform. Services now possible over a single IP/MPLS backbone include Ethernet private line, frame relay, and ATM services, as well as Internet access, transit, peering, and virtual private networks (VPNs).

MPLS: A Common Forwarding Plane for All Services

MPLS is an efficient tunneling mechanism with an IP control plane. It allows network engineers to create tunnels, called label-switched paths (LSPs), across their IP backbone. An MPLS–capable service edge router inserts packets into these tunnels by pre-pending one or more 4-octet labels to the packet. Interior MPLS capable devices, called label-switched routers, forward these packets based solely on these labels.

MPLS tunnels require less overhead than IP–based tunnels (such as L2TP, GRE, and IP in IP). In addition, MPLS tunnels offer the same security as frame relay or ATM permanent virtual circuits (PVCs) and are not as susceptible to denial-of-service attacks as IP–based tunnels. For example, an attacker may inject packets into an IP tunnel simply by sending traffic to the tunnel endpoint address. However, it is as difficult to inject packets into an MPLS tunnel as it is to inject them into an ATM or frame-relay PVC.

The first application of MPLS tunnels was traffic engineering, applied to the core of service-provider networks. The normal hop-by-hop, destination-based forwarding mechanism employed by IP routers tends to cause high utilization on certain network links, while other links remain relatively idle. MPLS gives service providers more control over the path IP traffic takes across the network. IP packets enter an MPLS tunnel near the edge of the network, and the service provider manipulates the path of each tunnel, enabling the provider to balance utilization on network links and increase overall efficiency.

Although traffic engineering is an important function in the network core, it is at the edge of the network that service providers can reap the greatest benefits of MPLS technology. Laurel Networks' MPLS implementation was designed specifically to support existing applications such as IP traffic engineering and Layer-3 VPNs, as well as Layer-2 transport—a promising emerging application of MPLS.

MPLS has two basic features that enable the transport of a variety of data services:

1. *Protocol Transparency:* Once an edge router forwards a set of MPLS labels, core devices forward packets based only upon these labels, not based upon any field inside the original packet. As a result, MPLS is not limited to IP transport. It can carry any type of traffic including frame relay, ATM, Ethernet, point-to-point protocol (PPP), and even time division multiplexing (TDM).
2. *Hierarchical Tunnels:* MPLS tunnels are hierarchical, meaning that an MPLS tunnel can be inserted inside another tunnel by using the MPLS label-stacking mechanism. This gives service providers tremendous flexibility and scalability, as many tunnels can be aggregated into a relatively small set of tunnels in the network core. This also has service restoration benefits, since a core network failure results in fewer connections to reroute.

MPLS: A Natural Evolution from ATM Networks

Until recently, ATM switches enjoyed a capacity and interface throughput advantage over routers, leading to widespread adoption of ATM switches at the core of service-provider networks. Some of the largest IP networks are based on a Layer-2 switched core. This design—called the overlay model—allows the provider to achieve virtual connectivity across physical backbone links, which is beneficial in terms of flexibility and traffic engineering. However, like the frame-relay switches before them, capacity-constrained ATM switches are being steadily removed from the core of most IP networks and replaced with core IP routers. The reason is speed.

The development of MPLS technology and new router interfaces based on high-speed Ethernet and packet over SONET (POS) have increased the speed and capacity of routers beyond that of Layer-2 switches, while lowering the cost per bit forwarded. Router and MPLS switch interfaces now enjoy a significant speed advantage over ATM switches. While current router ATM interfaces are limited to optical carrier (OC)–12c/synchronous transfer mode (STM)–4 (622 Mbps), POS interfaces scale to OC–192c/STM–64 (10 Gbps). ATM's cell tax—unusable bandwidth due to cell overhead—has made it an easy target for criticism. Fixed size cells allow ATM to offer deterministic delay characteristics. This functionality is most applicable to controlling latency of real-time service delivery such as voice on lower-speed access links. Yet, its fixed cell size makes ATM inefficient as a high-speed backbone.

ATM was adopted due to another advantage it had over routers: traffic engineering. Since Layer-2 switches are connection-oriented (unlike connectionless IP routers), service providers can better control the path that traffic traverses through the network to optimize network utilization and control the use of expensive long-haul links.

The need for traffic engineering in IP networks like that found in ATM networks led to the development of MPLS. MPLS provides an IP network with the same traffic-engineering advantages of the Layer-2 overlay model, while collapsing the function of routing and traffic engineering into a single device.

Benefits of an IP/MPLS Service Infrastructure

Service providers derive a number of benefits by adding Layer-2 services to their IP/MPLS networks:

- *Higher Capacity:* Demand for IP–based services continues to grow, and analysts expect revenues to surpass those from traditional frame-based services. Equipment vendors have responded by producing MPLS–capable routers that exceed the capacity of today's ATM switches.
- *Edge Service Creation:* Traditional frame-relay and ATM provisioning models require the service provider to maintain the connection state throughout the core network. In contrast, Layer-2 services over MPLS require the service provider to maintain connection state only at the edge of the network—service creation at the edge and service transparency at the core. Once inside the tunnel, all packet types are forwarded via label swapping in the core, allowing for a more scalable service backbone.
- *Common Control Plane:* Because MPLS switching is compatible with the IP routing control plane, a common control plane can be used for the converged network, improving overall network and service ease of management.
- *Fewer Connections to Manage:* In an ATM network, the call signaling rate is a critical measurement of performance, as a core network failure can cause thousands of connections to be cleared and rerouted. MPLS hierarchical tunneling requires far fewer core connections to reroute, eliminating most of the signaling burden when compared to an ATM network.
- *Network Consolidation:* A common MPLS core becomes the backbone for IP, ATM, frame-relay, and Ethernet service networks, reducing the investment required to scale existing services while enabling new services and service bundles.
- *Fast Restoration:* Advanced MPLS features such as primary/secondary explicitly routed paths, standby paths, and pre-emption allow service providers to define varying degrees of service restoration.

Combining Edge Routing with Layer-2 Services

Service edge routers combine the full IP functionality of a high-capacity edge router with the ability to create native Layer-2 services across an IP/MPLS backbone. The service edge router is an integral part of a service provider's IP network because it enables the sophisticated policy driven accounting and packet classification models needed for a provider to deliver and bill for new, premium services. The service edge router participates in Internet routing and therefore knows the ultimate destination of traffic (BGP next-hop with community), the number and capacity of the links (IGP LSDB) that the packet will traverse, and the set of ISPs (AS Path) that the packet must traverse to reach its final destination. The service edge router is capable of maintaining separate virtual routing tables for each customer site and of advertising the entire Internet routing table to a number of customers. It is this routing intelligence, combined with high-speed packet classification and accounting, that enables the use of the same IP/MPLS platform for all services.

Service edge routers are now being offered that include Layer-2 transport technology based on the following Internet drafts:

- *Transport of Layer-2 Frames over MPLS* (*draft-martini-l2circuit-trans-mpls-06.txt*) defines a signaling mechanism, based on the MPLS label-distribution protocol (LDP), which allows for the creation and status notification of Layer-2 transports.
- *Encapsulation Methods for Transport of Layer-2 Frames over MPLS* (*draft-martini-l2circuit-encap-mpls-02.txt*) defines the encapsulation for various Layer-2 frames, such as frame relay, Ethernet, ATM AAL–5, and ATM cell mode.

New Service Opportunity: Ethernet Private Line

Layer-2 transport technology (also called multiservice over MPLS) allows service providers to sustain revenue from existing ATM and frame-relay services. In addition, Layer-2 transport presents a new opportunity to extend Ethernet, a widely used and understood technology, beyond the reach of local and metropolitan-area networks (MANs). The ability to transport Layer-2 Ethernet traffic over the IP/MPLS backbone opens up the possibility of long-haul Ethernet private line (EPL) services between remote sites. This leverages the equipment already in place in the enterprise and the IP/MPLS infrastructure deployed by service providers.

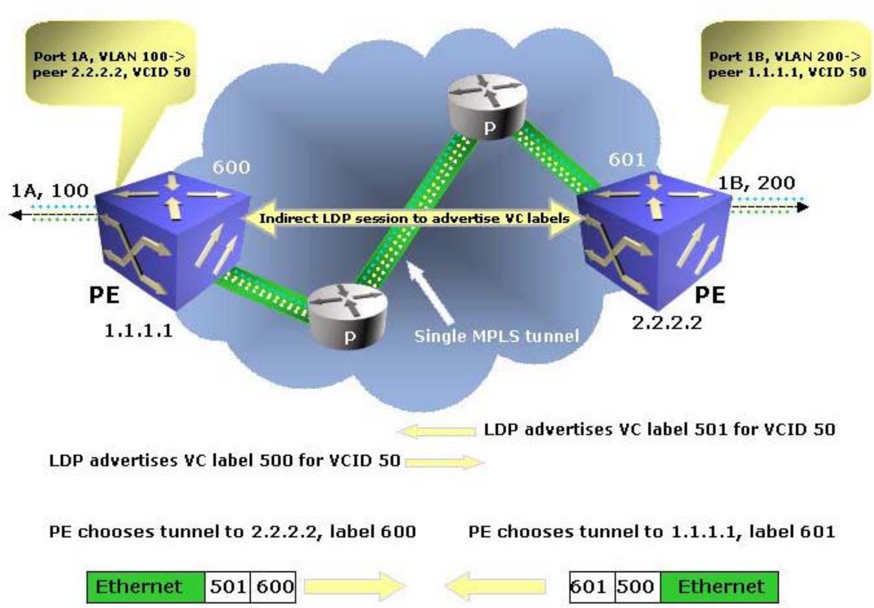
The network architecture to implement EPL across an IP/MPLS backbone is illustrated in *Figure 1*. A service edge router is deployed in the service-provider point of presence (POP), delivering a Gigabit Ethernet port to the customer. The service provider may offer Internet access on one virtual local-area network (VLAN), while using other VLANs for EPL service. To deliver the EPL service, the service edge router adds two MPLS labels to each Ethernet frame received from the customer.

- The outer label or *tunnel label* defines the MPLS path between the two edge routers. All intermediate devices along the path forward packets based on the tunnel label.
- The inner label or *virtual connection (VC) label* associates the Ethernet frame with an outgoing port, enabling the service provider to support multiple EPL connections on the same tunnel.

The service provider provisions the Ethernet service by choosing two Ethernet ports to connect on the edge routers

FIGURE 1

Ethernet Private Line Service Using MPLS



and by defining the MPLS tunnel to transport the Ethernet frames. Upon configuration, each edge router binds a locally significant VC label to its Ethernet port, and then advertises this label to its peer edge router. These labels are exchanged using LDP running in extended discovery mode, as defined in RFC 3036.

MPLS Tunnel Determines Service Characteristics

There are two choices when constructing an MPLS tunnels to carry Ethernet traffic: LDP and resource reservation protocol–traffic engineering (RSVP–TE). Tunnel creation and selection largely determine the attributes of the Layer-2 transport service offered.

Advantages of Using LDP for Tunnel Creation:

- *Simple Provisioning:* LDP can be configured to advertise only tunnels to the IP loopback addresses used to create Layer-2 service bindings.
- *Automatically Routed:* Tunnels follow the IP routed path.
- *Simple Class of Service:* Differentiated service levels are provided using simple DiffServ markings to indicate for the service class for Layer-2 transport frames on the MPLS backbone.

Advantages of Using RSVP–TE for Tunnel Creation:

- *Provides Bandwidth Reservation across the Core:* A service provider may request dedicated bandwidth for a particular tunnel, guaranteeing service levels for a group of Layer-2 transport services.
- *Provider-Controlled Path Selection:* RSVP–TE's source routing mechanism allows a provider to control the path that its Layer-2 services takes through its network (i.e., traffic engineering).
- *Optional Fast Recovery Schemes:* RSVP–TE signaling allows a service provider to control path re-optimization after a failure. Once a failure occurs and a tunnel is rerouted, the service provider may not want to automatically switch back to the previous path when it becomes available.

Conclusion

Layer-2 private data services such as frame relay and ATM are an important source of service-provider revenue today, while IP-–based services represent future revenue growth. New products combine the traffic management of today's frame-relay and ATM switches with the IP forwarding capabilities of an Internet scale router, enabling service providers to offer traditional private data services, as well new services, such as Ethernet private line, on a combined IP/MPLS network.

Driving Managed IP Service Profitability with Dense Virtual Routing

Gerald Wesel
President and Chief Executive Officer
Crescent Networks, Inc.

To build a sustainable and competitive portfolio of enterprise data services, network service providers (NSPs) need to find ways to increase the profitability of their Internet protocol (IP) services. This pursuit has led many service providers to extend beyond conventional dedicated Internet access services and begin offering a variety of managed IP services. Unlike traditional Internet access service, where a NSP simply delivers a bandwidth pipe between an enterprise user and an Internet service provider (ISP), in a managed service, a network provider takes on additional responsibilities for deploying, configuring, and managing wide-area network (WAN) switching and routing equipment for enterprise customers. Managed services enable enterprise users to reduce their operating expenses and focus on their core business by outsourcing their WAN backbone to an NSP partner. This also allow NSPs to increase the profit margins of their IP service portfolio and increase customer retention by taking over management of their enterprise customer's strategic WAN. As a result, the market research firm Gartner Group projects that managed-service revenue growth will outpace that of all other public data services through 2005, growing to a market of more than $9 billion in 2005.

This paper reviews a number of different architecture models that are available to NSPs for managed IP services, including a managed customer-premises equipment (CPE) router architecture, a network-based stacked edge router architecture, RFC 2547, and dense virtual routed networking (DVRN).

Enterprise-Based WAN Solutions

Traditionally, to interconnect their sites, enterprises deployed dedicated access routers at each of their locations and then interconnected these routers over a set of Layer-2 logical connections and Layer-1 physical links (e.g., frame relay, leased line, or Ethernet). The resulting network provided enterprises with a relatively secure backbone for their intranet traffic with consistent and predictable performance. Although the traffic of multiple customers was transported on the same physical facilities over the backbone, their traffic was separated into different timeslots, asynchronous transfer mode (ATM) virtual channels, or frame-relay connections.

In this model, the enterprise incurred the capital expense of purchasing the routers, and, more importantly, incurred the ongoing operating expense of configuring and maintaining each of the routers. Many enterprises have found it very difficult and expensive to attract and retain qualified support personnel with the necessary level of experience with routed networks.

A second approach that some enterprises have taken is to use tunneling technologies—such as IPsec, point-to-point tunneling protocol (PPTP), and Layer-2 tunneling protocol (L2TP)—to interconnect their sites over the public Internet. With this approach, businesses place a virtual private network (VPN) gateway network element and an access router at each site and configure a set of Layer-2 tunnels over a service provider's IP backbone network to interconnect their sites. All traffic is encrypted at the customer's premise by the VPN gateway before being routed to the backbone. It is then decrypted at the destination by another VPN gateway.

While this approach provides an additional level of security for enterprise users without the ongoing expense of leased lines, frame relay, or ATM connections, it requires higher up-front capital equipment expenditure for the VPN gateways. In addition, because of the complexity of configuring and maintaining the necessary tunnels and encryptions keys, this model usually results in higher recurring operating expenses than the first model.

The Introduction of Managed Services

NSPs initially entered the managed services market several years ago to enable enterprises to outsource the day-to-day management of their WAN access routers to the NSP. The

NSP combined management of CPE routers with frame relay or IP services into a single managed service, and took on the responsibility for managing enterprise customers' routers at each office location of the customers network. A number of NSPs have also begun leasing and reselling WAN access routers to enterprise customers as part of their managed service offering, giving enterprises a single point of contact and responsibility for all of their data WAN needs.

Enterprises continue to use routed networks for their WAN data traffic because it is the only way to achieve some essential requirements, including the following:

Media and Layer-2 Protocol Diversity
Routers enable an enterprise to communicate between sites with a mixture of frame relay, ATM, leased line, and Ethernet connections in their WAN.

Eliminates Need for Full N^2 Mesh of Layer-1 or Layer-2 Connections
The use of routers significantly reduces the number and cost of leased lines or virtual circuits that are required for a fully connected enterprise WAN.

Resiliency to Network Failures
Routers provide a fault-tolerant, self-healing mechanism for automatically rerouting traffic in the event of network failures.

This first generation of managed services has enabled enterprise users to save money by outsourcing their backbone WAN for data services to an NSP. However, NSPs have been prevented from scaling these types of managed CPE services to all of their enterprise customers because of the operational cost and complexity of configuring and maintaining many CPE routers in many different locations. The cost and management complexity has simply been transferred from the enterprise to the NSP.

Network-Based Solutions for Managed Services

Stacked Edge Routers
Because of the high operating expense of deploying and managing a large number of widely-distributed CPE access routers, NSPs modified their managed service offering and started to move the regional hub routers of enterprise customers to their own point-of-presence (POP) locations. This allowed the service provider to reduce the number of truck rolls required for router maintenance and the number of support staff required for their managed services. The NSP installed a separate edge router in their POP for each enterprise customer to ensure separation of route tables, support consistent performance, and make sure that problems in one customer's network (e.g., distributed denial-of-service [DDOS] attack) would not impact that of another customer. Without this type of physical separation, one enterprise customer could monopolize the memory, bandwidth, or processing resources of a router, adversely impacting the service level of other customers.

Although this network-based managed router service reduced the NSPs' operating expenses compared to the managed CPE router model, it required additional rack space and power in the NSPs' POP locations and still required a high initial capital equipment expenditure per customer and high ongoing operational expenses for configuration and management of multiple POP–based edge routers. As a result, the economics of this network-based model with discrete edge routers prevented NSPs from delivering managed services to all but their largest enterprise customers.

RFC 2547
The network working group of the Internet Engineering Task Force (IETF) has developed an approach to enable multiple IP VPNs to be delivered over a shared IP backbone network based on extensions to the border gateway protocol (BGP) routing protocol. This approach is described in RFC 2547bis, "BGP/MPLS VPNs." NSPs can use RFC 2547 to support several different enterprise customers on a single edge router, each with their own separate virtual route forwarding (VRF) instance. Multiprotocol label switching (MPLS) label-switched paths (LSPs) are also employed as tunnels to separate the traffic of different customers over an IP backbone network.

In smaller scale applications, RFC 2547 allows service providers to deliver managed services to multiple enterprise customers from a POP location without deploying and maintaining a separate edge router for each customer. However, a number of NSPs that have tested RFC 2547 and deployed it on a limited basis in their networks have identified several issues with the technology, including the following:

- RFC 2547 advertises VRF information on each customer's VPN into the global routing table, resulting in accelerated growth in the size of BGP route tables on every router in the NSPs BGP network.
- Provisioning of RFC 2547 VRFs requires extensive manual configuration with basic command line interface tools, which drives up operating expenses and lengthens the NSPs service delivery interval.
- Changes are often required in the enterprise customer's open shortest path first (OSPF) network design, since many features–such as preservation of link metrics, multiple areas, virtual links, and passive interfaces—are not supported by RFC 2547.
- Forwarding performance of edge routers decreases as more VRFs are provisioned, limiting the effective scalability of RFC 2547 networks.

RFC 2547 extends the value of service-provider investments in core and edge routers and can support multiple VPNs over a shared IP backbone network. However, the technology has still not enabled NSPs to extend managed services to the majority of their enterprise customers that have larger networks.

Dense Virtual Routing
Crescent Networks has introduced an alternative architecture for managed services called dense virtual routed networking (DVRN) that enables network service providers to deliver large numbers of dedicated virtual routed networks (VRNs) to individual customers.

The virtual router–based model, as realized with the DVRN architecture, provides features that extend beyond those in conventional RFC 2547. The virtual-router model permits each customer's service to be independently configured for routing protocols, policies, traffic engineering, and quality of service (QoS), with no impact on the customer's existing IP address scheme. The virtual-router model is the best fit for NSPs that are targeting medium to large enterprises that today run their business on leased-line, frame-relay, and ATM WANs and are looking for cost-effective managed service. Furthermore, the virtual-router model is ideally suited to complement emerging MPLS/optical networks, since it does not rely on any specific routing protocol in the core network. The DVRN architecture can run over a pure label-switched router (LSR) core or dedicated packet over SONET (PoS)/GigE on an optical backbone network.

A DVRN deployment consists of DVRN–capable service edge routers plus DVRN service-management software. The DVRN service edge router combines several types of virtual routing with MPLS label edge routing functions. Virtual-router types include virtual access routers (VARs) for individual subscribers and a virtual backbone router (VBR) for service edge router discovery, internetworking, and aggregate traffic engineering.

The VARs are then interconnected with a collection of tunnels, such as MPLS LSPs, ATM virtual circuits, or generic routing encapsulation (GRE) tunnels over an IP backbone. If MPLS LSPs are used, they may be traffic-engineered in conjunction with other core LSRs. The use of stacked tunnels provides tremendous granularity for individual customers. Stacked tunnels also enable core scalability by aggregating the many routed network instances into a manageable number of logical connections into the core. The VARs and interconnecting tunnels of an enterprise customer comprise a VRN for that enterprise over the service provider's backbone network.

To enable NSPs to scale the delivery of managed services to all of their enterprise customers, the operational cost of provisioning new customers must be significantly reduced. This can be accomplished by minimizing the amount of network engineering that must be done for each new customer and by delivering graphical provisioning and management tools that simplify and accelerate the service-delivery process.

DVRN service management automates much of the service design and provisioning process, requiring minimal intervention (through an application programming interface [API] or graphical user interface [GUI]) to customize the service for a customer. Once a VRN has been established, additional sites can be easily added to or deleted from the VRN, and additional service enhancements can be added beyond the basic managed service. For instance, a hosted storage service with specific QoS requirements can be provisioned through a single "drag-and-drop" action onto the VRN, rather than with hours of complex manual provisioning with command line interface tools. The service-management tools of DVRN can reduce operating expenses for managed services by as much as 70 percent.

The DVRN architecture is capable of supporting a wide range of applications, including managed services and conventional dedicated Internet access services. For instance, an NSP can initially offer a standard dedicated Internet access service, extend the service with a managed service offering for improved enterprise connectivity, and then bundle the managed service with xSP infrastructure services, such as content delivery, hosted storage, and applications hosting. Each VRN operates as a distinct customized routed network tuned to the needs of its particular customer and applications. A NSP may set up VRNs to seamlessly connect xSPs with their enterprise customers. VRNs can also be provisioned to provide xSPs a way to expand into new geographic regions.

DVRN provides a platform for a cost-effective and seamless suite of managed IP services—such as intranet and extranet—along with conventional dedicated Internet access services. VRNs can create dynamic any-to-any connectivity between a corporate headquarters over optical Ethernet or leased-line connections, branch offices over frame relay and digital subscriber line (DSL), teleworkers, and partners over remote-access VPN tunnels. If an enterprise has already deployed a routed WAN, this network can be outsourced to a provider-based managed service with no impact on the customer's local-area network (LAN) or routed backbone network architecture.

The DVRN architecture delivers several significant advantages other alternative approaches for managed services, including the following:

- Significantly lower capital expense than approaches based on stacked edge routers or RFC 2547
- Dramatically reduced operations expense based on use of traffic-engineering protocols and graphical provisioning and management tools
- Protocol flexibility—DVRN enables service providers to offer their customers their choice of interior gateway protocols (IGPs), along with supporting managed services over ATM, IP, and MPLS backbone networks
- Enhanced scalability, including the ability to support hundreds of enterprise and service-provider customers from a single platform

As a result, the use of DVRN can dramatically increase the profitability of NSP managed IP services over alternative network-based or enterprise-based solutions.

Summary

In their efforts to improve the profitability of their IP service portfolio, NSPs have begun to offer a variety of managed IP services to their enterprise customers, allowing these customers to outsource the deployment and management of their data backbone network to the NSP. Several architectural models have developed for the deployment of managed services, including a managed CPE router, stacked edge router, RFC 2547, and DVRN. The DVRN architecture can dramatically increase the profitability of NSP managed IP services by lowering the initial capital equipment expense, and ongoing operating expense, of managed services.

Broadband and the Opportunity Before Us

Edward E. Whitacre, Jr.
Chairman and Chief Executive Officer
SBC Communications Inc.

My discussion here focuses on the need for balanced broadband regulation. It reminds me of the time a young teacher was up for a job in a small, unsophisticated country town. During the interview, the principal asked the young man if he taught that the Earth was round or flat. Anxious to get the job, he said, "Well, I can teach it either way."

When it comes to talking about broadband, I'm sure many of us feel the same way. I know where our competitors stand on the issues. I understand most regulators concerns. And I'm sure you have a pretty good sense of my views. We are familiar with each other's positions, and we know what familiarity breeds, right? However, I want to say at the outset that there is no room for contempt in this issue. I appreciate the stake that everyone has taken in this important debate. I have done my level best to understand them. Of course, there are some legitimate disagreements.

But as I look over the telecom landscape, especially broadband, I see that we share many common goals. And I see a lot of room for agreement. I think all of us are optimistic over the prospect of a fresh start in 2002, particularly after the year we went through in 2001.

But we have more to be hopeful for than just a fresh start. I believe that there are significant opportunities just within our grasp. Opportunities to provide Americans with an amazing array of new communications products and services. Opportunities to create jobs in an economy that lost 2 million last year—more than 300,000 in the telecom sector alone. Opportunities to pull the nation's contracting economy out of the doldrums by generating billions of dollars of growth annually. I believe that we have before us the opportunity to return the information technology (IT) sector to its role as one of the leading elements of economic expansion in America—and to ensure that Americans remain at the forefront of the technology curve.

We can do all of that if we, as industry leaders and as policymakers, accept our responsibility to get the policy regarding broadband right—and if we act quickly.

I mentioned that I see many of areas of agreement on this, and I would like to spend a little time now reviewing those areas. If we can accept this set of facts, I believe it will lead us all to a similar conclusion about the need for a consistent national broadband policy.

First, we share a common goal of deploying broadband to consumers and the businesses. There is remarkable agreement on this point—from Silicon Valley to the marble hallways of Washington. I do not think that anyone seriously disputes the importance of broadband. Certainly, everyone understands the value of bigger, faster connections to homes and businesses. We recognize the incredible transformational potential of broadband in communications, in entertainment, and in how we do business.

Brookings Institution economist Robert Crandall estimates that accelerated broadband deployment could generate half a trillion dollars annually in economic growth. Now *that* is an economic stimulus package worthy of the name. And the even better news is that these benefits would come with no strings attached. No increased government spending, no taxes—nothing—so long as we allow the market to work fairly.

The second issue that we agree on is that consumers will certainly benefit from a wide array of choices. Consumers are best served when many competitors offer services over their own facilities using their own technologies. The good news is that situation exists today—for now. Today, there are at least four technologies competing to offer essentially similar broadband services: cable modem, satellite, fixed wireless, and digital subscriber line (DSL). None controls the only way into a consumer's home or place of business. Each serves its customers over its own facilities.

However, regulators have so far focused only on mandating additional competition for DSL service, but consumers do not distinguish among technology choices. Consumers only see a single broadband market, which is how it ought to be regulated.

How attractive is that market? The evidence is everywhere. It is in the $72 billion that Comcast is paying to acquire AT&T Broadband. Once that sale is complete, Comcast will become the nation's biggest cable company with 22 million subscribers. Not surprisingly, it will be the biggest broadband provider, too. The evidence is also in the $26 billion that EchoStar is paying to acquire DirecTV. Once that deal closes, EchosStar will command the satellite market, with a customer base of more than 16 million subscribers. And the evidence is in the billions that SBC is investing in new networks to bring DSL to our customers, and the billions more that other telephone companies are spending as well.

The third issue we can agree on is that all of this potential is tempered by reality—and the harsh reality is that for a variety of reasons, including uncertainty in the regulatory environment, America's broadband leadership is in question and in danger of slipping. Today, less than 10 percent of Americans have broadband service. That percentage is simply too low to attract the investment needed from software developers and equipment manufacturers to make the promise of broadband a reality. We have not yet reached the critical mass needed to produce the kinds of services that broadband can and will one day provide.

Worse still, we are falling behind other nations in the race to bring broadband to the mass market. Growth of broadband in the United States is significantly behind the growth rate in other regions. Take DSL, for example. During the second quarter of 2001, DSL grew at a rate of 35 percent in Europe and 37 percent in the Asian-Pacific. Here in America, DSL grew about half as fast in the same quarter at about 15 percent.

No one wants to see this nation lag the world in broadband. America cannot lead the world in growth if we do not act soon to remove the narrowband governor on our economy. In my view, these are the broad issues on which we can all agree: The telecom and broadband industry is hurting right now, which stymies the delivery of advanced services to consumers.

The potential of the broadband marketplace remains huge, as well as attractive enough to competitors that we are making equally huge bets on it. And the market is open to a range of companies, competing via different technologies. So, the logical question to ask is "What's the hold up?" We have the ingredients for a perfect storm of broadband competition: sizeable customer demand, numerous companies offering competing technologies and willing to invest big, and no barriers to customers. So why aren't we seeing more rapid deployment of broadband?

For us, the answer lies in one last indisputable issue: Of the competing broadband technologies, only one is regulated, and pervasively so. And in a strange twist, the regulated provider is not the one that controls 70 percent of the market. It is not the one that is closed to competitors that want access to their networks. That, of course, is cable.

Instead, it is telephone-company–provided DSL service that is regulated. It is DSL, which serves about 28 percent of the broadband market, that has been subject to rules and regulations intended for a bygone era of communications—while cable threatens to run away with the market, to the detriment of consumers.

The Telecommunications Act of 1996 set up rules under which our voice networks were opened to competitors: co-location, line sharing, deeply discounted pricing. We accept that for our legacy voice networks, which were built when we had an exclusive franchise, at prices set to recover costs. Yet this strategy does not work for new investments in new networks, where no cost recovery or customer is promised.

By applying yesterday's rules to today's networks, we have, in George Gilder's memorable phrase, "privatized the risk and socialized the reward." For incumbent local-exchange carriers (ILECs), such as SBC, the message is clear: Make the investment in new networks. Take the financial risk. Carry the excess capacity. If the bet pays off, competitors can piggyback on that investment at rent-controlled rates without investing a dime and without deploying any new technology of their own. If the bet fails, our shareholders are left holding the bag.

This is not an academic argument. The environment that we are in has real-world affects on our ability to deploy new networks efficiently and on our ability to compete effectively. Here's what I mean: In 1999, we unveiled a $6 billion project to bring broadband to many more customers across our region. But first, we were required to create a brand-new, standalone data subsidiary to provide DSL service. We had to hire, train, and transfer new employees; create new databases; transfer the network; and transfer customers to the new company. We created complex, duplicative systems that by themselves added $250 million in costs to us but zero to the value of the service being provided. You can imagine the millions it cost to create a new subsidiary, but you cannot imagine the damage it cost in terms of our ability to efficiently meet customer expectations. The cable companies cannot imagine it either, since they face no similar requirement.

Still, we plowed ahead with our new network—key elements of which are the thousands of neighborhood broadband gateways that we will install. These units house the electronics that make DSL possible. We are putting them in neighborhoods across our territory—rich and poor, urban and suburban—without cherry-picking communities. However, before we could turn these broadband gateways on, we asked for a ruling on a simple question: Who should own the equipment in the gateways—our telephone company or our advanced services subsidiary? The answer would determine how competitors would use our equipment.

This took almost nine months to resolve, thanks mostly to our competitors, which turned it into a contested regulatory proceeding. In that time, unregulated cable companies raced ahead with their deployment. We lost ground to them. And millions of consumers were forced to continue waiting for DSL.

Finally, the issues were settled with a great, big "yes…but." *Yes*, we could move forward, *but* SBC—and only SBC—was required to make our broadband gateways bigger to accommodate potential competitors. We were mandated to deploy optical concentration devices and to implement other requirements. All of this raised the cost of DSL deployment by more than $350 million, and here's the kicker: No competitor is using the optical concentration devices (OCDs) or the remote terminals (RTs). None.

Competitors may have gained something from the lengthy delay, but consumers and DSL technology were the losers. It is a simple proposition. If higher costs are incurred, customers must pay more for the service. Or, they will choose another technology instead. It diminishes our ability to deploy DSL, and the technology is harmed.

Broadband deployment requires massive capital investment. Responsible companies cannot make this level of investment on a whim. They do not do so if they believe the market is closed or if the opportunity to effectively compete is shut off. At SBC, we are investing in new networks because we are convinced of the viability of the broadband market, and we want to be a leader in it. But the reality is that the capital risk is squarely on our shareholders. While there is good demand for broadband, no one is promised anything. Some people do not use the Internet now and never will. Others are satisfied with dial-up. And those who want broadband have an array of choices.

However, if regulatory burdens cause DSL to be priced out of the market, we must make rational decisions and adjust our investment accordingly. This affects competing competitive local-exchange carriers (CLECs) as well as customers, but customers stand to lose the most if cable is left as the dominant, unregulated provider. That's not an outcome that anyone wants.

This asymmetrical regulation will lead us to an outcome that is bad for consumers and for our economy. It creates a disincentive for companies such as SBC to invest in and deploy new advanced networks. It forces the provider best able to compete against cable to slow down and reassess its strategy instead of pursuing it as vigorously as possible. That is certainly the case at SBC, where we have had to slow our broadband deployment.

The asymmetrical regulation also gives all competitors but one free rein to operate without concern for added cost and delay that regulation inevitably brings with it. That's bad news for my sector of the industry, but it's worse news for consumers who deserve a full range of broadband choices. On top of this, our competitors are urging state regulators to consider even more onerous and more expensive requirements on broadband, further clouding the future with uncertainty. So I hope it's clear why we so strongly support a coherent, pre-emptive federal broadband policy.

For us to seize the opportunity to keep American consumers at the vanguard of the broadband revolution, policymakers must seize this moment and let the free market work freely. We must create a consistent national policy on broadband and other advanced services. SBC and others like us want to compete under the same rules and investment incentives that apply to the dominant player in the broadband market. The real beauty is that removing the disincentives that we face would cost nothing—in terms of money or in the ability of competitors to maintain access to our networks. Competitors would keep their ability to resell our service or use our network to reach their customers. We will continue to make our networks open to Internet service providers (ISPs) without discrimination. In fact, by leveling the playing field, the only real threat of discrimination that hangs over this debate would be eliminated. Singling out one non-dominant technology for regulation, while the others are left alone, is unfair.

Common sense tells us that by allowing this asymmetrical environment to exist, policymakers have put themselves in a tough spot. They may not be perceived as having picked the winner in the broadband race, but they could be viewed as having settled on a loser. I know that's not what any of us wants. And I do not believe that is anyone's intent. But that is the potential affect.

When you get right down to it, the only threat is in not taking action. The threat lies in maintaining the status quo or allowing it to deteriorate into 50 different sets of rules and regulations. A patchwork quilt of regulations that apply to only one competitor—the one that is a distant second to the market leader—will not produce the results that this nation needs.

Yet it does not have to be this way, as history shows. Industry and policymakers have faced similar situations before, and made the right decision, to the benefit of millions of consumers. Years ago, the Federal Communications Commission (FCC) decided against applying legacy voice network rules to the emerging wireless industry. It deregulated the industry and pre-empted the states. Artificial long-distance boundaries were erased. Policymakers took a hands-off approach, choosing instead to let the emerging industry develop and mature on its own. No regulatory burdens were added. No disincentives were created. Many competitors came into the business and invested heavily in their own technologies and networks. As a result, the industry has flourished. Prices continue to fall, while innovation proceeds swiftly.

We can produce the same results in broadband. And I am optimistic that we will—not just because it's the New Year, but also because of some very encouraging words from FCC Chairman Michael Powell. Last October, Chairman Powell made it very clear that broadband infrastructure deployment is the FCC's central communications policy objective. In his announcement, he said that "substantial investment is required to build out the networks, and we should limit regulatory costs and regulatory uncertainty." And he added: "Broadband service should exist in a minimally regulated space."

When I heard those remarks, it was one of those "I wish I'd said that" moments. Still, we all know that stating policy goals and achieving them are two different things. Yet I believe that this is one goal that must be met. The promise that broadband offers to our economic well being and technological leadership is real. And the opportunity is now.

We can do exactly what Chairman Powell has described, in a way that protects competition and ensures a level playing field for all. Accomplishing that goal would be a resolution that every American would benefit from seeing us keep.

This presentation was made on January 14, 2002, at the Emerging Issues Policy Forum.

Integrating Enhanced Voice Collaboration Services in a Converged Network

Ed Yackey
Chief Technology Officer
Voyant Technologies

This paper will discuss how the network is changing and evolving, how those changes are reshaping voice collaboration, and what the future of voice collaboration will be within these networks.

The Network Is Shifting from Monolithic to Distributed

A recurring theme in today's communications market is the shift from monolithic to distributed networks. This evolution has affected the overall development and deployment of applications in the network.

The Monolithic Network

For example, the traditional circuit-switched architecture uses a monolithic network. It has a mainframe mentality, where one vendor provides all the services and equipment. It tends to be a closed and slow-moving environment in which it is difficult to drive innovation and be creative. Its advantages are that it is well understood and very stable. Additionally, from a service provider's perspective, an advantage is that a single accountable vendor provides a single point of contact when there are problems.

The Distributed Network

As the distributed network emerges, Internet protocol (IP) is becoming the foundation of the emerging packet-switched architecture. The distributed network offers integrated services and best-of-breed components. It is an open environment with fast time to market for new applications. Its main disadvantage is the uncertainty in standards that are still evolving. This has lead to integration challenges.

In the distributed network, services are "in the cloud." These services may include presence, voice conferencing, data conferencing, voice recognition, and billing services. Services may be interdependent or can be tied together to create new applications. Here, the focus is on the application, not the technology.

Some advantages of a distributed architecture include the option to select best-of-breed services, the ability to add new services without affecting existing ones, the capacity to scale each service independently, and the ability for multiple applications to use the same services. The distributed architecture significantly lowers the barriers to developing and deploying new applications, and it allows specialized vertical applications.

The Future of Collaborative Voice

The shift from a monolithic to a distributed network will change voice collaboration in several ways. It will make collaboration at a distance more convenient by making it possible to connect from any communication tool. It will make collaborative voice easy to use by allowing meetings to be controlled in a natural manner—not via touchtones. Finally, it will make voice collaboration more cost-efficient, removing price as a barrier.

These effects could result from the distributed network providing various endpoints, such as wireless, IP, personal computer (PC)–based software phones, and public switched telephone network (PSTN) phones. The network will also allow versatile controls, including controls based on voice, touchtone, PC, personal digital assistant (PDA), and wireless phone "browsers." Seamless convergence will make services natural and easy to use, hiding underlying technology. The network will address cost issues by leveraging technology to reduce operation, network, and equipment costs.

Network Innovation + Ease of Use + Application Adoption = Growth

Reservation-Based Audioconferencing

Around 20 years ago, audioconferencing was first created and deployed on reservation-based systems. In a reservation-based system, audioconference calls are considered events. The call has to be planned ahead and requires operator assistance. Back then, conferencing resources were limited and required a large operations staff. Thus, conferencing was treated as a very scarce resource.

Subscription-Based Audioconferencing

In the mid-to-late 1990s, subscription-based models for audioconferencing began to emerge. In this model, a conference user establishes a financial relationship with the service provider upon subscribing to the service. Users are given a phone number to use whenever they want to have a conference. Whenever that phone number is dialed, the conference is available and ready to use. Along with that subscription comes a profile that specifies the conference; for example, how many people might be in a conference, whether international dialing is included, whether it is possible to dial out, etc. The features associated with the profile are stored by the system.

In moving from a reservation-based model to a subscription-based model, existing customer usage typically increases 20 percent. In some cases this increase is seen almost immediately. This jump in usage exists primarily because of the system's ease of use and because an operator is not required for a conference. But subscription-based conferencing still accounts for only about 1 percent of long-distance telephony minutes. Thus, subscription-based conferencing is only a step in the overall evolution of collaborative voice.

Instant Conferencing

The next step is the instant model, in which the system itself has no forward knowledge of the event. Removing the need to provision customers in the system removes all ties from the underlying services to the application itself. This allows more applications to use the same services.

Figure 1 shows a graph that compares ease of use and volume of calls for collaborative voice services over time. After more than 15 years with no significant growth in reservation-based systems, growth in reservationless conferencing skyrocketed in only five years. Following that growth, the instant model, which uses IP, is expected to take hold as market trends continue. Ease of use, user interfaces, control, time, convenience, and transparency are all improving. There is an endpoint explosion, driven by wireless technology. Access to additional resources is also increasing, and the price per minute continues to decline.

A Transformation toward Unified Communications

Another way to look at this point is shown in *Figure 2*. Voice collaboration started as a stand-alone application with a decent-sized market, but it was not that interesting by itself.

As other applications were added along with voice conferencing, service providers started to offer voice- and data-sharing applications. Today, several service providers offer unified applications with voice conferencing and data conferencing. The applications are deployed to the end user as one service. End users are unaware that two systems underlie this application. Users receive access to a Web page that allows them to control both their data conferencing and their audioconferencing.

As the industry moves forward, audioconferencing is becoming a smaller piece of a larger application pie. It is becoming more of an enabling technology that other applications use. This is true for voice conferencing and for other services as well.

Example: IM + Presence + Conference

The following example shows how some of these services can start to be deployed in converged networks. Gary, who is at his desk, wants to talk with three coworkers. Typically,

FIGURE 1

Network Innovation + Ease of Use + Application Adoption = Growth

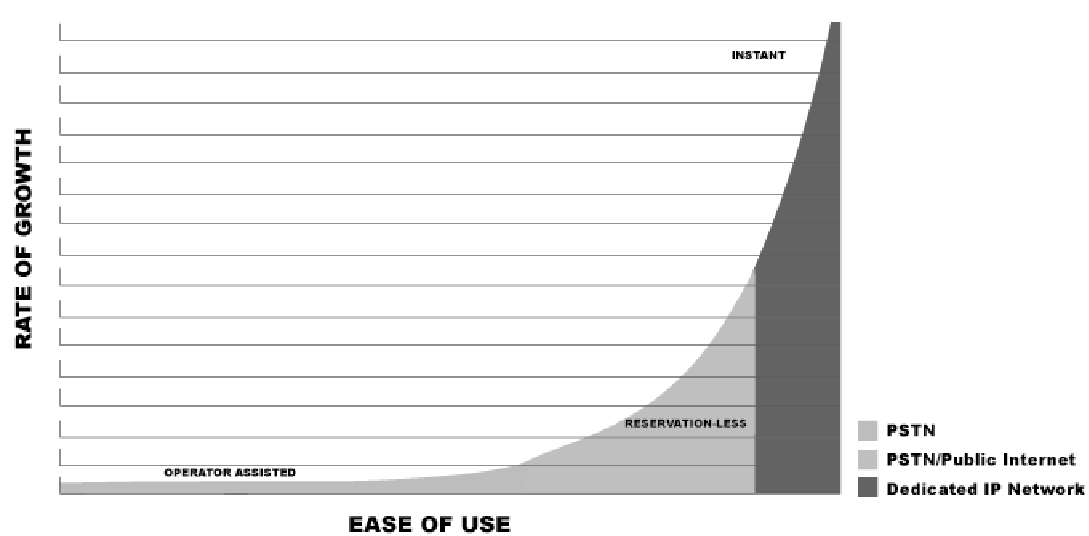


FIGURE 2

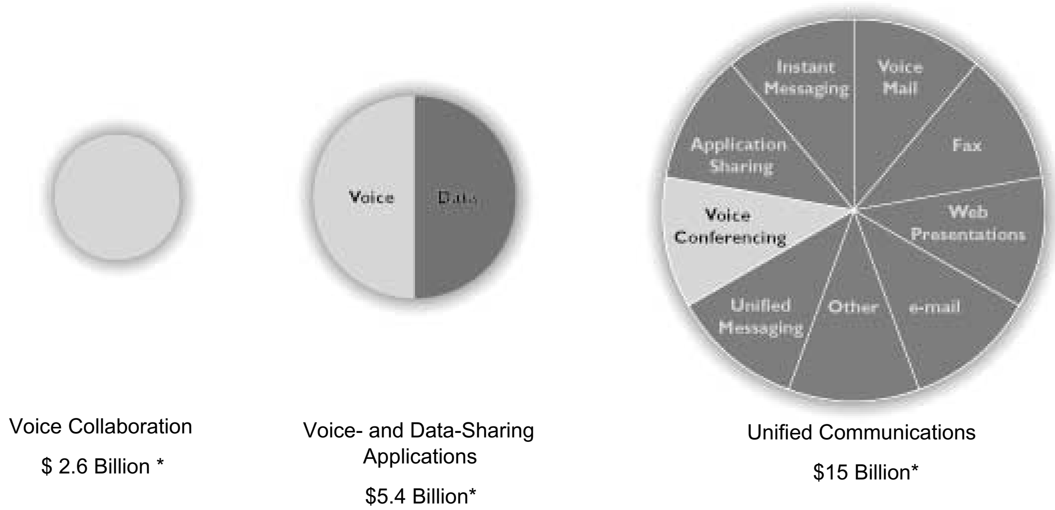
A Transformation toward Unified Communications



* Revenue figures are for 2003; cited by Telespan, IDC, and Piper Jaffery, respectively

he might walk outside his office to try to find the coworkers and pull them into the conference room. However, in this example he looks at his desk to check their presence and sees that none is currently available. He then logs onto his presence server on his desktop, clicks on the three people he wants to talk to on the PC instant messaging (IM) client, and then clicks on "voice" and "as soon as possible." That request registers with an application server in the network.

When all four people are available, the system initiates the voice conference by dialing out to them and placing them into a conference call. The people at their desktops communicate over their PSTN phones. Others talk over IP or wireless phones. If there is a need to share a slide or a spreadsheet during the conference, instead of stopping and restarting things, Gary can simply select "data" on his IM client to start a data conference and push up a slide show or spreadsheet. The slide show or spreadsheet will be shared over a PC at individual desktops, or over a PDA for users on the road.

Coupling the presence concept with the conferencing concept provides all the power needed to schedule the conference. Gary, in the example, does not have to know how to reach each person. All he has to do is enter a request to talk to them. Convergence of these different technologies and networks starts to provide a very rich experience that affects the end user's business day in a positive way.

Manage the Internal Changes to Fit the External Changes to Win the Competition in the New Era

Robert Zhang
Chief Executive Officer and President
ZoMatch (China), Inc.

The wireless telecommunications industry is changing rapidly. Because of the inventions and applications of new technologies, the new business model that is suitable to the new technologies and applications needs to be developed. Therefore, it is very critical how a company manages the internal changes to fit the external changes through aligning strategy and organization to position itself to win the competition in the future wireless telecommunications industry, especially the radio frequency (RF) components industry.

Background

Today' telecommunications industry is being shaped by several key factors: a rapid growth in mobile communications, explosive growth in broadband, stagnating revenues from core telephone services, falling prices and spreading competition, liberalization, and privatization.

Present and Future External Environment

According to research companies' studies, wireless mobile business is continuously growing strongly. In the developing market, the continuous expansion of the mobile network is necessary to support subscription growth. While in the developed market, the demand for mobile Internet is under the development. Third generation (3G) is close to implementation. Wireless data also looks as though it is going to be a huge business, such as IEEE802.11x standard–based wireless local-area network (WLAN) and IEEE802.16 standard–based wireless metropolitan-area network (WMAN) applications. According to J.P. Morgan's estimation, the European market alone for wireless data will be worth some $82.4 billion by 2010, with wireless data revenues in 2006 being larger than the existing voice market (by revenues) in 1999.

Furthermore, the three big wireless markets—the United States, Europe, and Asia (mainly China, Japan, Korea, and Taiwan)—are all growing, and the Chinese market is growing most rapidly. For example, looking at the Chinese market situation, the subscriber base increases at an unbelievable rate—the total for mobile subscribers there was about 140 million at the end of 2001. However, the penetration rate is only about 10 percent of the total population. There is still a lot of room to grow. More wireless infrastructure needs to be deployed to either increase network capacity or cover the uncovered areas. This is good news for equipment suppliers.

All of those factors are pushing up infrastructure demand. Similarly, mobile infrastructure will be heavily invested in during the next few years. However, on the other hand, the price erosion of telecom equipment is becoming worse. Because of this, the demand for RF components, with the lowest price for a given performance requirement product, will be huge and will continue to grow for quite a few years. The RF components business is not the same as the wireless or mobile infrastructure business. It doesn't depend on protocols. No matter what types of protocols the system houses adopt, they will need to have RF components to build their system.

RF Component Market Characteristics and Strategic Considerations

The RF component market is in high speed, characterized by rapid-fire technological change, short product cycles, and rapidly evolving customer requirements and expectations—all occurring at once. To be competitively successful in fast-changing markets, the following elements need to be considered when developing a corporate strategy:

- Invest aggressively in R&D to stay on the leading edge of technology know-how. Translate the advances into innovative new products. It is also important to focus R&D efforts in a few critical areas to avoid stretching the limited resources too thinly and to deepen expertise.
- Develop the organizational capability to respond quickly to important new events. Quick reaction times are essential because it is impossible to predict or foresee all of the changes that will occur. Resource flexibility tends to be a key successful factor in creating new

competencies and capabilities. Being a fast follower, if not the first mover, is critical.
- Rely on strategic partnerships with outside suppliers and with companies making tie-in products to perform those activities in the total industry value chain where they have specialized expertise and capabilities.
- Cutting-edge know-how and first-to-market capabilities are very valuable competitive assets.
- Strike a good balance between building a rich internal resource base that, on one hand, keeps time from being at the mercy of its suppliers and allies and, on the other hand, maintains organizational agility by relying on the resources and expertise of outsiders.

Strategy to Win the Competition

Companies need to develop suitable strategies according to external and internal environment and conditions. More importantly, the strategy that a company is going to develop or adopt needs to be able to utilize one's core competencies, create competitiveness, and build the entry barrier for other competitors. Because of the nature of the RF component industry, the strategy of being a best-cost supplier is recommended.

The reason to adopt this strategy is that it aims at giving customers more value for their money. It combines a strategic emphasis on low cost with a strategic emphasis on more than minimally acceptable quality, service, features, and performance. The idea is to create superior value by meeting or exceeding customers' expectations of key quality/service/features/performance attributes and by beating their expectations on price. The aim is to become the low-cost provider of a product or service with good-to-excellent attributes, and then use the cost advantage to under-price brands with comparable attributes.

What distinguishes a successful best-cost provider is having the resources, know-how, and capabilities to incorporate upscale product attributes at a low cost.

The advantages of this strategy are as follows:

- It has great appeal from the standpoint of competitive positioning.
- It produces superior customer value by balancing a strategic emphasis on low cost against a strategic emphasis on differentiation.
- It is a hybrid strategy that allows us to combine the competitive advantage of both low cost and differentiation to deliver superior customer value.

In markets where customer diversity makes product differentiation the norm, and where many customers are price- and value-sensitive, a best-cost producer strategy can be more advantageous than either a pure low-cost producer strategy or a pure differentiation strategy keyed to product superiority. This is because a best-cost supplier/provider can position itself near the middle of the market with either a medium-quality product at a below-average price, or a very good product at a medium price. Often the majority of customers prefer a mid-range product rather than the cheap, basic product of a low-cost producer or the expensive product of a top-of-the-line differentiator.

The next question is how a company can realize this crafted strategy—i.e., how does one implement it? The recommended strategy suggests that we need to develop an efficient organization to implement it. Because the organization consists of processes and individuals, we thus need to look at all of these levels.

Organization to Align with the Strategy

To build an efficient organization to fulfill the aforementioned requirements, one should focus on developing the organization and improving the performance from three levels: organization, process, and job/performer. With each level, three factors/variables will be adopted to evaluate performance needs, which determine effectiveness at each level and the effectiveness of any system. Combining theses three levels with the performance needs results in nine performance variables. *Table 1* illustrates the comprehensive set of improvement levers that a company's managers are suggested to use at any level.

To implement and apply this, one should do the following:

At the organization level, design the organization to implement the strategy effectively and efficiently—i.e., organization structure. Key success indicators need be developed throughout the targeted implementation areas in the company.

At the process level, key processes/procedures need to be developed, especially regarding manufacturing and quality

TABLE 1

	Goals	***Design***	***Management***
Organization Level	Organization Goals	Organization Design	Organization Management
Process Level	Process Goals	Process Design	Process Management
Job/Performer Level	Job Goals	Job Design	Job Management

control. Here is a sample list of processes/procedures needs to be developed:

- Business decision-making process
- Risk-control process
- Go/no-go business decision-making process
- Marketing process
- Customer-assessment process
- Resource -allocation process
- Project-management process
- R&D process/procedure
- Manufacturing process/procedures
- Quality-control process
- Supply-chain–control process

At the individual level, design the value and activity chains and jobs. Incorporate a system of reward and recognition that promotes implementation of the plans and stimulates employees' motivation. Design jobs, select people, and build and focus competence on corresponding key activities. Set team and individual performance objectives and allocate resources and support for achievements.

- Set progress milestones and review dates using project-management and evaluation tools to improve performance and measure progress.
- Identify major business risks and uncertainties. Develop control-driven contingency plans and protocols to deal with the unexpected.

Plan for Change

Today's telecommunication industry is an emerging industry. The speed of telecom-industry development is very fast compared with other industries. The external environment and competition landscape change quickly and frequently. The demand for organizational change has accelerated at an extraordinary pace in recent years. For example, mobile technology (from analogue to digital) has not only opened a big market for voice/data communications, but it also is replacing traditional circuit-based technology in the voice market. In the near future, the broadband wireless integrated services (voice, data, and image) will further impact the services on fixed wireline networks.

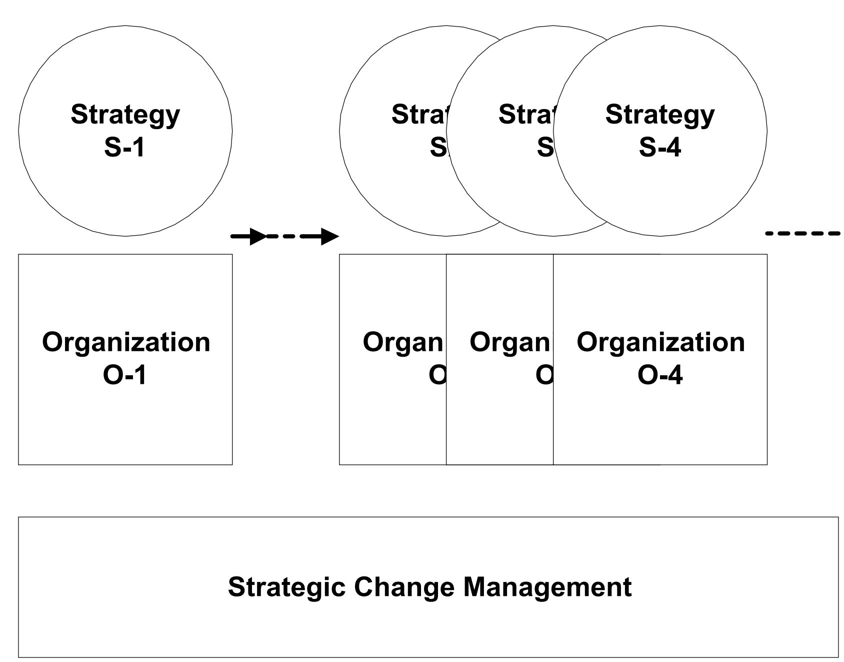
Enormous industry changes have brought us breathtaking opportunities. However, due to the needs to adopt new technologies and new business models, the old business strategy and organizational structure are under great pressure to be changed or modified. The companies in the telecommunications industry are all facing questions such as the following: What does it take for a company to be a part of this dynamic industry? How can we develop a strategy and build up an organizational structure that can adopt the external changes? This is indeed a challenge.

Modified Integrated Strategic Change Model

Considering the continuous changes in the outside environment, a Modified Integrated Strategic Change Model (MISCM) is suggested for adoption in order to fully accommodate external environment changes (see *Figure 1*).

While implementing strategic change, a company has to examine the alignment of strategic change. For the strategic analysis period, one needs to search for misfits, to pay attention to the process of aligning, and to define the specification of future alignment.

FIGURE 1



The MISCM suggests building up a timely strategic change-management system in the organization to manage the internal changes (strategy and organization) to fit the external changes. The MISCM provides a long-term source of competitive advantage—the capability to create and implement strategic change over and over again. Understanding this objective requires an understanding the sources, nature, and limits of competitive advantage. In the long run, however, any source of competitive advantage, while salient and important for a period of time, eventually shifts to other sources. The resources that once conferred an advantage to a company become irrelevant or depreciate in value. Thus, for any company, even sustainable advantages may provide performance enhancements only for a given time period.

Summary

Although the telecom industry is changing rapidly and many telecom companies failed quickly, I believe that a company is able to sustain its success as long as they successfully manage the internal changes (strategy and organization) to fit the external changes. It is a key management factor to being successful in the future, even faster-changing, telecom industry.

Section II:

Business, Marketing, and Regulatory Issues

Telecommunications Industry Overview

Market Dynamics Are Driving the Transition to a Converged Voice and Data Access World

Rob Avery

Vice President, Marketing

Gluon Networks, Inc.

Overview

We are living on the edge of the digital divide. Virtually every telephone worldwide is connected through an obsolete access network to a local switch that is not capable of delivering the services that users demand. Internet content and corporate virtual private networks (VPNs) have become richer, while large investments have been made in the core network adding up to terabits of capacity.

The access network and central office (CO) infrastructure are collectively viewed as the last remaining bottleneck to universal enhanced services. Two major forces are driving these changes in the telecommunications industry today: deregulation and technology.

Deregulation is driving the exponential growth of competitive services. The break-up of the Bell System in 1984 and the Telecommunications Act of 1996, which resulted in the creation of competitive local-exchange carriers (CLECs), were major catalysts of change. As a result, the domestic competitive landscape continues to accelerate while global competition is increasing due to World Trade Organization (WTO), European Union (E.U.), and other country directives.

Technology and market forces have also unleashed a whirlwind of change, including the recent dramatic growth of the Internet, the time division multiplexing (TDM)–to-packet network evolution, and an increased demand for broadband services. To meet these demands, a major transition from circuit-switched technology to packet-switched technology is occurring.

Packetized voice brings the advantages of lower capital and operational expense. It also has the ability to offer enhanced services cost-effectively and rapidly. Furthermore, it offers the efficient transport of voice and data on a common network infrastructure while providing increased networking flexibility and forward migration capability.

This transition is being reflected in market-analyst reports. In an August 2000 study by the Yankee Group, analysts concluded that service providers must provide a suite of integrated offerings including voice, data, and other broadband services while simplifying customer interaction and support. According to this study, network solutions should also provide the means for provisioning services and billing in a convenient manner.

Also driving the transition from circuit-switched technology to packet technology is the explosive growth in demand for high-speed data, both in the backbone of the network and in the local access loop. But, as reported in a front-page article in the *Wall Street Journal* (May 11, 2001), some 97 percent of the optical capacity of the core network is not being used today. This is due, in large part, to a lack of multiservice local access exchanges that could fill this gap by enabling a variety of advanced broadband offerings to move up stream.

As a result, both transport and converged switching capabilities are in high demand in the local-exchange and access network in order to adequately justify the high-bandwidth pipeline in the core network.

Demographics and cost-of-living economics are also contributing to the distribution of broadband services, as customers continue to move to the suburbs or rural areas. These customers are increasingly demanding advanced services. These demands are placing a heavy burden on the COs as local service providers attempt to find cost-effective solutions. According to one industry luminary:

"The first mile remains an important bottleneck. Fiber is still too expensive compared with copper, except where very high-speed applications are present… The core of the network has become a hybrid of wavelength (optical) switching and massive IP routing."

—Dr. John McQuillan
NGN Ventures, 2001

Historical Perspectives

From 1900 to the 1970s, beyond the provisioning of basic service, there were very few improvements in customer applications. Later on, Centrex features and custom calling services, or custom local-area signaling services (CLASS), provided by the local CO and new, colorful desktop/wall-mount customer-premises equipment (CPE) were the focus. On the business side during this period, upgrades included a wide range of private branch exchange (PBX) and key system features. Again, these were primarily focused on the provision of voice-grade services. Early forays into data services, such as the integrated services digital network (ISDN), were very expensive to implement, and high monthly subscription rates—coupled with a real lack of applications—kept widespread adoption at bay. In the final analysis, dial tone has not changed in more than 100 years.

At the same time, internal telephone company plant equipment, switches, and transmission facilities were being built at a hurried pace to match the rapid adoption of basic telephone service.

At the heart of the public switching network, the legacy Class-5 office handles local call switching and customer application features. The Class-5 office is the critical, initial point of access to the network for every subscriber line connected to the local exchange.

As the port of entry for all users of the public switched telecommunications highway and the originating source for dial-tone and telephony services, the end office is in a unique position. It influences all calls channeled through the various switching layers of the national hierarchy.

It is at the local CO, recently coined the "service point of presence" (SPOP), that cost-efficiency can be maximized and service provisioning and maintenance services can be optimized, with the help of intelligent softswitch functionality and packet connectivity layers.

Local Switching Adoption Cycles

Before exploring the critical, new role that Class-5 end-offices play in the emerging network, a brief overview of the five local switching adoption cycles that have occurred since the late 1800s is in order. While each cycle had a definite start date, in most cases, succeeding generations of switches overlap prior ones by a number of years, existing side by side at different locations. Each major cycle change has been a once-in-a-lifetime event (see *Figure 1*).

Cycle 1

In 1891, an undertaker by the name of Almon B. Strowger developed a dial-pulse–driven, electromechanical (or step-by-step) switch in response to his personal desire to thwart rivals from learning about his new business leads through operator-assisted calls.

Although he was not a telephone engineer, he reasoned that if users could dial calls directly, it would eliminate the need for an operator, and thus save his sagging funeral business from encroaching competition. He believed that the operator was diverting calls to his hometown competitor.

The "stepper," as it was called, was rugged and reliable. In fact, it was so robust that it remained in service as the principal network switching system for more than 75 years.

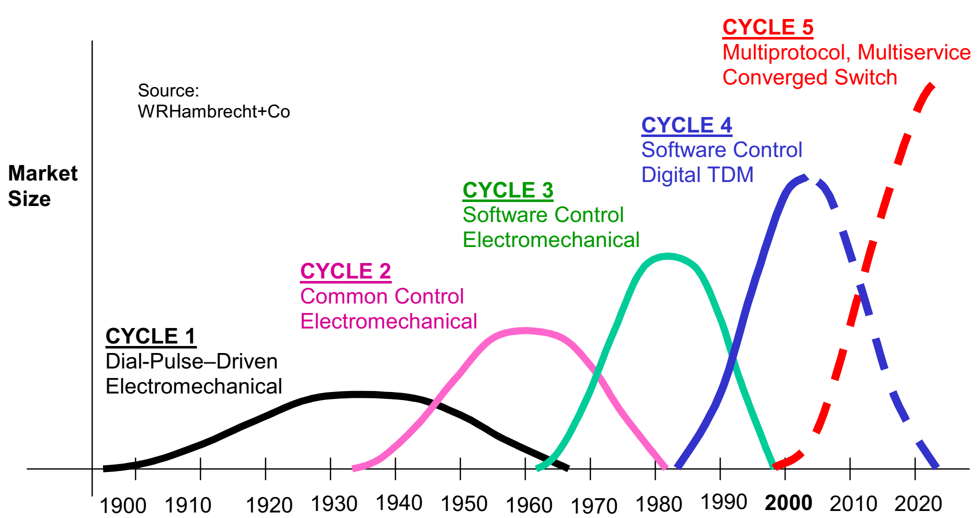
It is interesting to note that, from the beginning, innovation and early adoption of new switching and other technologies did not come from large, established service providers, but from smaller, independent phone companies and entrepreneurs.

Cycle 2

1938 witnessed the introduction of a common control electromechanical switch, known as the No.5 Crossbar, first installed in Brooklyn, New York. The crossbar switch greatly increased processing speed and switching volumes but retained overall system "intelligence" in the hardware.

FIGURE 1

The Five Adoption Cycles of Switching



Cycle 3

By 1965 computing technology had advanced to the point where the Bell System could deploy the first software-controlled electronic switching system, known as the No.1 ESS, initially in two New Jersey locations: Succasunna and Trenton. This system became the principal switching platform used in COs for some 35 years.

Cycle 4

The late 1960s and early 1970s saw the dawn of the Internet and the concurrent rise in digital data technologies. This led to the introduction of a new breed of software-controlled, TDM (64 kbps timeslot) switches. Known as the No.5 ESS, this switch is still considered to be the workhorse of the CO today.

As Internet traffic volumes exploded in the 1990s, service providers searched for alternative switching solutions to help offload the heavy Internet traffic volume while also paving the way for advanced data and broadband services and other sources of new revenue.

By the end of the 20th century, the voice market represented some 80 percent of total revenue, but voice-service growth was slowing. At the same time, demand for data services was increasing, but legacy switches were not designed to process digital data beyond 64 kbps, and revenues from emerging data services were not filling the gap. The stage was set for an entirely new breed of converged voice and data local-exchange switch, with scaleable capacity, to offer a host of new services.

Cycle 5

Today. Next-generation (fifth adoption cycle) local switches entering the network in the new millennium must be designed to handle the transition from a circuit-switched (legacy voice, TDM, and public switched telephone network [PSTN] services) world to a packet-switched network environment. This new "converged" next-generation switch must be able to handle the following:

- Data services, up to the gigabit Ethernet broadband service level
- Multiprotocol services, including the following:
  - Internet protocol (IP)
  - Asynchronous transfer mode (ATM)
  - Synchronous optical network (SONET)
  - Base revenues derived from legacy TDM voice

Three Transitional Influences

According to Bear Stearns analysts in *Saving Telecommunications: The Next-Generation Access and Services Evolution* (March 30, 2001), "Today, the three primary transitionary influences are wreaking havoc on the telecommunications industry. These three influences can be summarized as follows:

1. We are transitioning to a period where the focus must be on *access modernization* versus core network modernization,
2. We are transitioning towards *next-generation networking* (in all segments of the network) from old-generation networking, primarily outside of the core, which has already moved so destructively down the modernization path, and
3. We have the most fundamental shift of all taking place today (*the move to data services from voice services* and thus to broadband networking from narrowband networking."

One of the key operative terms in this research report is *"access modernization"* (translated as the Class-5 local-exchange upgrades and physical copper lines). We are already transitioning toward *"next-generation networking"* in all segments of the network—away from old-generation networking primarily outside of the core, which has already moved destructively down the modernization path. Furthermore, the most fundamental shift of all is taking place today—*"the move to data services from voice services"* and, thus, to broadband networking from narrowband networking.

This next-generation solution must, of necessity, involve a converged voice/data solution while combining legacy and advanced services in a single package that is both backward and forward compatible.

The new integrated communications providers (ICPs) are experiencing similar challenges due to the number of subscribers needed to ramp up their business. At the same time, there are strong forces demanding early profitability. The average number of ICP digital subscriber line (DSL) lines in any given co-location is low, and voice services typically must be profitable while ramping from 0 to 20 percent market-share in targeted markets.

In the incumbent–CO as well as the competitive-carrier situation, there is a compelling need for a system that provides low-to-medium line-count cost-effectiveness. For ICPs, this requires a high degree of scalability to handle the extremes from a few subscribers up to, and including, high-volume growth. In this scenario, a scaleable approach addresses the low–line-count cases.

Furthermore, there is a good opportunity in the present mode of operation to increase efficiency and simplify operations by integrating once disparate systems into a single, converged system.

The Challenges of Today's Infrastructure

In summary, traditional networks over the years were designed and built based on the need to provide reliable voice services. As demand for data applications has exploded, there has been an aggressive buildout of data networks to overlay or co-exist—as in the case of DSL, DSL access multiplexers (DSLAMs), and edge ATM—with the voice network. This has resulted in the following:

- Multiple systems that must interoperate; requiring extensive space, power, human resources, and time
- Disparate network-management and billing systems
- Switching systems optimized for very large deployments that do not scale well for smaller markets

The existing network infrastructure has evolved from a voice-only network to a high–data-traffic network in recent years. This rapid expansion of data services has resulted in a separate (overlay) network on top of the existing voice architecture.

While this multibox system has supplied the means for providing new services, it has proven itself to be an inefficient solution—since at least two networks are necessary for total service provision to a single end user. Today, this conglomerate solution is in danger of collapsing under its own weight.

Legacy Class-5 TDM Switches Must Be Replaced

The case for replacing existing Class-5 switches can be supported from many vantage points. First, as has been discussed, they are not data friendly, nor are they broadband capable. Second, the cost involved to upgrade the current generation is prohibitively high. Even if this could be done, today's CO switches are too large, their software pace is too slow and operational, and maintenance expenses are too high.

All things considered, there is an even more urgent reason to adopt a total replacement strategy: Several manufacturers, including Lucent Technologies, Nortel Networks, Ericsson, and NEC have announced that they will discontinue supporting their small CO products.

Since 85 percent of U.S. COs serve fewer than 4,000 lines, this means that most of the U.S. telephone network is operating on obsolete systems. Internationally, 90 percent of local exchanges serve 3,500 lines or less. The end result is that almost all of the world's population is connected to, and uses, an obsolete PSTN.

Criteria for a Next-Generation Converged Local Exchange

Local service providers must find a cost-effective broadband solution for suburban and rural COs—one that will continue to support the legacy services that provide the bulk of their revenue while using minimal CO space. Furthermore, this new switch must be capable of providing robust, always-available connectivity in emergencies and be highly responsive to the real-time service provisioning required to meet end-user demands. Beyond these basics, such a solution must minimize the need for up-front capital, installation, configuration, and ongoing maintenance costs. Putting one "box" in the place of many sounds like a tall order, especially at a time when service providers are concerned about losing their TDM revenue.

The answer lies in the prospect of finding a packet-capable voice and data-networking device that can furnish the necessities at an easily affordable price. The replacement issue goes directly to the bottom line. Independent operating carrier (IOC)/ICP customers can no longer afford to make use of current switching solutions and expect to maintain profitability and continued revenue growth for broadband services.

The Need for Softswitch Technology in Fringe Areas

There is much discussion today over whether or not softswitch intelligence should reside in the core or at the edge of the network. The term "softswitch" refers to software that provides call control, routing instructions, and features in a next-generation voice network. A softswitch (also known as a call agent or media gateway controller) connects to a media gateway and directs calls through a packet-based network. Proponents of a centralized softswitch approach are attempting to offer solutions that fill the core with converged switching solutions but do not address key local office and access issues.

With more and more people moving from cities to suburban or rural areas, and others spending more work hours telecommuting from home or using the Internet, there is an increased demand for broadband services in fringe areas. The problem is to remove the existing bottleneck and fill high-bandwidth systems in the core network. It is interesting to note that these are the very same geographic areas currently served by the obsolete small exchange.

A growing number of service providers now believe that these new, so-called core-centric architectures are flawed. They embrace the notion of a "smart edge" with a "dumb core." Supporters of this concept argue that there is a need to push softswitch intelligence down to the SPOP to avoid reliability issues and to ensure end-office survivability in emergencies. In moving intelligence away from the edge, local COs will lack the ability to stand alone, providing mandatory services such as E-911, call processing, and service provisioning.

Furthermore, there is a mandate in all areas for local law-enforcement authorities to have the ability to impose lawful intercepts under the Communications Act for Law Enforcement Agencies (CALEA) when required to fight crime, including illegal alcohol and drug trafficking. With softswitch intelligence in the core, complete CALEA and 911 requirements cannot be met. A new, 21st-century end-office switching criteria can only be provided using an entirely new breed of converged local exchange.

Big City Solutions Do Not Fit the Small CO Model

Some have proposed taking switches designed for large metropolitan-area markets and adapting them for service in small-town COs. On the surface, this idea may appear to have merit, but a closer look leads to an opposite conclusion.

Solutions that repackage the larger switch into a smaller, line-size switch with added packet services may appear, on the surface, to make sense. But because end-users served by small COs still want the same services as those available in the big cities, these solutions involve multiple-box, multi-rack solutions.

This dilemma is compounded because businesses want multi-line, low-cost voice and data access, and both residence and business customers want high-speed Internet access. Both of these groups require services in emergencies.

The Answer: "CO in a Box" or "Softswitch in a Hard Shell"

The ideal solution is to provide CO services in a single box—a small, scalable multiservice, multiprotocol system that stands alone as a basic switch, interworks with the packet and softswitch core, and provides legacy and advanced services. Until recently, attempts at delivering this type of product have only produced partial solutions.

Gluon Networks, Inc. has designed and developed a single, converged local-exchange solution that meets the criteria outlined in this paper. This solution, called the converged local exchange (CLX), offers the value proposition of increased revenue at lower cost—revenue from voice and data with a single infrastructure at 1/6th the capital costs, only 1/20th of the footprint now required, and only 1/10th of the average time-to-revenue.

This product is a small, flexible carrier-class voice and data switch that combines the functionality of a Class-5 voice switch with physical access, DSLAM, an ATM switch, SONET, and packet transport.

Asia and Australia Telecommunications Industry Overview

Paul Budde
Telecommunications Consultant
Paul Budde Communication

1. Asian Market Overview

1.1. Asian Telecommunications Champion of the World

Whether you are talking about mobile growth, Internet expansion, submarine cable projects, or fixed phone lines, Asia now leads the world in every segment of the telecommunications market.

In most of these markets, growth in Asia is twice, sometimes three times, that of Europe or North America. The developments are widespread:

- South Korea is leading the world in broadband growth.
- Japan is the world leader in mobile applications.
- Asia as a whole is leading global Internet growth.
- China leads the world in sheer subscriber number growth.
- Hong Kong is positioning itself as the international telecom hub.
- The Philippines and Taiwan are championing short message services (SMSs).

There is no obvious telecommunications recession in Asia, and, with the ongoing exception of Indonesia, growth is spread throughout the region—perhaps not always equally, but far more widespread than, for example, in Latin America and Eastern Europe. India appears to have at last turned the bureaucratic corner and is now better positioned to kick off on a potentially significant growth spurt. In virtually all segments of the telecommunications industry, pent-up demand amongst its middle class is larger than the total telecommunications market of many European countries. India will soon follow China in an unprecedented growth in telecommunications.

And, as we have indicated in previous years, Asia is still in the early stages of its information and communications boom. Asian people are amongst the most enthusiastic users of communications and information in the world. Apart from the obvious commercial opportunities, other sectors, such as education and community services, are seeing incredible growth.

In an industry dominated by Western cultures and values, global statistical overviews are always based on the Western principles, ignoring the differences inherent in the societal structures of the Asian people. In Asia, it is not essential for every individual in a family or community to own his or her own mobile phone, Internet connection, and television. Often, one single device services from 10 to 50 people. Based on this principle, well over 50% of all adults in Asia have access to mobile telephony, Internet, television, etc. Again, this is higher than in several of the Western countries. Furthermore, current developments are producing an ongoing increase in this high penetration figure. Yet, the official statistics continue to talk about teledensity (telephones per 100 people) levels of 10% to 20%.

Western-based companies still dominate the technology supply lines, and most of these fail to adequately address community-based needs. In general terms, they continue to take an individual approach. However, companies that are capable of changing their business models to incorporate products and services that allow sharing of networks, devices, and services will do very well. Although Asia also may develop over time into a more individual-oriented society, this could take as many as 25 years.

On the other side, after the dramatic terrorist activities of 2001, there is also the possibility, of course, that the West, in its own search for social solutions, will adopt some of the more community-oriented ways of living, especially if such alternatives are supported by the technological product developments coming out of Asia.

Nevertheless, there will always be a distinct cultural difference between the West and the East.

2. Australian Market Overview

2.1. The Collapse of Competition

Developments during the first half of 2001 can only be described as disastrous for competition in telecommunications in Australia. There is a more than 50% chance that the country will end up with a duopoly in this industry, with Cable & Wireless Optus being the only certain survivor to Telstra.

Overall growth in the industry has dwindled from 14% in 2000 to –0.1% in 2001 but will slightly recover in 2002 to 6% (see *Table 1*). It will not be until 2003/2005 that broadband will have caught up sufficiently to lead the market into new growth. As there will be significant pent-up demand for both broadband access and broadband services, spectacular growth is anticipated in the second half of this decade, resulting in a $90 billion[1] market by 2010.

According to the findings in our Telecommunications Industry Report 2001/2002[2], the new telco industry will not grow to the initially expected $5 billion-plus market this year; instead, it will contract by 5% to a level of $3.5 billion.

After the spectacular collapse of One.Tel, another champion of competition bit the dust. WorldxChange single-handedly changed the nature of competition in the long-distance telephone market in Australia. It guided the industry to the level of call charges that we currently enjoy. Hutchison sold its resale business and thus also dropped from the list of major telcos (annual revenues of $100 million).

At the same time, companies such as PowerTel and UECom failed to live up to their promise and never created a real impact on the market in Australia. WorldCom, another CBD operator, has been dormant for nearly 18 months and is only now emerging from its long sleep. This has also resulted, finally, in a revival of OzEmail. This promising Internet service provider (ISP) lost its number-one position to Telstra and is now a very distant number-two player in the market. It has also lost ground in the emerging broadband market.

While there are now more than 60 carrier service providers, the top six account for 95% of the total market. All the regional operators together have less than a 0.5% market-share.

3. Asian Fixed Network Market

Projected demand for telecommunications services in Asia indicates that at least U.S.$1 trillion will be invested in new infrastructure over the current decade. Regional governments have recognized, and consistently placed an emphasis on, the role of telecommunications in national development. Even before the Asian economic crisis, they were acknowledging the need to encourage private-sector investment to help meet the shortfall in investment capital. This involvement by the private sector is now even more vital, with an increasing interest in attracting foreign capital becoming obvious.

Although infrastructure developments slowed with the economic crisis of the late 1990s, demand for wholesale services has risen. Driven in the short term by voice services, but in the longer term by data services (such as the Internet), demand for wholesale services is expected to treble by 2002. Planned fiber network build-outs in the region should boost bandwidth 20-fold. The year 2003 will see close to 90% of all new connections made through optical fiber-to-the-home (FTTH) or fiber-to-the-curb (FTTC). Already by the middle of this decade, it is estimated that Asia will lead the FTTH market, as the operators of legacy networks in other parts of the world will try to protect their vested interests in copper-based networks.

Telecommunications emerged largely "crisis proof" during the dark days of the Asian financial meltdown due to strong pent-up demand for wireline and wireless services. Growth in main telephone lines during this period slowed only slightly and remained at 10%, which was twice the world average. Telcos in some of Asia's developing economies (China, India, Indonesia, Malaysia, the Philippines, Thailand, and Vietnam) serviced 90% of total demand for telephones lines (150 million), an indicator of Asia's appetite for telecommunications.

The decade of the 1990s saw a three-fold increase in the number of telephone users. Asia now accounts for a third of the world's telephone users.

One problem for the established fixed network operators in Asia has been voice over Internet protocol (VoIP) telephony. Without any real investment in infrastructure, an interesting mix of licensed and unlicensed service providers across the region are beginning to offer heavily discounted national and international VoIP–based telephony services. The entry of these operators into the market poses a serious threat to the revenues of the mainstream telcos. Possibly more significantly, it has raised fundamental questions about the adequacy of national policies and regulatory regimes governing telecommunications.

4. Australian Fixed Network Market

The country is currently peddling backwards. Telstra, through yet another appeal, wants to increase the wholesale rates. This is diametrically opposed to developments that are taking place overseas. They are also using a loophole in the legislation to refuse termination on their network from certain competitors; Telstra was the company that lobbied the hardest for the current termination rules in the first place! Asymmetric digital subscriber line (ADSL) and local-call wholesale rates are totally unsustainable competitively, and the government has been merely paying lip service to the problem and promising changes to the regime to stop Telstra from delaying competition, year after year after year.

TABLE 1

Revenue Growth in the Australian Telecommunications Market, 2000–2002

Year	Fixed voice	Mobile	Data	Equipment	Total
2000	10.2%	12.4%	24.0%	11.7%	14.2%
2001 (e)	–2.1%	7.9%	18.0%	–12.5%	–0.1%
2002 (e)	–3.8%	–5.4%	27.2%	10.2%	5.7%

Source: Telecommunications Industry Report 2001/2002; Paul Budde Communication

Even if their latest appeal is not upheld, it could delay competition for another two to three years, and by that time, we won't have to worry any more because the market will have been re-monopolized.

4.1. Flawed Government Policies

While it would be easy to blame all of this on the Australian regulatory environment, it has certainly played a key role in the demise of competition in these cases. While some of the business plans from the aforementioned players have not been particularly sound, all of them had built into their plans better wholesale prices and access to customers—perhaps not immediately after deregulation in 1997, but at least one or two years later. As this didn't happen, they could no longer sustain the unprofitable wholesale margins that they received, and this eventually led to the downfall of the majority of them.

I was called a pessimist in 1997 when I indicated that Telstra could delay the introduction of competition by two years. Now, five years later, none of the key issues (interconnect, access to the local loop, and number portability) has been implemented. The technical regulator ACA has gone well beyond the call of duty to secure the introduction of number portability. Yet without a strong regulatory regime, it will not be able, even for those companies with the best business plans, to successfully operate in Australia.

5. Asian Internet Market

Internet growth in Asia continues to be led by the developed economies of the region: Australia, Japan, New Zealand, Hong Kong, Korea, Singapore, and Taiwan. By contrast, in the developing economies, Internet usage is only inching forward due to the high cost of access, poor telecommunications infrastructure, and the sluggish pace of deregulation. Nevertheless, even in the developing economies of Asia, promising economic returns generated by the Internet is compelling both government and private enterprise toward modernization. There is simply no other choice.

Asia made important strides in satisfying its huge appetite for the Internet in 2000. The world's third largest regional Internet market after the United States and Europe saw significant increases in the number of Internet users and e-commerce revenues during the year. More importantly, Asia continued to move rapidly ahead in high-speed Internet access, increasingly the preferred mode worldwide. South Korea had more broadband Internet subscribers than the United States, a country with five times its population.

6. Australian Internet Market

With such high stakes, carriers will try to dominate the Internet market. Tto survive, let alone flourish, ISPs will have to join forces within the Internet market as well as within the total telecommunications services market. The ISP market will grow from $1.2 billion in 2000 to $3.5 billion in 2002. The bigger companies are, in general, growing faster than the smaller ones. However the smaller ones are more profitable. There has been a marked improvement in operational margins. However, for the larger companies, this is not enough to cover their sales and marketing costs. Those ISPs that have an early start in ADSL will pick the results in 2002/2003 (iPrimus, Pacific Internet).

Overall developments in this market will eventually lead to the following:

- Half a dozen large ISPs
- Between 20 and 30 business market ISPs looking after market segments such as travel, education, games, government services, and financial advice services
- Perhaps as many as 50 to 100 ISPs servicing regional markets
- A large number of franchisees, agents, etc. (hundreds)

Note: Throughout Asia there is also a strong focus on providing public access to the Internet. Cybercafes are mushrooming in the major cities and even pushing out into the rural areas. In India, for example, it is estimated that a massive 60% of Internet users go on-line at the public access points.

Other ISPs might find niches in certain nonprofit, educational, and hobby markets. The vast majority of the current ISPs will disappear or will become agents and franchisees for the larger companies. Despite various reports on imminent shakeouts of the markets, the ISPs have so far proved very resilient; however, a steady decline in numbers began to occur over the 2000–2001 period.

With the discussion broadening on how to best implement the Internet, the focus is shifting from simply providing connection to offering value-added services. This, in its turn, is going to separate the men from the boys.

The key to this will be streaming media. We expect this market to take off commercially around 2003. By that time, we not only expect the technologies needed for this to be robust enough to operate within large-scale broadband networks, but, perhaps even more importantly, we expect that more bandwidth-sucking applications (BSAs) will become available. As soon as customers become accustomed to high-speed, always-on Internet services, they will be ready for new services (e-entertainment, home video, pictures, teleseminars, etc.). A problem for many of the dot-com content providers is their inability to distribute video-based content.

7. Asian Mobile Market

The mobile industry in Asia remains one of the fastest-growing markets in the world, with almost 234 million mobile phones by year-end 2000 and revenues of more than U.S.$100 billion in mid-2000, compared with U.S.$10 million in 1994. Revenues will be close to U.S.$150 billion in 2003. Investment between 1999 and 2004 is expected to be in the range of U.S.$300–600 billion. According to the International Telecommunications Union (ITU), the region is poised to become the world's mobile powerhouse. It predicts that by 2010, more than 50% of all mobile phone users in the world will be in the Asia-Pacific region, up from a 35% share in 2000.

Despite the economic downturn in the region, Asia had annual wireless growth rates of 50% in 1999 and 2000. Seriously affected by the economic crisis, Indonesia's mobile market barely grew by 16% in 1998, but soared more than 100% in 1999 and more than 62% in 2000.

Wireless technology holds much promise for promoting communication access in the region. Cambodia was the first country in the world to boast more mobile than fixed subscribers by 1993, and there are now more mobile than fixed phone subscribers in a number of other Asian countries, with several more very close to crossing the line.

The region is home to the two largest mobile companies in the world: China Mobile and Japan's NTT DoCoMo. During 2000, China moved ahead of Japan as the world's second biggest mobile market. At the current rate of growth (more than 65%), China will soon overtake the United States as the biggest market in the world. In markets such as Indonesia and the Philippines, growth has been mainly driven by prepaid services. In Japan and Korea, new Internet services have been the catalyst, whereas in Singapore and China, increased competition has been the prime mover.

7.1. Asian Mobile Data Market

Wireless data subscribers in Asia accounted for 39% of the world market at year-end 2000. Japan is expected to account for a quarter of the world total by 2003. The introduction of

third generation (3G)-related services in Japan during 2001 will be the principal driver behind the growth in the number of wireless data subscribers. IDC forecasts 142 million wireless Internet users in the region (excluding Japan) by 2004.

With the possible exception of Japan and South Korea, the initial rollout for 3G services in Asia will most likely follow the pattern set forth by wireless application protocol (WAP), with expectations far exceeding reality. User acceptance level is likely to be relatively low due to the high price of 3G handsets and the initial speed for 3G-related services failing to meet expectations. Another important issue is how many useful applications will become available for 3G when it is launched. A wide range of value-added applications is critical to increase wireless data usage.

8. Australian Mobile Market

8.1. Another Two-Horse Race

The collapse of One.Tel was nothing less than spectacular, but it has to be noted that this had more to do with the involvement of Packer and Murdoch than with the life and death of the telco itself. True, in the end the directors are the ones that have to bear the responsibility and, as we indicated 18 months ago, they went off the rails when they changed their business model from being a virtual telco operator to being a carrier.

Different business models are needed for this, and, as was proved in the long run, they could not be rolled into one. Having said this, there was at one stage plenty of room to change the business model back to its original form, and One.Tel could have been saved. One.Tel has been critical to progress of competition in Australia, and after its demise we have seen a dramatic downturn of competition in the mobile market—with Telstra increasing prepaid prices and Vodafone severely curtailing its rollout of services to customers in the lower end of the market.

8.2. Mobile Growth Comes Again to a Grinding Halt

Once again growth in the market has come to a stand still. By mid-2001, the triopoly called it quits—no more aggressive drive for new customers, reduction in the acquisition of new customers at the bottom end of the market, and a consolidation of their average revenue per user (ARPUs). Aggressive competition during 1999 and 2000 saw the penetration of mobile phones increase from 40% to 60%. The cellular companies (celcos) have been heavily involved, particularly in 2000, in price competition that saw their mobile revenues per user dropping quite dramatically.

The prepaid market, bringing in new customers, has been the main driver of growth; however, many customers are youngsters and teenagers with a very low spend per month. Prepaid now accounts for the majority of new subscribers to the network. Their annual spend is often less than $250. This, of course, is a drain on the celcos, as their organizations are not equipped to deal with such small customers. Their overheads are far too high to operate profitably in such markets. This is yet another reason why celcos should look more closely at opening up their networks to wholesale customers, who would be much better positioned to service specific markets. The development of mobile data is another reason to use the virtual mobile networks operators (VMNOs) model, as specialized companies are far better equipped to develop this market. However, with the exception of C&W Optus, none of the others are keen to allow these virtual mobile networks operators onto their network.

As for 2002, we predict a negative overall growth in the mobile market as the products become commoditized. This will continue for another two or three years until the market begins to stabilize around 2005. It will be interesting to see if new business models will have been developed (allowed) by that time; only these new models will bring back the revenue growth in this market. It looks like industry restructuring cannot be done on a "voluntary" basis; in Europe, it is currently the financial market that is forcing such changes through in order to get the operators to reduce their huge debts.

The future of mobile will not be in mobile data; this will remain a niche market. Low-level data services—such as SMS, competitions, ticketing, and transfers—will provide some revenue relief; however, these services will mainly be

TABLE 6

Average Revenue per Mobile Customer, 1993–2005

Year	ARPU p.a.
1993	$1500
1995	$1000
1997	$800
1999	$780
2001 (e)	$630
2003 (e)	$610
2005 (e)	$680

Source: Telecommunications Industry Report 2001/2002, Paul Budde Communication
Note: Excluding handsets and fixed to mobile revenues

offered as promotional services to attract new customers and/or to stop churn. High SMS traffic also requires a better mobile infrastructure to cope with the increase in demand. This, of course, adds extra costs to what often prove to be marginal services. Nevertheless, having said this, over time these services could make up between 15% and 20% of all mobile revenue.

9. Asian Broadband Market

Asia looks to broadband to efficiently deliver the next generation of Internet services, such as interactive television and streaming media. However, broadband has so far only managed to make an impact in Asia's developed economies. Everywhere else in the region, dial-up narrowband access predominates, at best achieving 56 kilobits per second (kbps).

Broadband subscribers in Asia are forecast to increase from less than 500,000 in 1999 to about 35 million by 2003.

The potential of broadband as the premier Internet delivery technology is being held in check by its high cost. However, in countries with strong broadband demand, such as South Korea, the issue is not so much cost as the shortage of suitable high-speed local language content.

With an estimated 2 million broadband subscribers by the end of 2000, and a growing rate of 25% per month, South Korea is the world's leading broadband country. The high density living patterns found in South Korea have made broadband more cost-effective than in other markets. Forecasts are for 15 million digital subscriber line (DSL) subscribers and 2.4 million cable-modem users by 2004.

Although Hong Kong has one of the world's most advanced and sophisticated telecommunications infrastructure, with 100% of the territory and 90% of all homes covered by broadband connections by the close of 2000, growth in broadband subscriptions has been relatively slow. By February 2001, there were only 417,000 broadband customers from a population of 6.7 million, compared with 2.2 million dial-up subscribers.

In Singapore, almost 100% of the island's homes and businesses are passed by broadband infrastructure. There were an estimated 275,000 broadband users in February 2001, up from 100,000 users at year-end 1999.

China had an estimated 175,000 broadband subscribers at the end of 2000, as opposed to 880,000 narrowband subscribers. Broadband growth in China is projected to surpass that of narrowband by 2002 and should reach close to a million subscribers by 2004.

With 92,000 DSL subscribers and 72,000 cable-modem users in Taiwan in 2000, the country is set to have 1.5 million DSL subscribers and 410,000 cable-modem subscribers in 2004.

Somewhat surprisingly, broadband is still relatively in its infancy in Japan, with little more than half a million people using broadband access through cable or ADSL in early 2001. But the government's e-Japan Priority Policy Program has set the goal of having five million broadband subscriptions by 2002 and 30 million broadband households by 2005.

10. Australian Broadband Market

10.1. The Broadband Crusade

During 2000, it became abundantly clear that broadband was not growing as fast in Australia as it was in other parts of the world. So I decided that 2001 would be my Year of the Broadband Crusade. The main reason for the crusade was the announcement in late 2000 that Telstra was predicting a meagre 625,000 ADSL users by 2005 (one million if you include cable-modem users).

I am clearly disappointed with Telstra's one million-plus forecast, especially in view of the fact that the company actually is rolling out broadband networks.

I see broadband as a crucial factor in the development of our country, from both a community and an economic perspective. In comparison to other countries, we are currently running 18 months behind on the information superhighway, and if Telstra's plan succeeds, this gap will increase to three years by 2005.

Broadband is more of a concept than a defined technology. It provides convenient and affordable access to information, entertainment, and communication (ADSL, cable modems,

TABLE 7

South Korea Broadband Users, 2001

Access Method	Subscribers
ADSL	3,469,600
Cable Modem	1,944,100
Satellite	9,000

Source: Telecommunications and Information Highways in Asia Report, Paul Budde Communication, 2001

integrated services digital network (ISDN), and even an always-on flat rate 56K modem service could be seen by some customers as a broadband service). Once video-based content becomes more widely available, customers will automatically have higher broadband expectations, and so higher-speed services will increasingly be linked to their concept of broadband (45 megabits per second [Mbps] by 2010). Broadband empowers individuals to choose the services they want, rather than being restricted to what the media and telco barons are prepared to dole out to them. It is also the infrastructure key to the concept of a knowledge-based society and an e-economy.

So versatile is this technology that it can be applied in many ways, in accordance with user demand. For example, in Korea, the country with the highest broadband penetration in the world (57% penetration amongst Internet households), the market is driven by tele-education. In the United States, teleworking is operating as a key driver, while always-on, high-speed Internet access is the favourite application in Europe. Gambling and porn are also very strong market drivers.

The impetus for broadband can occur in three ways:

- A national vision translated into government policies (the governments of the Netherlands, Sweden, and France are actively involved in the rollout of broadband), possibly leading to the concept of LoopCo.
- Bold telcos and cable operators leading the charge (Spain, Germany, Korea)
- Competition between delivery platforms such as telecoms, cable television, and digital television (United States, United Kingdom, Hong Kong)

Australia does not have any of the above drivers, hence my crusade, in which I have endeavored to open up the subject by using the media to generate public awareness and debate. The ultimate defeat of the current generation of telcos would be if a future government has to nationalize the telecoms infrastructure (LoopCo) in order to secure a first-call infrastructure for our e-society and e-economy.

"LoopCo will have to be separated from the rest of the telco business."

11. The Crash of the Equipment Market

Disaster struck in 2001, when this segment of the industry contracted by more than a quarter. Total Australian equipment revenue (telco and datacoms) will fall to $8 billion instead of growing to $11 billion as had been forecasted. While the market will recover, major structural damage will have been done to the vendor industry. While most of the big six global vendors will survive, a major restructuring will be needed, during which, among other things, the issues subsequently listed will need to be addressed.

The key elements of the crash were as follows:

- Hyped up technology expectations, especially in the mobile market and long-haul access market
- Collapse of a totally unsustainable dot-com market in the United States, fuelled by a greedy investment market
- Lackluster development in local broadband access
- Promotion of big iron technologies, such as long-haul telecommunications infrastructure instead of lean, mean access technologies for residential and small-to-medium enterprise (SME) customers
- Holding on to outmoded business models linked to "old" telco models

It is sad to see that the immediate reaction to the crisis focused on accountancy solutions aimed at protecting the current pie. Only a few are trying to work through the emergency through growth (Nokia and Marconi). Lucent Technologies has so far been the only one that has announced a major restructuring. Again, others, such as Siemens and Philips, have been less affected, because their communications divisions are supported by other activities.

As in the operator industry, massive restructuring along horizontal lines is needed to turn the industry around.

12. New Generation of Telcos

As the first and second generation of telcos are faltering, a new breed of competitors is entering the market. Some have re-engineered themselves; others are first entrants. They are as follows:

- Broadband telcos
- Virtual operators
- Regional operators
- E-business service providers, application service providers (ASPs), service bureaus, and data-center operators

Their business models are not formulated along the same lines as those used by the "old" telcos but on specialization into key market segments, such as regional markets, broadband, wholesale infrastructure, etc.

Furthermore, voice telecommunications constitutes only a minor part of their business models; they are concentrating on data services, content delivery, and multi-access technologies.

It looks as though the old competition model is dead but not yet buried, and it will take a few years before the new generation of telcos establish themselves. This will also depend on regulatory issues, most importantly the local-loop unbundling issue.

Already re-engineered companies include Premium Rate service providers (audiotext services) and facsimile bureaus. They are rapidly developing into permission-based, multimedia-based services bureaus (SMS, e-mail, voic-email, fax, etc.).

Multichannel Digital Broadcast Application over ADSL

Kenneth Clancy
Director, Technology Adoption
Aliant Telecom

Cindy Robichaud
Broadband Architect
Aliant Telecom

Kevin Hastings
Chief Architect, Digital Broadcast Services
Aliant Telecom

1. Abstract

This paper describes the development and deployment of a multichannel interactive digital television (iDTV) application.

In January 2000, Aliant Telecom launched a multichannel interactive digital television (TV) application over its broadband network. This application introduction resulted from a plan to migrate from providing "narrowband telephony services" to providing a full suite of interactive broadband multimedia services. This was deemed necessary to counter both the encroaching service capabilities of the cable and satellite providers and the potential customer losses. A full 6 megabits per second (Mbps) of bandwidth is required to the consumer residence over standard asymmetric digital subscriber line (ADSL) to meet the full interactive communications needs of the residence. This includes local and enhanced telephony, long distance, high-speed Internet (HSI) access, multichannel digital TV, and multichannel digital video to the personal computer (PC), all over a single copper wire to the home.

2. Telecom Industry Video Opportunity

2.1. The Competitive Imperative

iDTV is imperative to the success of incumbent telecommunications service providers (telecoms) facing intense competitive pressures, especially from cable TV companies. To date, two-way coaxial architectures as deployed by the cable TV providers and one-way satellite architectures as deployed by the direct-to-home providers have dominated the current broadband solutions to the home.

Previously leading in meeting consumer telecommunications needs, the telecom industry has generally been slow to embrace this new consumer demand. By waiting too long to deploy broadband networks and associated applications, telecoms missed their first opportunity, which allowed the cable companies to be first to market with HSI access service introductions. With cable companies now positioned to deliver a full suite of interactive broadband services such as local telephone, long distance, and HSI over their existing broadcast-based infrastructure, an immediate solution is required for the telecom that exploits the strength of its embedded copper investments and existing customer relationships.

Telecoms are now responding with fiber/copper solutions based on the deployment of ADSL. This paper will show how telecoms can leverage their broadband investments to deliver multichannel digital applications to the consumer.

2.2. Service Description

HSI and digital TV service are the telecom's anchor tenants on its high-bandwidth network. The following summary provides the current view of the iDTV service.

The service attributes include the following:

- 210 digital channels, comprising 123 broadcast video channels, 19 pay-per-view television channels, three Web channels, and 65 stereo audio channels
- Simultaneous support for two TV set-tops, TV–on–PC service, HSI access service, and local and enhanced telephony services
- Local on-demand video and audio content -
- An interactive program guide (IPG)
- Instant pay-per-view access on demand via the customer's remote control
- Internet access through the television; e.g., e-mail, Web browsing
- TV convergent Internet protocol (IP) portal with themed categories of content: news, weather, entertainment highlights
- Seamless navigation through the broadcast and Internet content
- 10 digital video broadcast channels to the PC
- Presentation of on-line or paper detailed bill for all

usage and subscription services: long distance, local, enhanced services, Internet, and iDTV

Pricing is competitive, and choosing a bundled service rewards customers with package discounts. For example, one service bundle offers the iDTV service plus unlimited use of each of the following: HSI, local and long-distance calling, and enhanced telephony. This bundling of services is a proven revenue protector, revenue generator, and, most importantly, positions the telecom for future revenue streams that will come from new broadband services and applications that use this same infrastructure investment (video on demand [VOD], e-commerce, and advertising).

3. Technical Solution

3.1. Technical Overview and Challenges

Figure 1 provides an overview of the integrated IP/asynchronous transfer mode (ATM) solution for delivering the multichannel digital broadcast application. In the digital head end, content is aggregated, groomed, and encoded into MPEG-2 or MPEG-4 IP multicast streams as appropriate for TV– or PC–based applications. Common telecom IP, ATM, and synchronous optical network (SONET) infrastructures are involved in broadcasting this content to broadband digital subscriber line access multiplexers (DSLAMs).

Distribution from the DSLAM involves a switched digital video architecture that streams channels to the customer's modem only when specifically selected by the customer's IPG (in the case of TV viewing) or PC client. Inside the home, a standard broadband ADSL modem connects to a PC or TV set-top equipment through standard Ethernet wiring solutions. The network must transport both multicast and unicast traffic as appropriate for broadcast and on-demand applications, respectively. Location of the head end can be centralized or distributed. This is an architectural choice that depends largely on the service provider's fiber transport, real estate, and operations assets.

The development and deployment of an iDTV application requires solutions to a number of technical challenges that are described in the following sections.

3.2. Video Encoding and Compression

The heart of the digital head end involves state-of-the-art satellite or fiber-based content acquisition systems and motion picture experts group (MPEG) compression systems. Pristine copies of all broadcast networks are required in order to generate high-quality compressed streams suitable for recovery at the digital set-top box. Provided that the sources are optimum, the process of encoding those programs to MPEG program streams will be the key determinant of picture quality.

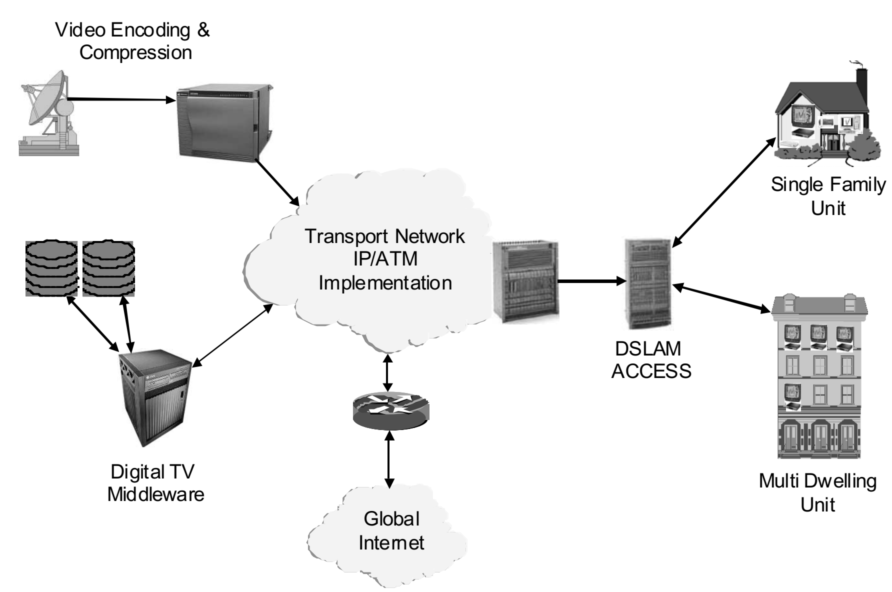
The MPEG-2 encoders used for TV, and MPEG-4 encoders used in PC-TV applications accomplish fixed bit-rate stream generation for all video channels, their audio, and audio-only channels.

ADSL access networks, though broadband in nature, do not offer the "thick pipe" bandwidths seen in satellite or fiber to every customer; rather, the presentation of a 6 Mbps fixed pipe for all simultaneous services implies that bandwidth is fixed to reasonable allocations, despite the broadcaster's source bit-rate. This implies that in a two-TV environment, the MPEG compression process must be exceptionally efficient.

Sophisticated video noise-reduction technology is employed to minimize compression efforts for noise, and complex motion estimation processing is involved in maintaining high picture detail even in rapid motion content being broadcast.

FIGURE 1

Integrated IP/ATM Solution Overview



The competitive 7x24 nature of the broadcasting service dictates that the encoding facility be equipped with restoration facilities, spare equipment, and backup power systems.

Further, in-service maintenance maneuverability is assured through video-audio program switching equipment that interfaces the encoding systems and the satellite/fiber source systems. In regulatory environments where simultaneous program substitution is required to protect the distribution rights of local broadcasters, the video-audio program switch also meets this need.

3.3. Digital TV Middleware

A critical component of the solution is the digital TV middleware application. This application meets a number of critical requirements, including management of the user interface, customer subscriptions, and IPG and providing the operational service and interfaces required for customer activation, provisioning, and telecom billing.

The major capabilities provided by the middleware are as follows:

Content: The digital TV middleware manages the content availability in packaged format or on an individual channel subscription basis; i.e., pay-per-view (PPV).

Set-Top Management: The digital TV middleware manages the set-top and customer configuration and the software integration with the set-top's operating system. The set-top also translates the channel request to the network IP address required to source the appropriate content.

Interactive Program Guide: The IPG is a key navigation tool, given the large channel line-up involved. The middleware creates the IPG data fields and ensures that the information is delivered and available to the set-top according to consumer-acceptable channel-change requirements. Seven days of IPG formatted information is provided and managed.

Customer-Usage Reporting: The middleware also provides the event-management software, as well as the customer reporting. Application program interfaces (APIs) upload usage information so that the single bill for the packages and PPV events can be identified to the customer bill. User interfaces are provided to support all administration functions as well. Finally, broadcaster billing and invoicing is generated by this middleware to facilitate broadcaster content-distribution fee settlements.

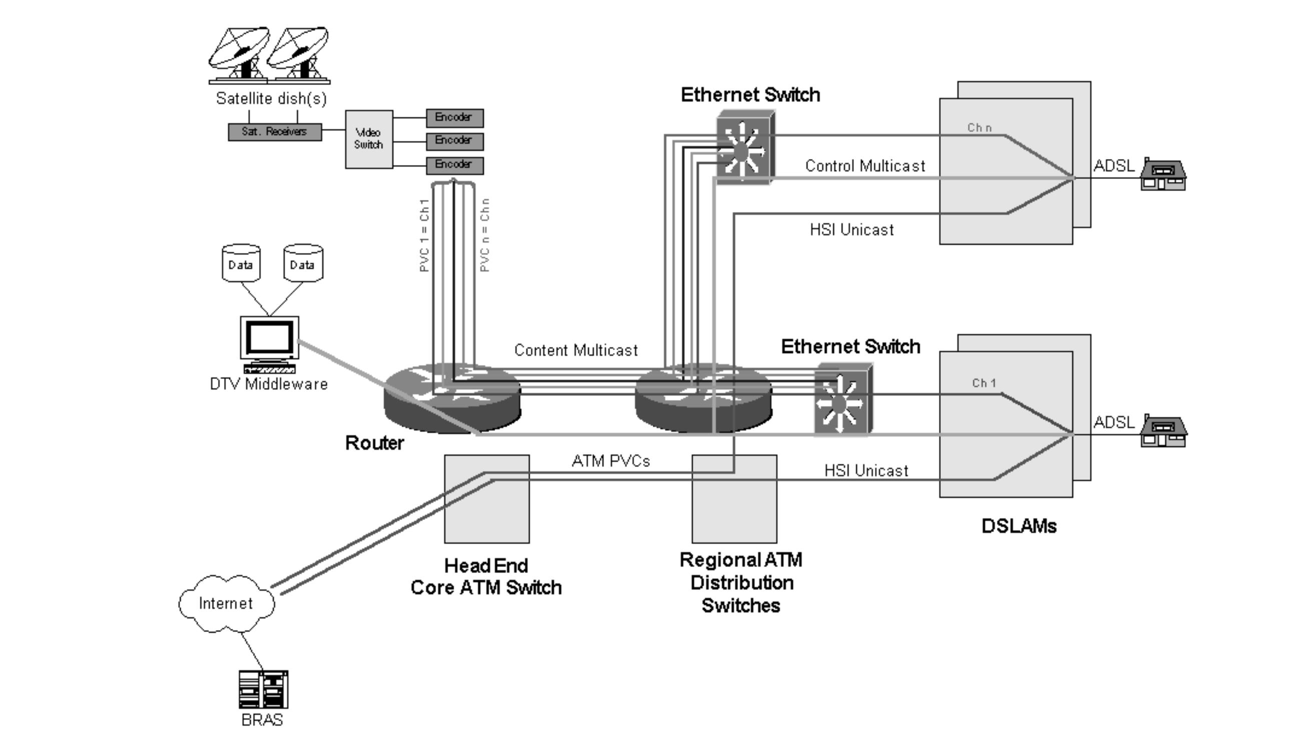
3.4. Transport Network IP/ATM Implementation

There are several approaches that can be implemented to distribute digital content throughout a broadband network. One approach utilizes classical IP solutions and another is based on an integrated IP and ATM solution.

The classical IP approach, illustrated in *Figure 2*, utilizes Layer-3, IP–based technology. Constraints with the manageability and scalability of a pure IP–based multicast network become apparent as the number of customers and channels increase. Operations personnel would require intensive Layer-3 training in order to manage a complex IP multicast network where each individual channel must be carried as a separate entity. Also, signal integrity is not assured

FIGURE 2

Classical IP Distribution



through current implementations of Layer-3 networks, as all traffic is of equal priority.

The second approach, based on an integrated IP and ATM design, offers several advantages in a telecom environment. ATM, by design, is a multiservice protocol. By implementing an ATM infrastructure, many of the complexities inherent in a Layer-3 infrastructure can be overcome. ATM enables the distribution of both unicast and multicast content on the same network using separate permanent virtual circuits (PVCs), as shown in *Figure 3*. Content can be inserted directly in to the ATM network, and since most DSLAMs are ATM–interfaced, distribution of the content to the customer is carried out with ease. The inherent quality of service (QoS) capabilities of an ATM network enables service providers to ensure that video traffic traverses the network without disruptive delays that could affect picture quality and channel-change latency.

The ability to format content as ATM traffic directly from a digital head end allows content to be collapsed onto point-to-multipoint ATM paths, which can easily be scaled and distributed throughout the entire network. The Layer-3 expertise required to manage complicated IP multicast traffic is no longer required by operations personnel who are already well trained in ATM technologies.

3.5. DSLAM Access Implementation

Several features and enhancements to improve broadband video distribution are becoming more prevalent in DSLAM vendors' offerings. A high-bandwidth link to the distribution network, such as optical carrier (OC)–12 ATM, allows the content to reside at the edge of the network where access times will be optimized. IP awareness within the DSLAM eliminates the need for a traditional Layer-3 overlay infrastructure and again optimizes content access speed. The network infrastructure necessary to support video applications and other feature-rich services simplifies, as the features available within the DSLAM improve. Higher-density shelves, with remote installation options, are also reducing the cost of creating a broader serviceable area.

Bandwidth requirements increase as services become more and more rich. Establishing a "service mask," or the tradeoff between bandwidth-rich services and servable areas becomes a key consideration, as illustrated in *Figure 4*. To maximize revenue opportunities, telecoms will have two service masks for their ADSL access network. In the example shown, the customer can be offered a full service broadband solution, including iDTV, His, and telephony at a 2 km loop length. Customers with loop lengths between 2 km and 4 km can receive both HSI and telephony services. Broadcast video on the PC is also available to any customer with HSI service.

Since interactive broadband services demand a high level of performance from ADSL, work must be carried out to achieve a stable connection to the customer's home. Testing to determine the optimum ATM and ADSL parameters to use on the DSLAM to ensure peak performance and stability of the ADSL line must be carried out. Careful consideration must be given, based on collected data, to the bandwidth available on certain copper loop lengths that contain

FIGURE 3

Multicast and Unicast Network

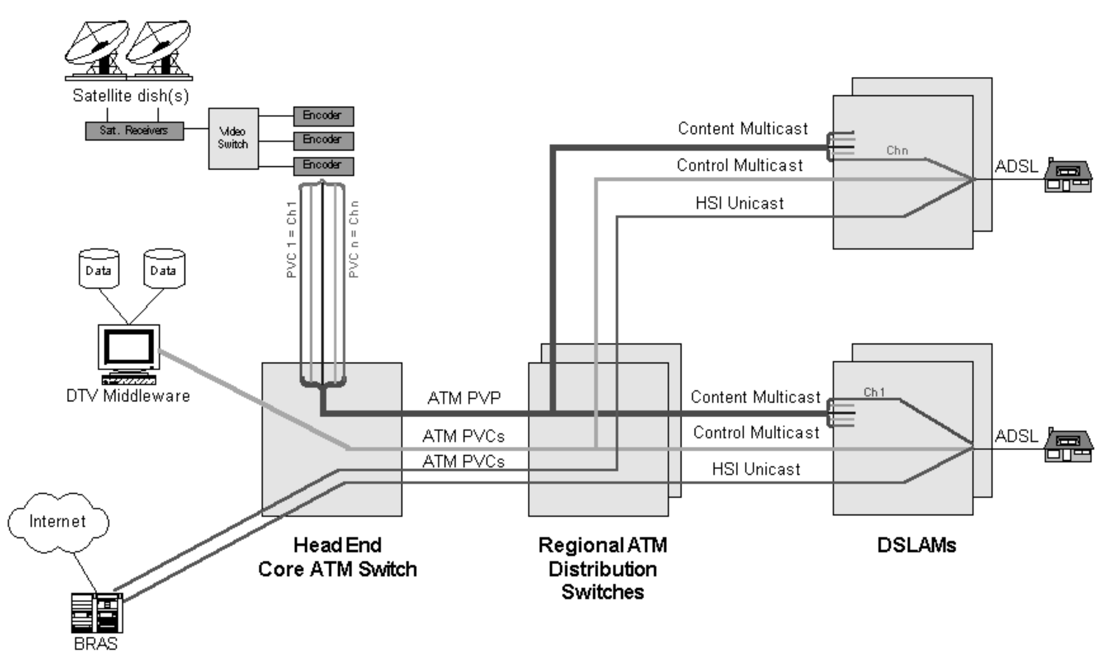


FIGURE 4

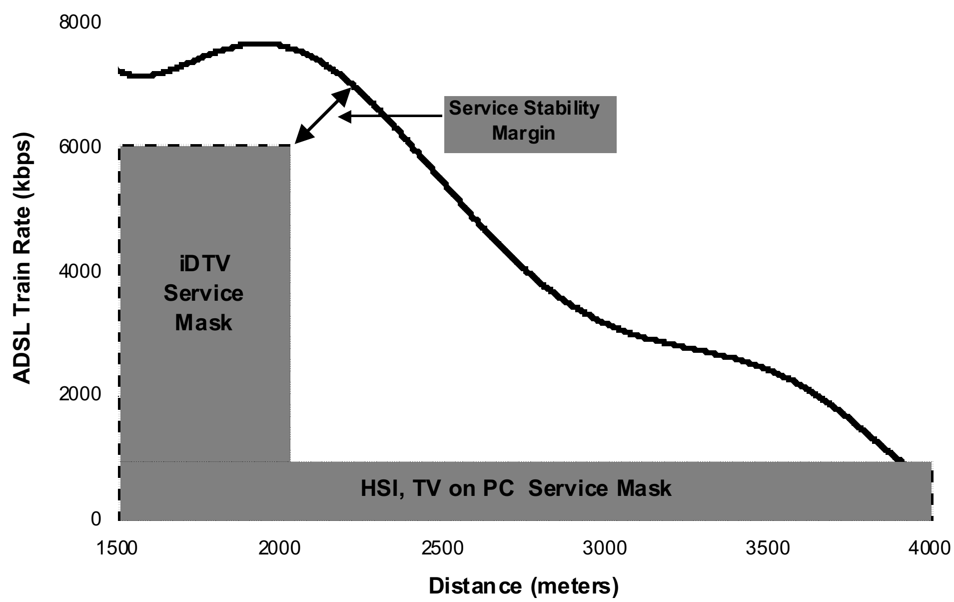
Service Mask



bridge taps and various gauges of copper wire, and guidelines for servable areas must be established. Technical improvements made by the DSLAM vendors have constantly been increasing the performance and stability of ADSL, which will improve the service readiness and reach of currently deployed infrastructures.

3.6. Residential Network

In the customer's home, new equipment must be introduced for iDTV service, including an ADSL splitter, ADSL modem, 10/100 BaseT hubs, TV set-top unit, and standard 10/100 BaseT wiring structure, as illustrated in *Figure 5*. The ADSL modem in the home is the key point of conversion from the carrier's ATM– and ADSL–based distribution network to the customer's 10/100 BaseT Ethernet–enabled home. The modem used must therefore be feature-rich and able to support multiple applications. This requires high throughput levels and advanced ATM PVC support that is becoming more readily available in standard HSI modems.

In approximately 50 percent of customer homes, the TV and PC appliances are located in the same room. Unfortunately, the remaining customers typically locate their two TVs and their PCs across several floors and rooms—making the modem and hub location a site-specific choice.

The popularity of 10/100 BaseT structures in modern homes, and frequent use of it in local-area network (LAN) and other PC environments, has made its introduction to consumers less difficult than initially expected. The growth of IP applications within the home is unprecedented and has contributed to application interworking challenges, such as dynamic host configuration protocol (DHCP) and security.

Finally, the cost of the customer-premises equipment (CPE) involved in this approach has been historically high and is only now descending toward an appropriate range, given the following:

- The emergence of digital set-tops incorporating the ADSL modem
- The widespread acceptance of 10/100 BaseT network interface cards (NICs) in store-bought PCs
- The development of customer-friendly self-serve applications for HSI access
- The mass marketing of consumer IP equipment (modems, hubs, routers), which has driven volume and fostered lower per-unit pricing

4. iDTV Results

4.1. Mandatory External Relationships

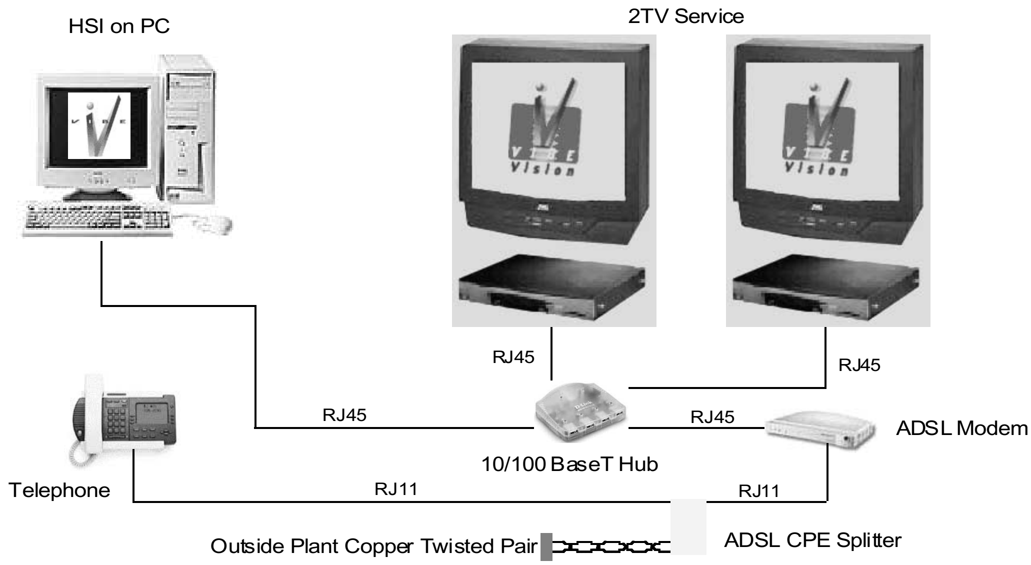
Relationships with at least two external agencies are required for successful iDTV service: appeasement of appropriate regulatory agencies and the establishment of appropriate business relationships with content owners.

Federal and municipal regulators have established relationships with incumbent broadcasters and may require time investments by new service providers to reach acceptance. This could range from federal broadcast license agreements to local permits or easements for Earth station and ADSL structures.

Telephone companies generally do not have relationships or credibility with most broadcast content owners, which introduces some risk to the broadband business where "content is everything." Federal broadcasting requirements, which must be respected, typically force the carriage of selected content, and even if that were not so, a competitive channel line-up normally dictates that formal content carriage contracts be signed with perhaps hundreds of content owners. In selected cases, these content owners may not

FIGURE 5

Residential Inside Wiring



encourage new carriers, whose business presence and technology are unfamiliar to them. Program carriage fees paid to content owners represents the largest single cost to an established operator, and, as such, this topic has considerable impact on the iDTV business case.

4.2. Component Costs

There are new industry trends that have contributed to cost reductions during the past few years. The standardization of ADSL, the underlying technology developments in silicon, and the corresponding increase in volumes have reduced the DSLAM cost per port. Anticipating these trends, it then became urgent to focus on innovative exploitation of the supporting telecom technologies.

The major observations of industry trends are as follows:

- Component capital cost trends are progressing in the right direction: ~ 35 percent cost reduction on the total of these components over four years.
- Industry focus will drive further reductions, especially in the CPE cost area: set-top, modem, and wiring reuse.
- ATM/IP integration breakthrough occurred in 2000 and resulted in a $500 reduction per set-top served.
- High-density technology for the core and access components occurred in 2001, resulting in significant cost reduction and support cost reductions because of lower power and space requirements.
- Current design will support two TVs at 2000 meters.
- Cost does not include access rearrangement cost, which may be required in some jurisdictions.

The anticipated cost reductions have materialized as anticipated. *Figure 6* shows this trend over the past four years.

4.3. Revenue Opportunity

With technical trials now complete, the industry is now concentrating on enhancing the business model for the deployment of multichannel digital broadcast applications over ADSL. The initial deployment strategy is to focus on the telecom's most competitive major markets. The addition of iDTV to HSI will significantly increase the company's revenue per customer, as shown in *Figure 7*. When examining the early trends, the opportunities for increased revenues are clear.

Customers are currently adopting the new service in the home. The IPG is highly valued and has changed the customers approach to channel surfing. This is attributed to the interactive aspect of being able to get program information when desired. The use of PPV has also recently grown from 20 percent of the customer base to 52 percent. Again, this growth is attributed to the customer's ability to instantly select a movie or pre-schedule a movie, all from the convenience of their home.

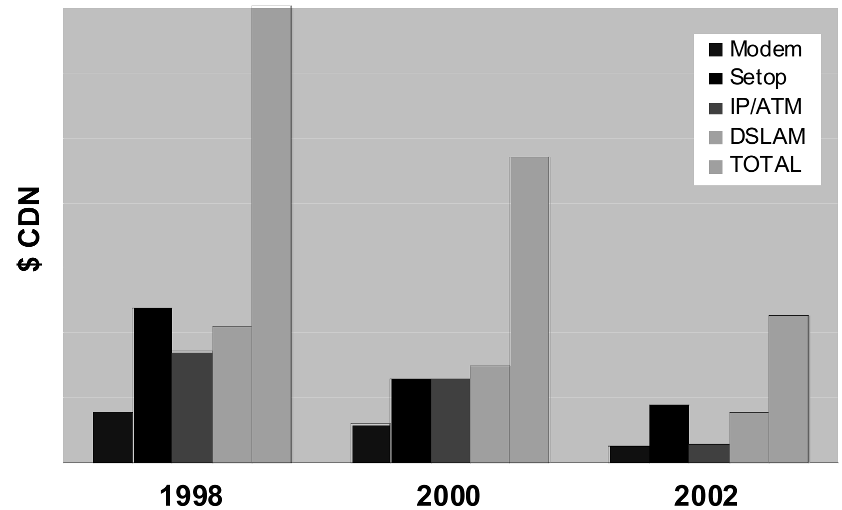
5. Conclusion

Telecoms must respect the consumer's need for converged services. Now is the time to deliver the applications that will meet the consumer expectations and generate new revenue for the telecom. Those service providers that do not embrace this trend will face higher opportunity costs, continued market-share erosion, lost competitive advantage, and revenue loss.

This paper has shown the current viable technical solutions available to the telecom for delivering a full service application set to the consumer, including multichannel digital

FIGURE 6

Component Costs Trends



broadcast. The challenge remaining to the telecom is to recognize the opportunity, adopt an architecture, and complete a business model.

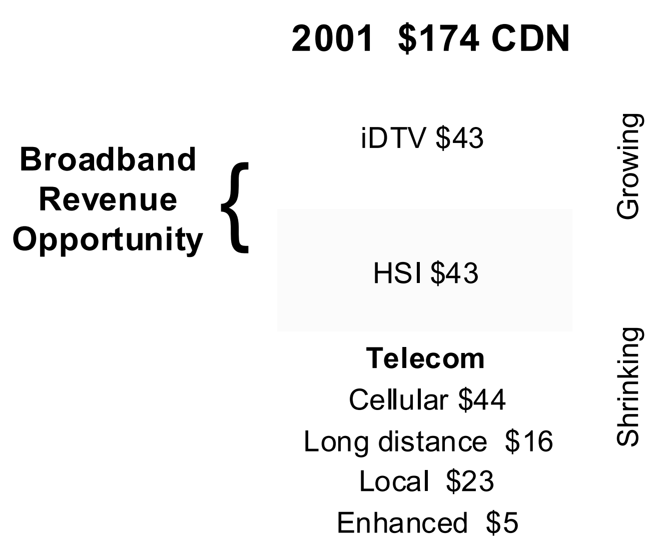
Monthly Broadband Revenue Opportunity



The Benefits of Automated Decision Analytics

Jeffrey Cleveland
Senior Principal and Director, Credit and Collections Risk Management Practice, New Media and Communications
American Management Systems, Inc.

Overview

This position paper details the following:

Two *primary challenges* faced by telecommunications providers today in the management of credit risk:

1. The assessment of up-front credit risk during the acquisition and provisioning process
2. The ongoing assessment of risk in the accounts receivable portfolio over time

A potential *solution framework*, which includes the following components:

- Up-front credit scoring and automation
- Periodic rescoring of accounts using behavior scores
- Automated decisioning capabilities
- A data mart for capturing, retaining, and analyzing account performance

The anticipated benefits stream, obtained from the following:

- Increased revenue
- Reduced Net Bad Debt (NBD) expense
- Improvement in cash flow (as measured by DSO)
- Reduced operating expenses

Current Challenges

In the telecommunications industry today, few firms have adequate processes and policies for measuring and managing credit risk at the customer or account level. And in those institutions that do happen to employ various risk-management strategies and tactics, there is more often than not the fact that the desired levels of benefits have not been met. In general, these shortcomings can be viewed as a result of two factors:

1. A lack of understanding and management around initial credit risk for new applicants
2. The inability to measure the ongoing riskiness, and changes in those levels of risk, in the overall customer portfolio

Up-Front Credit Assessment

Inconsistency in Decisioning: Decisioning data, provided by the applicant and obtained from third parties (i.e., credit-reporting agencies), is used to determine likely credit risk, overall creditworthiness, and applicable risk mitigation strategies and tactics. However, since these credit evaluations are often performed on a subjective and manual basis, most telecommunication firms' credit-provisioning standards are subject to a variety of individual standards, criteria, and biases. These factors result in a decisioning environment that is, from a credit-granting perspective, inconsistent. This inconsistency, in turn, subsequently leads to the following:

- Difficulties in measuring credit-decision effectiveness
- Potential increases in overall portfolio risk due to provisioning of higher-risk accounts
- Potential suppression of revenue due to declination or application of risk mitigation strategies and tactics to accounts that, in fact, do not present any undue incremental risk to the firm's portfolio

Inefficiency in Initial/Pre-Screen Processing: At many telecommunication firms serving the small- and medium-sized–business markets, there is often a major disconnect between the sales, marketing, and risk-management staffs. For example, during the initial sales evaluation phases, the sales staff frequently lacks any kind of tool to quickly pre-screen or pre-qualify, from a credit-risk perspective, potential or target accounts. This results in process inefficiencies at the sales level, as business developers may be spending time trying to target and acquire potential customers whose risk profile places them outside of the firm's acceptable and/or manageable levels of risk.

Ongoing Portfolio Assessment

Once a telecommunications firm has provisioned an account on their network/system, there is typically no set method or process to continually re-evaluate the overall risk composition of the accounts receivable portfolio. Specific challenges include the following:

Inability to Measure and Understand Changes in Portfolio Composition and Risk: Customers' levels of risk over time tend to be dynamic rather than static. That is, accounts that were viewed as "low risk" when they were part of the through-the-door population at time of acquisition and provisioning may very well turn out to be higher-risk customers. Likewise, through-the-door customers that were originally deemed "high- risk" might, by their own performance and behavior, actually turn out to be fairly low-risk accounts. The key element required in proactive portfolio management is the ability to measure and understand the following:

- The *distribution* of portfolio credit risk at any given point in time
- The *changes in distribution* of portfolio credit risk over time

Inability to Respond to Changes in Portfolio Risk: It is highly likely that a customer's level of credit risk that is assigned during the up-front credit assessment process is the same level that remains assigned to the account during that account's life. This poses two serious risks:

1. Accounts whose behavior indicates a lower level of risk may still have revenue-suppressing risk mitigation strategies and tactics being applied to it.
2. Accounts whose behavior indicates a higher level of risk may be avoiding the application of risk mitigation strategies and tactics being applied to it.

Inability to Measure Cost-Efficiency and Cost-Effectiveness of Strategic and Tactical Decisions: Over the lifetime of a given customer or account, hundreds of decisions are made, with each decision intending to affect customer behavior in some way, shape, or form. However, most firms have no way to determine which individual decisions are having the most impact and influence on customer behavior without a systemic way of continually testing and evaluating decision effectiveness.

Potential Solution Framework

Addressing these challenges in managing credit risk, both during the initial credit assessment and over the course of an account's life, requires a multiphased approach:

- Up-front credit scoring and automation
- Periodic re-scoring of accounts using behavior scores
- Automated decisioning capabilities
- A data mart for capturing, retaining, and analyzing account performance

Up-Front Credit Scoring and Automation

To address the issues regarding inconsistency in decisioning and inefficiency in pre-screening during the initial credit process, telecommunications firms can take their cue from the financial services industry, which makes extensive use of statistically derived *credit models* to predict initial/early life credit risk.

Credit models use applicant performance data as reported by *other* credit grantors and are used to assess the likelihood of risk in the absence of any direct experience with an applicant. Basically, the use of a credit score allows potential credit grantors to answer the following question:

"Since my firm doesn't have any direct performance experience with this applicant, how likely is this applicant to become seriously delinquent and/or write-off with us based on this applicant's credit usage and payment performance with other creditors?"

The model life cycle has four distinct phases:

1. *Model Strategy Design:* It is crucial in the beginning of any model development/deployment effort to outline the high-level designs of the overall program. For example, what type of behavior and results are attempting to be predicted? Where in the overall process will the model(s) be introduced and calculated? What kind of infrastructure is required to implement and support the model(s)?
2. *Model Development:* This phase typically involves a great deal of data preparation, from data access to cleansing and manipulation. Once the data is ready, the actual processes involved in creating and validating the scorecard are relatively straightforward.
3. *Model Implementation:* Once the model has been developed, the model scorecard must be integrated into and tested with existing production environments.
4. *Model Usage:* It is typically at this point where statistically trained model developers exit and more broad experience-based portfolio managers come into play. Understanding how to use models, particularly in areas such as time series analysis, score cut-offs, and controlled experimentation, is critical at this stage to gain the maximum leverage and lift from the overall modeling effort.

In addition to the use of credit models, the Internet makes it possible to deploy a Web-based credit system for use by both credit analysts and business developers. By utilizing an automated tool for data capture, scoring, and decisioning, telecommunications firms can significantly improve the consistency in credit decision-making, as well as improve the overall throughput in the credit process.

Periodic Re-Scoring of Accounts Using Behavior Scores

The use of credit scores on the through-the-door population is designed to predict short-term credit risk (i.e., within one year of account acquisition and usually inside of six months). However, once an account has been active for four to six months, behavior and performance are much better overall predictors of future risk. More importantly, that customer's level of risk changes as their behavior changes over time.

To measure these changes in riskiness, successful companies deploy statistically derived *behavior models* to predict ongoing credit risk for accounts in their portfolio.

Behavior models use a firm's own customer performance data to assess the likelihood of future risk based on past performance. Basically, the use of a behavior score would allow a telecommunications firm to answer the following question:

"Based on my firm's direct experience with this customer, how likely is this customer to become seriously delinquent and/or write-off some time in the future, based on this customer's credit usage and payment performance?"

The same four model life-cycle phases described in the previous section are also applicable here: Model Strategy Design, Model Development, Model Implementation, and Model Usage.

Automated Decisioning

When using predictive models, such as credit scores or behavior scores, to assess potential future risk, one of the two significant considerations to be taken into account is at which point to set the score cut-off. For example, when using a score that has a range of 0 to 500 (where the lower the number, the higher the risk, and vice versa), a decision may be made to set a score cut-off at, say, 300. That decision drives two actions: accounts scoring above 300 may have no action taken against them, while accounts scoring at or below 300 would have a certain treatment applied.

The second important consideration is that of the treatment itself, which is, in theory, designed to influence account behavior.

Like all decisions, however, these two types are subject to specific scrutiny:

"How do I know if the score cut-off set by my firm is at the right point? Perhaps it should be higher? Or lower?"

"Once the scoring decision has been made, how do I know if the treatment action is the most cost-efficient and cost-effective one available?"

The way to determine the answers to these types of questions comes from continuous learning through ongoing decision testing. For example, to test the cost-efficiency and cost-effectiveness of treatments, accounts that are statistically similar would be segmented randomly, with some accounts receiving "Treatment "X" and other accounts receiving "Treatment "Y." Both decision and subsequent account performance data (including delinquency/NBD measures and treatment costs) would be captured over time and analyzed. This type of testing must be performed in a production environment.

Leading firms (again, looking at the financial services industry as a guide) use an automated decision engine to implement and manage this type of testing in their production environment. An automated decision engine would need to contain the following characteristics to provide the right benefits in terms of managing credit risk:

- Customer assessment using predictive model scorecards (both credit models and behavior models)
- Customer segmentation of accounts into logical groupings
- Flexible decision logic aimed at providing differentiated treatment
- "Test-and-learn" capabilities to continually challenge assumptions about how decisions are (or aren't) affecting customer behavior
- Volume-simulation processing using production volumes to determine operational impacts of potential decision changes
- Comprehensive reporting, including decision effectiveness reporting, model validation, and score/attribute reporting

Account-Performance Data Mart

One of the key elements in any credit risk-management program is the analysis of data. More than just "standard reporting," detailed time series analyses of account performance and decision data is the hallmark of leading-edge accounts receivable management firms, particularly within the financial services industry.

There are four types of data that need to be captured and retained for analysis purposes:

1. *New Account Data:* This includes all relevant data on the through-the-door population in general and on provisioned new accounts in particular. Basically, how did the applicant look when they first came through the door, and how were they evaluated and treated?
2. *Monthly Performance Data:* This type of data, usually obtained from the billing system(s) on a monthly basis, is where detailed account performance, such as usage, payments, and newly calculated behavior scores, is obtained.
3. *Decision Data:* At each and every decision point that affects customer behavior, a copy of that decision, along with the account in question, is stored for future analysis.
4. *Treatment Data:* This includes any type of risk mitigation strategies and tactics, and collection treatments.

In addition to the capture and retention of data, a method of accessing and manipulating the data is required as well.

Benefits

By implementing the previous four initiatives, telecommunications firms can expect to see both top-line and bottom-line benefits in the following areas:

- Increased revenue
- Reduced net bad debt (NBD) expense
- Improvement in cash flow (as measured by days sales outstanding [DSO])
- Reduced operating expenses

Increased Revenues

By using predictive scores (both credit and behavior), companies can better segment their customer base throughout the entire credit life cycle, from account acquisition and provisioning to balance management, to collections and recoveries.

Since predictive scores allow for the rank ordering of accounts by risk, telecommunications firms can avoid treating low-risk accounts (i.e., those accounts with a low probability of becoming delinquent and/or writing off in the future) with tactics and actions aimed at higher-risk customers. By treating low-risk accounts with, say, non-aggressive treatments, it is possible to avoid the potential (and unintentional) suppression of revenues that might not have been permitted by low-risk accounts being treated with more aggressive tactics. Additionally, there may be improvements in customer retention.

Moreover, by deploying automated decisioning capabilities and a data mart to continually test and measure the efficiency and effectiveness of strategy and tactics decisions, many firms are able to quantitatively prove that they are optimizing their decision-management framework.

Reduced NBD Expense

In most instances, *reductions in NBD represent the greatest opportunity for bottom-line improvement*. Predictive scores (both credit and behavior) provide companies with the ability to divide both their applicant and customer bases into risk-based segments and match treatments (i.e., aggressive versus lenient) with associated risk classes.

Reductions in NBD come from both sides of the write-off equation. First, telecommunication firms experience a *reduction in the number of accounts that become delinquent and go to write-off*. This is achieved primarily through the use of credit scores to exclude high-risk accounts (that is, accounts that have a higher propensity to become delinquent and/or write-off than the firm is willing to accept) during the new account acquisition and provisioning process.

Second, companies experience a *reduction in the average write-off balance for accounts that do end up writing off*. This is achieved primarily through the use of behavior scores to minimize balance build-up on accounts that, although non-delinquent today, are at serious risk of becoming delinquent and/or writing off in the future.

Additionally, by deploying automated decisioning capabilities and a data mart to continually test and measure the efficiency and effectiveness of strategy and tactics decisions, it is possible to quantitatively prove that the decision-management framework is being optimizing.

Improved Cash Flow (DSO)

By improving their ability to manage both the number of delinquent accounts and their balances, telecom providers' integrated risk-management approach acts as a force multiplier: In addition to reductions in bad debt, improvements in cash flow as measured by DSO are often achieved.

Since DSO is essentially a measure of the distribution (by age) of the accounts receivable portfolio, a successful risk-management program results in fewer delinquent accounts and lower average balances on those accounts. The net result is that fewer A/R dollars (because of fewer accounts and lower balances) end up being delinquent (i.e., skewed toward the "right side" of a distribution curve). Conversely, more A/R dollars, in absolute and percentage terms, end up being current (i.e., skewed toward the "left side" of a distribution curve). This translates into improved cash flow.

Reduced Operating Expenses

Most companies experience savings in expenses associated with the management of their credit-risk processes, primarily through reduced account volumes in collections. This is achieved in two ways. First, the use of up-front credit scores during the new account acquisition and provisioning process allows firms to exclude high-risk accounts that would most likely end up in collections.

Second, the use of behavior scores, particularly those developed for newly delinquent accounts, provides for the rank ordering of accounts in collections by risk. These rank-ordered accounts are then matched against risk-differentiated treatment strategies, allowing for limited collection resources to be applied to accounts in the most need of direct collector contact. Conversely, lower-risk accounts (i.e., those accounts most likely to pay with minimal or no collector intervention) are then routed to collection-treatment scenarios that don't incur higher-costing collector intervention.

Other Benefits

Many telecom providers are able to achieve two other benefits that, while not directly bottom-line–measurable, are crucial to effective credit-risk management:

Consistency in Decisioning: In most manual/subjective environments, the application of decisions is inconsistent across two compounding dimensions: 1) different individuals make different decisions, and 2) the same individual makes different decisions over time. Leading-edge companies resolve these two inconsistencies through the use of predictive scores (both credit and behavior) and the application of decision logic through an automated decision engine.

Ability to Prove Decision Optimization: By incorporating "test-and-learn" strategies across the entire decision-management framework in conjunction with a dedicated data mart, both "champion/challenger" and "control" groups can be created to prove quantitatively that all credit-risk–related decisions are being made to optimize overall A/R portfolio results.

FCC Tackles Number Conservation—Again

David Crowe
President
Cellular Networking Perspectives Ltd.

In December 2000, the Federal Communications Commission (FCC) released a second Report & Order[1] regarding numbering resource optimization—the conservation of the rapidly dwindling North American numbering resource. Although the FCC only has authority over U.S. phone numbers, and even though it shares this authority with the States, any changes adopted by the FCC will have a big influence on Canada and the Caribbean nations that share this numbering space.

Wireless carriers will be heavily affected by the various initiatives being considered by the FCC, particularly number pooling.

Thousands-Block Pooling

The FCC is still enamored of thousands-block pooling, implying it is superior to other methods of number conservation. Unfortunately, number pooling works only if wireless carriers adhere to the same number of assignment boundaries (rate centers) as landline carriers, and this will reduce the efficiency of number assignment considerably.

Thousands-block pooling allows the current basic number allocation unit (10,000 numbers) to be shared among as many as 10 carriers. This could also be done by moving from a 6-digit to a 7-digit number analysis, but this has not been considered by the FCC, although it may have less impact on switching equipment.

It might seem unnecessary to share blocks of 10,000 numbers among carriers when there are hundreds of millions of phone numbers in use. There are two reasons for this:

1. Competition in the local-exchange market is resulting in more companies assigning numbers to phones. Note that competition in the long-distance market did not have this effect because these carriers do not assign phone numbers.
2. The rate centers are small. The rate center is the geographical area within which numbers are assigned by local-exchange carriers (LECs). This means even large customers may not always be able to fill a block of 10,000 numbers.

Competition is only going to get more intense, but rate centers are artificial areas that could be merged together, allowing more carriers to obtain several thousand customers in each rate center, which would make pooling unnecessary.

The reason behind the FCC's enthusiasm may be that pooling makes use of the local number portability (LNP) infrastructure mandated by them, and it therefore may make the expense and complexity more palatable. Number pooling, however, has some important differences from LNP. Whereas LNP has to support the migration of single or small blocks of numbers to another carrier, number pooling starts with at least 1,000 numbers moving. Number-portability systems (NPAC Release 3.0) have had to be modified to represent a pooled block by one record instead of 1,000. Straightforward implementations of LNP would collapse under the data storage requirements of number pooling.

Wireless Carriers and Pooling

Wireless carriers cannot participate in number pooling unless they adapt their number-assignment procedures to those of rate centers. Wireless carriers generally assign numbers in larger areas, resulting in a larger local calling area. If wireless carriers were to conform to rate center boundaries, their number allocations would instantly become much less efficient, and number pooling cannot be guaranteed to return wireless carriers to the level at which they started!

Timing for Wireless Carriers

The FCC has ruled that wireless carriers must support number pooling as soon as they are able to support LNP. The FCC declined to give any transition interval, even though LNP and number pooling are not identical capabilities.

Rate-Center Consolidation

Rate centers are the fundamental unit of number assignment and billing in the North American Numbering Plan (NANP). Every number within a rate center is considered to be in the same location for billing purposes, meaning that tolls cannot be charged within a rate center.

In many cases, there are multiple, adjacent rate centers between which long-distance charges do not apply. These could be consolidated with minimal impact on billing. By doing this, all number blocks within the enlarged rate center would be available for assignment. The only potentially negative effect of this is that the calculation of charges based on distance would be slightly different—higher for some calls and lower for others. However, with distance-insensitive billing for long distance increasing in popularity, and with the differences being small, this is probably not a serious problem.

Combining rate centers between which toll charges apply is more controversial; however, any loss here could easily be handled by adjusting local rates such that consumers would not see an increase in the overall costs of telecom services.

The FCC is warming toward rate-center consolidation. It would probably be more enthusiastic if rate-center boundaries were under FCC control, rather than under state control. Number pooling, by contrast, is largely within FCC jurisdiction.

Thresholds

The FCC requires carriers adhere to number utilization thresholds before being eligible for more numbering resources. The threshold will be set at 60% on March 29, 2001, and this will increase by 5% on June 30, 2002, and by another 5% each following year, to a maximum of 75% on June 30, 2004.

The calculation of thresholds is strictly:

$$\frac{\text{Numbers assigned to customers}}{\text{Numbers assigned to carrier}}$$

Numbers used for testing, numbers used for administrative purposes, or numbers being aged (i.e., taken from one customer but not eligible for reassignment to another customer for some time to prevent confusion) are not counted as "assigned to a customer." Thresholds are calculated separately for each rate center.

Audits

The FCC has claimed the right to audit carriers, randomly or for cause, to determine what their use of numbers really is.

Assigning New Area Codes: Splits versus Overlays

When numbering resources within an area code are nearly exhausted, a new area code must be assigned. To maintain number conservation objectives, this should be done efficiently. The basic choices are as follows:

- Splitting: Assigning a new area code to some existing customers
- Overlaying: Assigning a new area code for new numbers only

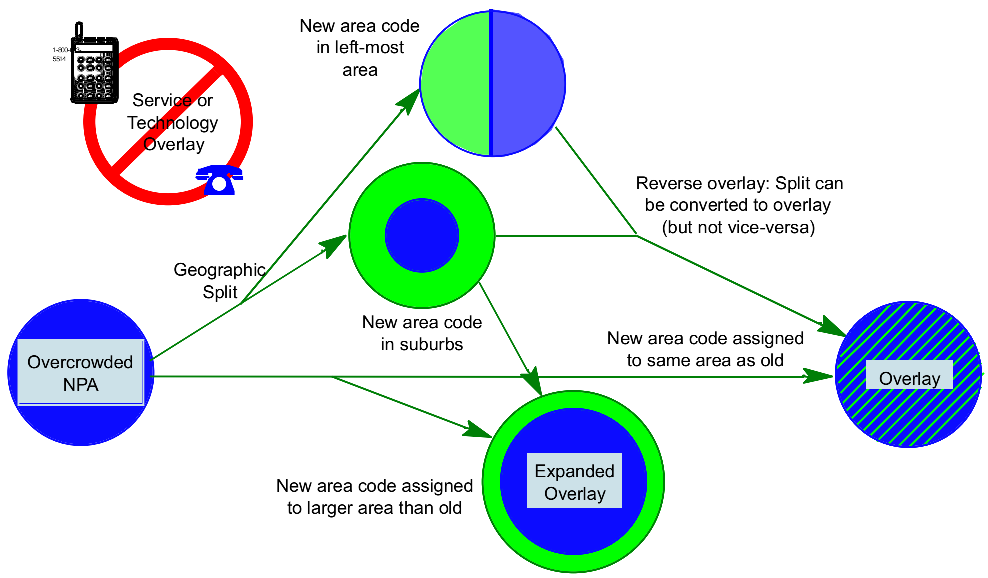
Area-Code Splits

Splitting an area code is the traditional way to assign new numbering resources, but this results in half of existing phones being assigned new numbers. Seven-digit dialing between the area codes can be preserved by "protecting" certain office codes from assignment in the new area code, but this does not meet number conservation objectives. Ten-digit dialing from one area code to another will be necessary, eventually, to allow all office codes to be utilized.

Figure 1 illustrates how splits can be performed. Often, the suburban area will receive the new area code (e.g., as in Dallas and Atlanta), but it is possible to split a region down the middle (e.g., a city straddling a river) or in any other way dividing the population approximately in half, with some consideration given to expected growth patterns.

FIGURE 1

Area-Code Splits and Overlays



Overlays
Overlays assign the new area code to the same geographical area as the old area code. The FCC has banned the use of service-specific or technology-specific overlays (e.g., all wireless phones in the new area code) as discriminatory. Overlays are used, instead, for new numbering requirements. This puts newer customers at a disadvantage, because the majority of customers need to dial 10 digits to reach them (and vice versa). Consequently, mandatory 10-digit dialing may be applied so that everyone may suffer for the benefit of the minority.

A variant on the overlay is the *expanded overlay*. In this instance, the new area code applies to a larger geographical area. This allows one area code's resources to provide relief to two existing areas, which is useful when growth is expected in suburban areas. Another variant, a *reverse overlay*, allows the conversion of an area-code split into an overlay; the assignment of both area codes is allowed over the entire area—a useful approach when population growth projections proved to be invalid.

No Nationwide 10-Digit Dialing

The FCC will not force nationwide 10-digit dialing, but it will creep in as area codes get smaller with splits and as areas affected by overlays mandate 10-digit dialing.

"D" Digit Expansion

The fourth digit of a NANP number (when expressed in its 10-digit format), known as the "D" digit, is restricted to "2" through "9" to allow 7-digit dialing. If this digit was a "0" or a "1," some switches would be confused, not being able to differentiate between local calling and operator/long-distance services.

Expanding the "D" digit would expand the capacity of each area code by about 25 percent, but nationwide 10-digit dialing would be a prerequisite. The FCC decided not to mandate this step—yet.

Conclusions

The FCC still favors thousands-block pooling, even though this may waste as many numbers as it saves, will cause wireless carriers significant costs, and could cause them to fail to assign numbers as efficiently as they do today.

Table 1 compares the major forms of number expansion and conservation being promoted by the FCC. Splits and overlays are required when numbering resources are exhausted and when the choice between them is not straightforward. Number pooling is inferior to rate centers because of its reliance on LNP, with its cost and reliability issues, and because carriers will be forced to adhere to rate-center boundaries, which, unless rate-center consolidation occurs, cannot be done efficiently. Additionally, if rate-center consolidation does occur, the need to share pools of less than 10,000 numbers may not exist.

Notes

1. The Report & Order is available at www.fcc.gov/Daily_Releases/Daily_Business/2000/db1229/ fcc00429.doc (or .txt).

Revitalizing Legacy Business Support Systems

Rolando Espinosa
Senior Vice President, Products and Strategy
Abiliti Solutions

It has been five years since the Telecommunications Act of 1996 legislation created this marketplace. A lot of "noise" has been produced by the changes in the investment in and valuation of technology companies, but through this, a very traditional trend has developed—the maturing of an industry.

As with other telecom markets that preceded it, the measure of a competitive local-exchange carrier's (CLEC's) value has shifted over time. Initially, network deployment and geographic coverage drove valuation. In other words, does the CLEC have the potential to succeed?

Second came customer acquisition. Could the company demonstrate its ability to succeed by winning customers?

Today, the CLEC market is in its third phase of maturity, where success is no longer measured by size alone, but by profitability.

A CLEC's view of its investment in business support systems (BSSs) needs to change to keep pace with its evolving objectives. In the early life-cycle phase, a BSS application was a security blanket facilitating growth to assure investors and customers of its stability. The more a CLEC spent on BSS, the greater the security.

In today's environment, efficiency is the goal of BSS expenditures. A dollar spent in BSS infrastructure must facilitate a cost savings or revenue increase of more than a dollar.

A shift from organic growth to acquisition creates challenges for the BSS infrastructure.

Firms that cannot achieve profitability become takeover candidates. Strong CLECs are becoming both larger and more profitable by acquiring their weaker brethren. A potentially negative by-product of this otherwise sound course of action is that CLECs are left with multiple BSS applications to manage and, therefore, face increased expenses.

- ***Training Personnel on Multiple Systems***
  Acquisitions create the redistribution of employees and ultimately layoffs. Employees need training to work on systems with which they are not familiar and have distinctly different user interfaces. Worse yet, employees may be required to work on multiple systems simultaneously. The efficiencies and profitability envisioned by the acquisition are then difficult to achieve.
- ***Implementing Products and Services in Multiple Systems***
  Acquisitions often result in the overlapping of markets and products and redundant BSS applications, which leads to the need for duplicate data entry. If a carrier wants to offer a common product suite across markets, this will usually require dual entry into multiple BSS applications. This also assumes that the two systems can support the same product set and service definitions.
- ***Developing Interfaces to New Call Record and Event Formats in Each System***
  Acquisitions result in new networks or network components or new downstream BSS components using the same network. Either way, if the network changes, through the acquisition of new elements or the introduction of new features or services, this will affect the interface/handoff of call detail records (CDRs) to downstream BSS components. A greater number of standalone components leads to a greater number of changes required and, therefore, increased cost.
- ***Managing the Same Information in Disparate Systems***
  Having the same customer in two systems (for example, one for Internet protocol (IP) billing and one for voice) requires dual entry. This translates to twice the time and potentially increases the number of mistakes. The more systems a CLEC manages, the greater the time and effort to maintain consistency. Maintenance costs increase exponentially with each new system addition.
- ***Producing Multiple Reports from Each System***
  Not only are users forced to interact with widely different user interfaces, but the reporting methodologies and tools may be vastly different as well. Information is fragmented across multiple systems, and the cost to converge databases and reports is another drain on the profitability of a CLEC.

The end result is inefficiency and revenue leakage due to redundancies, omissions, and inconsistencies.

The rollout of new products and services present another challenge to the BSS infrastructure.

When CLECs first entered the market, customers were looking for any alternative to the incumbent local-exchange carriers (ILECs). This demand coupled with the ability to bundle local and long-distance services and under-cut ILEC pricing plans fueled customer acquisition. However, this flood of customers will not last forever. New products and services are necessary to continue growth.

New service offerings lead to increased profitability for two reasons. First, the cost of upselling a new product to an existing customer is significantly less expensive than acquiring new users. Second, customers using a wide variety of a CLEC's services are less likely to churn.

CLECs are currently introducing the following products and services:

- ***Usage-Based IP Services:*** This includes billing customers based on actual usage, such as MB of disk space, e-mail messages sent, session duration, bytes transferred, number of documents downloaded, online gaming, etc.
- ***Quality of Service (QoS)–Based Pricing:*** This builds QoS metrics (e.g., network availability, connection setup time, and error performance) into pricing plans or service-level agreement (SLA) credits.
- ***Content Services:*** This includes the delivery of secure data transmissions, streaming media, frequent updates, or mission-critical applications.

How best to address the BSS challenges?

Whether facing a legacy BSS unable to support new products or determining how to manage a BSS environment, carriers have three options:

- ***Replace Their BSS Applications or Consolidate to One System.***
  This is the commonly implemented solution. However, the complexity of the migration increases with carrier size. Integrated links established over time with other operations support system (OSS) applications must be simultaneously redeveloped. Many employees must be retrained. During a large migration, a carrier will be less responsive to customer needs and competitive actions, posing a great detriment to a CLEC's success over the long term.
- ***Support New Services by Implementing Additional BSS Applications, Consequently Creating a Multiple Systems Environment.***
  There are inherent inefficiencies maintaining multiple systems. The expense of a secondary BSS (whether it supports a narrow product set or small geographic territory) will be allocated against a smaller revenue stream.
- ***Add an Event-Management and Rating System to the Legacy Environment to Overcome Limitations.***
  This solution enables a carrier to gain the necessary flexibility to address the unique needs of new services. This approach also offers more efficient transmission of data both into and between BSS applications, while avoiding costly duplication.

As the market matures, investment-driven growth must be replaced by profit-driven growth. CLECs today must be able to survive solely on the revenue they can garner from product and service sales. For this reason, greater emphasis must be placed on "revenue mining." Service providers must ensure they are mining their networks for every last billable nugget they can find. They must ask the following:

- Am I getting revenue out of each transaction on my network?
- How do I know I'm getting the maximum revenue available?
- Am I getting the most out of my existing legacy systems, or am I spending hard-earned dollars repeating the same tasks on multiple systems?
- How can I ensure that I'm billing all I can and that I am doing it at the lowest possible cost?

CLEC's can use a single, convergent event-management and rating system in conjunction with their legacy BSS applications to increase revenue from new service introductions while maintaining efficient, cost-effective operations.

This paper was previously published at CLEC.com, September 1, 2001.

Changing Business and Its Paradigms: Post 9/11/01

Robert S. Fleming
Professor, Management and Management Information Systems
Rowan University

The world in which we live, work, and travel changed on September 11, 2001. The terrorist attacks of that day and the ensuing attacks involving Anthrax letters following that date have caused individuals, groups, and organizations around the world to ponder the new realities of terrorism and attempt to make sense out of these new developments.

Unfortunately, the reality is that vulnerability to acts of terrorism has been recognized for some time. The 1993 bombing of the World Trade Center, the 1995 bombing of the Alfred P. Murrah Federal Building in Oklahoma City, and a number of less visible and publicized smaller events have called attention to this vulnerability well in advance of September 11, 2001. Those responsible for the information technology (IT) function in contemporary organizations have recognized this threat, particularly as it relates to cyberterrorism, for some time.

In recent years, governmental agencies, elected officials, emergency response agencies, and "first responders" have been diligently preparing for potential terrorist attacks. These preparation activities have been largely coordinated through the U.S. Department of Justice (DOJ) and the Federal Emergency Management Agency (FEMA). A particular focus of these efforts has been on protecting the governmental and business IT infrastructure.

In 1998, the U.S. Department of Justice Office for State and Local Domestic Preparedness Support convened the *Domestic Preparedness Stakeholders Forum* in the interest of assessing the level of preparedness to effectively and efficiently respond to a terrorist attack and to make recommendations regarding enhancing our level of preparation and readiness. This multidisciplinary panel was constituted to include representation from all of the agencies and major organizational entities that would be involved in responding to a major terrorist attack, particularly one involving weapons of mass destruction (WMD).

This panel identified a number of areas of our domestic preparedness for acts of terrorism that should be addressed, including comprehensive planning, coordination, incident management, training, equipment, and the interoperability of communications systems. A series of recommendations with respect to these issues was developed and presented to Attorney General Janet Reno and FEMA Director James Lee Witt. Both of these key members of the administration and the agencies that they led embraced the ever-present reality of the threat of domestic and international terrorism and embarked on a mission of enhancing our level of national preparedness.

The diligence of these federal agencies and others, coupled with their state and local partners, resulted in the development of a comprehensive system of response preparedness. The key to the success of this system is that it involves a coordination of local, state, and federal agencies and resources. This is imperative in that the initial response to any emergency incident will consist of local fire, law enforcement, emergency medical services, and emergency management resources.

Through a coordinated system of preparation and response, governmental entities and emergency management agencies have been preparing for inevitable terrorist attacks. The early preparation activities focused on our nation's 120 largest metropolitan areas. Later these initiatives were expanded to encompass 151 cities and/or metropolitan areas. More recently, these efforts have been further expanded to address the preparation of jurisdictions throughout the nation.

These preparation initiatives are designed to "plan for the worst" but assume that "the worst will never happen." It is indeed fortunate that governmental and emergency management officials had planned for the worst given that the worst did occur on September 11, 2001.

The fact that New York City and Washington, D.C. have been aggressive in their preparedness initiatives was also crucial to the outcomes of the events of September 11, 2001. The horrific events of this tragic day reinforced the importance of effective risk management and emergency planning and preparedness. While the loss of life on September 11, 2001 was massive, the ability of "first responders," including fire, law enforcement, and emergency medical services personnel, to evacuate and rescue so many individuals from the World Trade Center buildings attests to the importance of planning and preparedness. It is likely that if the events of September 11, 2001 were to have occurred on February 26, 1993, the day of the earlier World Trade Center bombing, the loss of life would have been much greater.

The importance of governmental agencies assessing vulnerability to acts of terrorism is evident, as is the importance of their planning and preparation. While as a nation we have made great strides in this pilgrimage, it is imperative that contemporary organizations likewise assess their vulnerability to acts of terrorism and engage in effective risk-management practices to address these vulnerabilities. An integral aspect of these initiatives must address the vulnerability and preparedness of an organization's IT resources.

The focus of this article will be on how assessment of organizational vulnerability and organizational preparedness has become a priority of most contemporary organizations since September 11, 2001. After relating a number of dimensions that should be addressed in assessing organizational vulnerability to acts of terrorism, we will examine what contemporary organizations and their IT functions can do to decrease their vulnerability to acts of terrorism and increase their level of preparedness to prevent, respond to, and recover from terrorist attacks.

Reality of the Terrorist Threat

The events of September 11, 2001, have clearly illuminated the fact that we as a nation, like other civilized countries around the world, face an ever-present threat of terrorism. Only through comprehensive and coordinated planning and preparedness can nations, communities, and organizations successfully prepare to defend against and respond to acts of terrorism.

Potential Threats

The five potential threats of terrorism that have been utilized in planning models have traditionally included biological events, chemical events, explosive events, incendiary events, and nuclear events. The potential for cyberterrorism has been recognized in recent years as a formidable means of terrorist attack. While some of these types of attack are certainly more probable than others, contemporary organizations should consider all six (including cyberterrorism) as they assess their vulnerability and preparedness.

Potential Harm

The harm resulting from a terrorist attack, invoked by one of the aforementioned means, can include asphyxiation harm, chemical harm, etiologic harm, mechanical harm, radiological harm, and thermal harm. These six types of harm are based on the five traditional types of terrorist attacks referenced and focus on harm invoked in terms of injuries, fatalities, and damage to tangible resources, including buildings, equipment, inventory, and infrastructure. The addition of cyberterrorism to the previous list should initiate contemplation of additional harm that an organization could suffer in terms of both tangible and intangible IT resources and infrastructure.

Vulnerability to Acts of Terrorism

Organizational vulnerability to acts of terrorism is influenced by a number of factors including: potential targets, environmental factors, organizational exposure, organizational preparedness, and business impact. Each of these dimensions must be considered as the contemporary organization engages in an assessment of its vulnerability to and preparedness for potential acts of terrorism.

Potential Targets

The potential targets of a terrorist attack can be categorized as general targets, organizational targets, and facility targets. In assessing their vulnerability to acts of terrorism, contemporary organizations must consider their organization in light of each of these types of potential targets. It must be understood that an organization may be a target from one or more of these perspectives.

General targets include controversial businesses, historical sites, infrastructure systems, places of assembly, public buildings, and symbolic targets. The World Trade Center and the Pentagon each involved a number of these characteristics of a general target. *Organizational targets* are based on the mission, products, services, political affiliation, and/or sociocultural position(s) of an organization. A given organizational facility may be a *facility target* based on its geographic location, proximity to other targets, products produced, services delivered, potential impact, or visibility.

Environmental Factors

A number of environmental factors may account for the ever-present reality of terrorism in general and for the vulnerability of specific organizations and their facilities to acts of domestic or international terrorism. These factors fall into the known general environment categories of political/legal, sociocultural, economic, and technological. The importance of the technological dimension must be emphasized given its relevance to the infrastructure utilized by and the business operations conducted by contemporary organizations.

Organizational Exposure

The two major determinants in assessing organizational exposure to vulnerability to acts of terrorism are the degree of exposure and the impact of exposure. *Degree of exposure* is influenced by mission-critical activities, centralization/decentralization, involved operations, and task interdependencies. In evaluating the *impact of exposure*, an organization should evaluate its ability to operate after a terrorist attack, its ability to survive after an attack, increased post-attack operating costs, and potential length of post-attack business interruption.

Organizational Preparedness

In evaluating organizational vulnerability to acts of terrorism, the current level of preparation to prevent, respond to, and recover from a terrorist attack must be fully understood. While an outcome of the process of assessing organizational vulnerability to acts of terrorism will likely be the development and implementation of organizational strategies to enhance organizational preparedness, the current level of organizational preparedness must be a key consideration in the evaluation of organizational vulnerability. While any number of attributes of the organization could prove to be either an organizational strength or an organizational weakness with respect to organizational preparedness, the areas of organizational planning, organizational structure, organizational controls, and risk-management programs are typically considered.

Organizational planning processes that provide for both comprehensive and contingency planning are desirable to enhance organizational preparedness, whereas ineffective or nonexistent planning compromises organizational preparedness. A decentralized *organizational structure* is an integral attribute of organizational preparedness, whereas a centralized organization contributes to an enhanced vulnerability. *Effective organizational controls*, in addition to ensuring an effective and efficient business operation, serve as a crucial component of organizational preparedness, thus organizations with ineffective control processes face an increased vulnerability.

Last, but certainly not least, are the *risk-management programs* currently operational within the organization. Effective risk-management programs are central to enhancing organizational preparedness for acts of terrorism, whereas ineffective risk-management programs or the absence of these programs greatly reduce organizational preparedness and increase organizational vulnerability.

Business Impact

In addition to the aforementioned considerations, the potential business impact of a terrorist attack must be considered in the evaluation of organizational vulnerability to acts of terrorism. This is a particularly important set of factors to consider as the contemporary organization seeks to realistically assess its vulnerability and to engage in proactive planning and preparation initiatives designed to enable the organization to prevent, respond to, and recover from a terrorist attack.

Factors to be considered with respect to business impact include business failure, customer/contract loss, personnel recruitment and retention, reduced market-share, reduced sales/revenues, reduced profitability, and reputation loss. One or more of these issues are likely to prove to be formidable issues for most contemporary organizations.

Rethinking Organizational Vulnerability and Preparedness

A recent research study conducted by the author sought to determine if contemporary organizations are rethinking their vulnerability to acts of terrorism in light of the recent tragic events. Corporate executives participating in the survey were asked to indicate if their perceptions of organizational vulnerability to acts of terrorism had increased, remained unchanged, or decreased since the tragic events of September 11, 2001.

Organizational Vulnerability

The majority of the survey respondents (87.3 percent) indicated that they recognized an increased organizational vulnerability to acts of terrorism since the events of September 11, 2001. The remaining 12.7 percent of the respondents indicated that the vulnerability of their organization had not changed based on the events of September 11, 2001.

Survey participants were asked if they expected the vulnerability of their organizations to acts of terrorism to increase, remain constant, or decrease over the next three years. The majority (89.8 percent) indicated that they anticipated that the vulnerability of their organization would increase over the next three years, while 10.2 percent indicated that it would remain constant.

Organizational Preparedness

The corporate executives participating in the research study were asked to indicate whether their perceptions of organizational preparedness for acts of terrorism had increased, remained unchanged, or decreased since September 11, 2001. The majority of survey respondents (82.2 percent) indicated that they perceived a decreased level of organizational preparedness, while 17.8 percent indicated that their perceptions of organizational preparedness had not changed since September 11, 2001.

Survey participants were asked if they expected the preparedness of their organization for acts of terrorism to increase, remain unchanged, or decrease over the next three years. A majority of the respondents (93.2 percent) expected that organizational preparedness would increase and only 6.8 percent anticipated that it would remain unchanged.

Changing Paradigms for Contemporary Organizations

The events that occurred on September 11, 2001, have since caused us as individuals, communities, organizations, and a nation to rethink how we live, work, and travel. Contemporary organizations are facing the reality of a new paradigm of conducting business. In recent years, we have heard highly respected and successful business leaders and academicians advocate that we must change the paradigms of how we do business. Our businesses have embraced the importance of quality management and made a commitment to continuous improvement and our economy has demonstrated the results. As with anything that is new, the quality movement had its early adopters, those organizations who bought in later, and those who held out and become late adopters.

The tragic events of September 11, 2001, served as the catalyst for a less subtle and much more timely paradigm shift. Contemporary organizations around the world are rethinking the way they conduct business. They are assessing their vulnerability to acts of terrorism and developing and implementing strategies to enhance their organizational preparedness for the formidable enemy of domestic and/or international terrorism. While for many organizations these analysis and planning processes are currently in process, it is anticipated that the outcomes of these proactive initiatives will include changing paradigms with respect to both business practices and conduct and the contemporary IT function.

Business Practices and Conduct

The ever-present threat of domestic and international terrorism, while a challenge that must be addressed by the leaders of contemporary organizations and the organizations that they lead, is not excepted to completely change the way in which the world of contemporary business functions or the business practices and conduct of a given contemporary organization. A proactive approach to embracing the threat of terrorism faced by the organization will, however, cause it to rethink a number of issues regarding the conduct of its business.

Organizational Mission: The mission of an organization drives organizational outputs, processes, and inputs. Organizational mission may cause an organization to become an organizational target. Contemporary organizations are thus advised to re-examine their mission in light of the threat of terrorism and revise their mission statement as appropriate.

Products and Services: The products produced and/or services delivered by an organization may make it an organizational target or facility target. A cost-benefit analysis may reveal that certain products and/or services currently offered contribute to an unacceptable vulnerability to terrorism.

Diversification: Contemporary organizations engage in a variety of diversification initiatives, including horizontal, vertical, and global diversification. They accomplish diversification through internal development, acquisition, and strategic partnerships. Contemporary organizations, interested in reducing their vulnerability to acts of terrorism, may consider making changes in their portfolio of business holdings and operations.

Organizational Planning: An integral component of the successful contemporary organization is its planning processes. The ability to manage in a proactive manner is based upon having comprehensive planning processes in place. The importance of assessing vulnerability to and preparedness for acts of terrorism while analyzing organizational strengths and weaknesses in light of environmental opportunities and threats cannot be overstated. Contingency planning must be addressed within the organization's planning processes.

Organizational Structure: The degree of centralization/decentralization of an organization can be a determinant of its ability to prevent, respond to, and recover from a terrorist attack. The more centralized the organization, the more vulnerable it will be to acts of terrorism. The more decentralized the organization, the less vulnerable it will be. The degree of centralization/decentralization can thus influence the various factors previously described with respect to the business impact of a terrorist attack. Organizations concerned about reducing their vulnerability are likely to implement strategies designed to further decentralize their operations and to enhance redundancy in the interest of business continuation should the organization experience a terrorist attack or other major emergency situation.

Organizational Controls: Organizations that lack control systems or have ineffective controls are likely to be more vulnerable to acts of terrorism than those that have effective control systems. It is imperative that contemporary organizations examine their control systems in light of the potential threat of terrorism.

Risk-Management Programs: The importance of having an effective risk-management program in place to protect the organization from the threat of terrorism should be obvious. This risk-management program should include both risk-assessment and risk-control measures.

Facility Site Selection: The physical location of a facility or its proximity to other targets can make one or more facilities of an organization a facility target. Potential vulnerability to acts of terrorism and the ability of an organization to defend itself against such attacks should be a new consideration when making facility site selection decisions.

Personnel Recruitment and Retention: The success of any contemporary organization is largely determined by its ability to attract, motivate, and retain a qualified and committed workforce. This will present an increased challenge given the concerns of existing and potential employees with respect to terrorism. Contemporary organizations must make the safety and protection of their personnel a priority.

Increased Use of Telecommunications: Concerns regarding terrorism have greatly reduced travel since September 11, 2001. Organizations are limiting traditional business travel and conducting more business meetings through the use of telecommunications. A benefit of this new approach to conducting business may be lower meeting costs and greater productivity. It is also expected that there will be a continuing trend toward the use of e-commerce.

The Contemporary IT Function

Each of the issues related to business practices and conduct just presented may have an impact on the organization's IT function. The decision-making involved in addressing these business issues will require IT support. Organizational decisions to change the mission, structure, products and/or services, or controls of the organization or to diversify its operations will pose many challenges for the IT function. IT resources will be central to the organization's risk management, human-resources management, and site-selection programs. The increased use of telecommunications will also result in increased stakeholder expectations regarding the organization's IT function.

In addition to responding to the IT challenges related to the changing business paradigms just discussed, the IT function within the contemporary organization will need to address the following issues regarding the provision of IT services that are effective, efficient, responsive, and secure.

Changing IT Role: The role of the IT function within the successful contemporary organization has undergone a significant evolution in recent years. The role and importance of the IT function are likely to be enhanced as a result of the new vulnerabilities that contemporary organizations are recognizing with respect to organizational vulnerability to terrorist attacks, including those involving cyberterrorism.

IT Resources That Support Business Needs: The IT function within the contemporary organization will be expected to continue to support the business needs of the organization. The importance of protecting organizational IT resources from attack will be paramount in both the present and the future. The preparedness of a contemporary organization to prevent, respond to, and recover from a terrorist attack will largely depend upon the security, redundancy, and robustness of its IT resources.

Recruitment and Retention of IT Personnel: The recruitment and retention of IT personnel is likely to become even more of a challenge in the future. Comprehensive screening approaches will be necessary to insure the preservation of IT resources through effective hiring and security practices.

Enhanced System Security: System security will become an increased priority in contemporary organizations. Vulnerability to traditional acts of terrorism, coupled with the potential of cyberterrorism, will result in the invocation of proactive strategies to ensure system security and the protection of organizational IT resources.

Protecting IT Resources: The importance of protecting IT resources should be obvious in light of the recent tragic events. The IT function will be expected to demonstrate proper stewardship for the organizational IT resources that have been entrusted to it. Strategies must be developed that ensure the protection of all IT resources, including hardware, software, and data.

System Configuration: Those responsible for the organization's IT resources should rethink the current configuration of their systems. This may prove to be a difficult and problematic issue. The traditional control and security advantages associated with centralized systems are now offset by the major disadvantages of IT resources that are primarily in one central location. Clearly, those responsible for protecting the physical systems in place within the World Trade Center buildings would likely not have imagined the physical attack experienced on September 11, 2001. Decentralized and distributed systems, which are properly secured, will likely be advantageous as an organization seeks to develop its preparedness to prevent, respond to, and recover from a terrorist attack.

Information System Controls: As always, information system controls must be our first line of defense in protecting IT resources. These control systems should include general controls, application controls, and network protection. The traditional types of general controls, including physical controls, access controls, data-security controls, communication controls, and administrative controls, will increase in importance. Application controls, designed to protect the system during input, processing, and output activities, will continue to be a mainstay of IT resource protection. Last, but certainly not least in light of the threat of cyberterrorism, will be the enhanced use of network-security measures and firewalls.

Disaster-Recovery Planning: Disaster-recovery planning will be central to an organization's preparedness for acts of terrorism. The ability of the organization to "get back in business" will determine the impact of its exposure to a terrorist attack. Organizations that are capable of restoring their mission-critical information systems in a timely manner will be able to restart their operations, survive, minimize increased operating costs, and limit the length of business interruption. This ability will consequentially reduce the potential business impact of a terrorist attack, including business failure, customer/contract loss, personnel recruitment and retention, reduced market-share, reduced profitability, reduced sales/revenues, and reputation loss.

Back-Up Systems: It goes without saying that the recent tragic events clearly illustrate the importance of system back-up routines that are religiously practiced, as well as the importance of off-site storage of back-ups.

Auditing Information Systems: Information systems should be audited periodically to ensure that they are operating properly in accordance with the business needs of the organization and acceptable business and information-processing practices. The issues considered in these audits must be expanded to include those practices that will reduce organizational vulnerability to acts of terrorism and will enable an organization to be prepared to prevent, respond to, and recover from a terrorist attack.

Preparing for a Successful and Safe Organizational Future

Contemporary organizations face many unprecedented challenges as a result of the ever-present reality of terrorism. The future success of the contemporary organization, the safety of its personnel, and the protection of its tangible and intangible assets will require a proactive management approach. Assessing organizational vulnerability to acts of terrorism and an organization's level of preparedness to prevent, respond to, and recover from a terrorist act is not an option.

Within the contemporary organization, we are all in this together. Corporate managers and the employees of the organizations they lead must embrace and aggressively respond to this challenge together. IT professionals must stand shoulder to shoulder with the organization's management team to ensure our readiness and defense. We stand together in the war on domestic and international terrorism.

Telecommunications Regulation in Puerto Rico: Past, Present, and Future

Phoebe Forsythe-Isales
President
Telecommunications Regulatory Board of Puerto Rico

The history of the telecommunications field in the Commonwealth of Puerto Rico is inseparably tied to that of our brethren in the continental United States. There is a shared monopolistic past; a common submission to the rule of law, be it federal or state; and a strong sense of fairness, all of which have given rise to corresponding approaches to the regulation and deregulation of telecommunications markets.

In 1934, during the Great Depression, Congress enacted the Federal Communications Act. The 1934 Act established an independent regulatory body, the Federal Communications Commission (FCC), with broad powers to make nationwide wire and radio communications services available to all at reasonable prices and through adequate facilities. However, the 1934 Act's scope was limited to interstate and foreign communications, leaving intrastate regulation in the hands of local agencies, usually called public service or public utility commissions (PSCs or PUCs).

During the decades that followed the adoption of the 1934 Act, the intrastate telecommunications market was assumed, both by federal and state regulators, to constitute a so-called natural monopoly, that is, a market that can best be serviced by a single local-exchange carrier (LEC). Under this view, the role of the state PUC was, fundamentally, to outlaw competition and authorize the incumbent LEC (ILEC) to charge high business rates while simultaneously pushing said incumbent to maximize telephone penetration in low-cost and often unprofitable residential markets. This meant that business customers subsidized residential customers.

In Puerto Rico, the telecommunications market had displayed its monopolistic colors since its origins in 1914. The high cost associated with the establishment of infrastructure as well as other technical difficulties left a deep monopolistic imprimatur. The monopoly eventually extended to local service and intra-island long-distance service and became government owned in 1974. By the same token, AT&T's stateside monopoly not only integrated local and long-distance service, but telephone manufacturing as well.

Excluding the federal antitrust action against AT&T during the late 1970s, which in 1984 brought about the breakup of AT&T from its regional Bell operating companies (RBOCs), local monopolies remained generally undisturbed until the landmark passage of the Federal Telecommunications Act of 1996.[1] The 1996 Act radically shifted the telecommunications paradigm that structured local telephony. Not only did the 1996 Act outlaw local barriers to market entry and competition, but ILECs would now bear substantial obligations toward competitors. Under the new regime, ILECs would now have to allow rivals to interconnect with its network elements (switches, loops, trunks, etc.) on an unbundled basis and at advantageous cost-based rates. ILECs would also be required to facilitate market entry by new competitive LECs (CLECs) by providing them, at wholesale discount rates, services that it normally sold retail to its subscribers. Upon a finding that RBOC ILECs had taken meaningful and sufficient steps to open local markets, the FCC would then allow ILECs to enter into the manufacturing and interstate long-distance markets.

The 1996 Act enabled PUCs and PSCs in the 50 states and Puerto Rico to steer the implementation of the newly deregulated intrastate telecommunications landscape. The local PSC would make sure that the ILEC abided by the new cost-based interconnection and wholesale service rules, as well as enforce other market-opening powers, such as local number portability (LNP) and dialing parity requirements, prohibition of the *cramming* of unwanted services into a user's package, proscription of the illicit change of a user's presubscribed carrier (*slamming*), regulation of rights of way and collocation, mediation and arbitration of interconnection agreements, reciprocal compensation arrangements, among others.

In Puerto Rico, the monopoly of intra-island service persisted. As a result, the Commonwealth Legislature saw fit to create a specialized and dedicated body to carry out the local aspects of the 1996 Act's mandate. Unlike stateside PUCs and PSCs, which oversee several utilities such as electricity, gas, water, and telecommunications, Puerto Rico opted for an agency established for the sole purpose of achieving the pro-competitive goals set by Congress, while minimizing the hindrance and complication that involves regulating multiple and radically different sectors of the economy. As such, and just seven months after the Federal 1996 Act was passed, the Governor of Puerto Rico signed into effect Act 213 of September 12, 1996, otherwise known as the Puerto Rico Telecommunications Act of 1996, the statute that created the Puerto Rico Telecommunications Regulatory Board (the Board).[2]

The Board was created with the powers and prerogatives ceded by the FCC to PUCs as per the 1996 Act and with a clear mandate to foster total, equal, and fair competition. As a direct consequence of the 1996 Act and of Act 213, the Commonwealth's incumbent, PRT, faced, for the first time in its 80-year history, the prospect of sharing its turf with new market-entrants. Specifically, the Board was constituted to a) ensure the availability of universal telecommunications services at affordable rates for all citizens of Puerto Rico; b) oversee the efficiency of telephone service and cable television, as well as other telecommunication services; c) assure the continuity in the rendering of services of a social nature, such as public telephones, according to the public need; d) promote competition; e) guarantee Puerto Ricans the same telecommunications and information privileges enjoyed by other United States citizens; and f) safeguard the public interest to the utmost. The Board, a three-member regulatory body, was not only instituted as a quasi-legislative entity, but also as a well-staffed, quasi-judicial, adversative and deliberative organism capable of receiving and resolving inter-company and consumer-to-company complaints.

Throughout the past five years, the Board has undertaken numerous initiatives in its quest to carry out its statutory duties. Amongst the most recent lies the commencement of telecommunications relay services (TRS) for citizens with speech and auditory impediments; the overlay of an additional area code (939) that shall ensure continued and sustainable growth in the Commonwealth's telecommunications industry (an area code equals 7,920,000 new telephone numbers); and the implementation of dialing parity or local-toll presubscription, which gives consumers the same options when selecting a telecommunications provider for local toll calls as when choosing a long-distance carrier (interexchange carriers [IXCs]). Furthermore, the Board, in conjunction with the Puerto Rico Education Department, has procured $115 million in federal Universal Service *School and Library Program* funds for the installation of facilities and connection of 1,540 public schools to the Internet and the World Wide Web (WWW) and has engaged in an island-wide promotion of federal Universal Service *Low Income* programs, particularly *lifeline* and *link-u*p, which provide telephony subsidies to people of lesser means who are on welfare.

The Board is making every effort to move Puerto Rico closer to the most economical and forward-thinking U.S. jurisdictions when it comes to the provision of telecommunications services. The Board strives to utilize competition and market forces as the primary setters of the prices, terms, availability, and conditions of telecommunications services, as long as prices are based on cost. Companies should always seek negotiated solutions for controversies among them. Conversely, decisive Board intervention is often required to rectify market iniquities. Cross-subsidization between competitive and noncompetitive services, price schemes that artificially sustain unreasonably low rates, and myriad other vestigial monopolistic and anti-competitive practices must be categorically eliminated in order to reap the full benefits of market liberalization. The Board's rule-making and adjudicative endeavors are slowly crafting a fair playing field that promotes competition and cost-based pricing, so that consumers pay for the services they are actually receiving.[3]

The aforementioned measures are, however, but first steps toward the realization of a much greater and ambitious goal spearheaded by the Board: the transformation of Puerto Rico into a hemispheric telecommunications hub, principally for the benefit of our Latin American and Caribbean environs. Puerto Rico possesses a 100% digital network, lies under the footprint of 92 satellites[4], is a landing spot for six major marine cables[5], and enjoys a substantial deployment of fiber-optic rings. The Board has been honored by the Caribbean Association of National Telecommunication Organizations' (CANTO)[6] acknowledgment of its regional relevance and the president of the Board has gladly provided technical assistance to telecommunications commissioners from the Dominican Republic, Jamaica, the Republic of Honduras, and the Commonwealth of the Bahamas, among others.

All in all, the Commonwealth's pro-competitive mindset, its comparatively advanced infrastructure, its stable government and financial institutions, its advantageous geographic location, its close relationship to the United States, and its cultural ties to the Spanish-speaking world provide unique opportunities for new entrepreneurs and already-established companies.

The Board is hard at work, setting in motion processes that are raising Puerto Rico's attractiveness as a home base for hemispheric telecommunications operations. Under the Board's auspices, Puerto Rico has witnessed an impressive expansion in the availability and quality of telecommunication goods and services. Two hundred and thirty three telecommunications companies have become established in the island during the last five-year period, and Puerto Rico boasts the highest per-capita Internet penetration rate in Latin America and the Caribbean. Competitive markets tend to drive down rates 40% to 50% lower than noncompetitive monopolies. As such, rates should continue their island-wide decrease across the whole spectrum of telecommunications services and particularly in the wireless market, where price wars benefiting the consumer are the order of the day. Although the ideal of total, equal, and fair competition has not yet been achieved, it can be said that the era of legally justified natural monopolies has come to a close in Puerto Rico.

The future of the telecommunications industry, which already is a $600 billion market, is quite bright. According to the FCC's latest numbers, CLEC market-share in the United States, including Puerto Rico, grew 93% over the one-year period of January to December of 2000, and the number of wireless service subscribers was 101 million, up from the previous 91 million reported for 1999. At least one CLEC was serving customers in 56% of the nation's zip codes, and about 88% of U.S. households reside in these zip codes.[7]

As per industry estimates, Puerto Rico boasts close to 1.7 million telephone lines, approximately 1,500,000 wireless phones in use, 551,600 Internet users, and 374,000 cable-television subscribers. The wireless market alone has experienced close to 300% growth during the past five years. In Puerto Rico, 54% of families own wireless phones, at around 1.6 units per home. These numbers will certainly rise, specifically with the deployment of nascent technologies such as digital subscriber line (DSL) services, cable modems, and third-generation (3G) wireless systems.[8] There is also ample space for growth in landline service. Island penetration lies at around 74.6%—quite lower than the highest level experienced stateside, which is actually 94.5%.

The new paradigm brought forth nationally by the 1996 Act and locally by Act 213 is already delivering substantial qualitative and quantitative movement toward a future in which telecommunications companies spur technological progress and ever-more complex services while battling for customers in a highly competitive marketplace. The final result is gain for all: Companies grow and profit, and Puerto Rico benefits from industrial expansion and higher employment. Meanwhile, the consumer receives high-quality products at excellent prices and has myriad companies from which to choose. The Board, on its part, shall continue to guard the legal regime that has made all of the foregoing possible.

Notes

1. Telecommunications Act of 1996, P.L. No. 104-104, 110 Stat. 56; 47 USC §§ 151 *et. seq*.
2. Act 213 of September 12, 1996, 27 L.P.R.A. § 265 *et seq*.
3. For general information or for further detail regarding ongoing legal proceedings visit the Board's Web site at http://www.jrtpr.gobierno.pr.
4. Among these satellites are 1) Aurora, 2) Morelos, 3) Satcom, 4) Solidaridad, 4) Galaxy, 5) Brazilsat, 6) Tel Star, 7) Intelsat, 8) Echo Star, and 9) Thor.
5. These marine cables are 1) Americas, 2) Arcos, 3) Florico II/TCSI, 4)Taíno, 5) Antillas, and 6) SAM USA.
6. CANTO is a regional telecommunications organization based in the Republic of Trinidad and Tobago that consists of 47 members, generally national operating telecommunications companies from the Caribbean and South, Central, and North America. Membership is open to operating companies in the region. A board of directors drawn from the membership governs the organization.
7. *Federal Communications Commission Releases Latest Data on Local Telephone Competition*, http://www.fcc.gov/ccb/stats.
8. Promising 3G technologies can transmit text and digitized audio and video at speeds up to 2 megabits per second (Mbps) in a stationary wireless service and at 384 kilobits per second (kbps) in a mobile environment. This allows for services such as fast wireless Internet and real-time videoconferencing.

DSL: The Customer Perspective

Duncan Greatwood
Vice President, Marketing
Virata Corporation

The telecommunications industry sometimes seems obsessed with improving the business case for digital subscriber line (DSL). In many ways that is a good mindset, as the industry will grow because of a strong business orientation. That approach, however, tends to ignore the other side of the story—the customer perspective on DSL. This paper looks at DSL from the customer side and examines the aspects of DSL that customers find especially appealing.

Cost Reduction

First of all, DSL customers are looking for lower cost—both lower equipment costs and lower service-delivery costs.

Reducing Equipment Costs

Today's equipment already contains local-area network (LAN) interfaces. The DSL transceiver, analog chip, and discreet circuitry are built in, enabling a cost reduction through integration. Digital integration is fairly well advanced, as today's equipment already provides the necessary level of integration of the transceiver, the processor, and the LAN interface. However, analog integration is more challenging because it does not scale down as easily into the silicon geometry as digital does. At this point, maintaining performance becomes an issue.

One solution is to optimize analog circuitry. The analog discreet circuit involves substantial cost, and analog optimization can provide substantial savings. The circuit can be integrated into the analog chip, including line drivers, receivers, and the other components. In addition, some of the functions implemented in analog circuits can be transferred into digital formats. When these analog functions are dropped into the digital chip and integrated with the transceiver, the solution is more cost effective because digital silicon costs less.

Thus if the software and hardware implementations are correctly partitioned on analog and digital chips, the best and highest-performance solution can be found. This solution is a system-wide one—and building the best system as a whole is the issue. Using hybrid technology to do so is much less expensive than a full-system design using a single protocol such as Internet protocol (IP).

Service-Delivery Costs

In the early days of DSL, service-delivery costs were extremely high. The costs included a truck roll to install the service, and one truck roll was seldom sufficient to get the copper wiring to work correctly. In addition, interoperability issues emerged between different DSL systems.

Those problems have, for the most part, been solved. DSL installation now means that the user installs pre-configured software and filters. The result is a more consistent user experience, a polite way of saying that DSL now works as expected on a regular basis. Interoperability in the physical layer has also removed some of the barriers that existed just a few years ago.

Volume continues to grow, however, and with it an important cost for service providers: the huge cost of digital subscriber line access multiplexers (DSLAMs). Installing the DSLAM to provide service generally involves a cash-flow problem for providers, who must invest a great deal at the front end and do not begin to recoup their investment until the service is deployed. One approach to this problem is to reduce the time gap between the investment and the service.

Thus, although service costs are declining, more remains to be accomplished.

Increasing Customer Value

While customers are concerned with costs; their perception of the value of the service delivered must also be considered. Value can develop in two ways. First, the service provider can provide a service directly and charge for it. For example, the provider can offer voice-over–DSL by providing multiple lines of voice over the DSL wire, pulling them off over the DSLAM, and routing them. This approach results in actual revenue streams. Another way to produce value is by providing applications that do not require the DSL service provider to participate at all. Examples of this type of application include Internet games or music download services. There is a whole category of broadband applications that flow over the DSL infrastructure but do not require the DSL service provider to take any action. This category is clearly of value to the service provider. Instead of paying $30 a month, consumers may be willing to pay $35 or even $50 for the extra value they perceive, and that makes a big difference in the provider's bottom line.

Building value in the eyes of the consumer is a significant change for service providers. DSL acceptance will accelerate as customers perceive it not only as a way to download the same things faster, but also as a way to do things that they otherwise could not. Building value in this way offers a much more compelling proposition.

Possible Applications

Anybody can deliver service. What will differentiate DSL providers is generating revenue in both the ways outlined above—by offering services themselves and by enabling other services that do not require their active participation. Voice, as briefly mentioned, is one such application, but because it has been available for so long it is no longer as compelling as some of the newer applications. New uses will drive demand more quickly. Broadband games will generate huge demand; home security is another big area, as the 6 million physical-security units sold annually could be easily converted to DSL. Photography storage and download capabilities are other areas that add value to DSL from the customer perspective.

The Future

DSL promises to transform the home through expanding uses of broadband technology. The broadband home will utilize multiple devices to access the Internet. This scenario will require a very simple, very easy-to-use network infrastructure in the home. Everything from the computer printer to the camera to the stereo system will be connected to this network to access Internet applications, thereby driving DSL usage.

To make this vision possible, customer-premises equipment (CPE) must become a platform for all the home uses envisioned. Today, CPE is regarded as a commodity, and providers have done well selling it as such. Increasingly, customers will want a platform they can use to build their own value-added services. DSL will support this view by working consistently and effectively with all other parts of the system at a low cost. Value creation will occur at the application level, in the digital loop carrier (DLC,) and in the DSLAM.

Among other requirements for enabling the application requirements, modularity will be especially important. Services such as asynchronous transfer mode (ATM) and IP for communications processing will have to be available through a range of different types of consumer equipment. Eventually, customers will be able to choose from a wide variety of equipment for different needs in a basic retail model.

Conclusions

DSL providers that consider the customer perspective will offer a better value proposition. The customer perspective involves reducing costs. Equipment costs can be reduced by providing an integrated hybrid system. Service-delivery costs are already declining, but more remains to be done to truly meet customer needs. Adding value through service delivery is the key to the customer perspective, and providers can add value by providing applications themselves, enabling other applications, or both.

When providers implement the customer perspective through lowering costs and delivering value-added services, they will provide the necessary support for using a CPE platform to make the broadband home a reality.

Choosing the Best Internet Data Center: Learning from the Japan Experience

Mike Heller
Senior Manager
Cisco Systems, Inc., USA

Kiochi Tamura
Manager
Cisco Japan KK, Tokyo, Japan

Introduction

Businesses of every size in countries all over the world are facing more challenges than ever before. They are finding increased competition and a faster pace of change. Their customers expect them to be open or accessible for longer hours (24 hours a day for many), to have the latest products and services more quickly, and always have competitive prices. These phenomena are present in Japan, just as in the United States, Europe, and other areas of the world.

The Internet, and in particular the World Wide Web (WWW), presents an opportunity for businesses to address these needs. An effective Web presence can help them to extend their reach and attract new customers, while lowering their costs of doing business.

When an organization investigates establishing a Web site, they quickly discover that this is not as simple as one might hope. An environmentally managed and secure room with a raised floor will be needed for the computer servers needed, along with an increased bandwidth connection to the Internet (dial-up connections are entirely unsuitable). But perhaps the most difficult challenge is that of hiring and retaining adequately knowledgeable staff. (Just to learn all the jargon and acronyms is a huge task!)

To help businesses take advantage of the Web, yet avoid these problems, a new industry has sprung up in recent years, sometimes called Web hosting and here referred to as Internet data centers (IDCs). IDCs may be operated by traditional telecommunications carriers or by specialist companies offering only those services.

IDCs typically offer a secure physical environment, perhaps a dedicated building or perhaps a secure area within a larger building. Twenty-four–hour staffed entry doors, key cards, or biometric personnel identification systems; video surveillance; and strict guest logging procedures are common. The data center will have uninterruptible power supplies (UPSs), along with redundant air conditioning and humidity-control systems. There will be a 24-hour network operations center (NOC), with a good database of the installed network and customers' systems, automated trouble ticketing, and escalation systems, etc.

If Your Business Relies on the Web, Your IDC Must Be Reliable

Using an IDC is not without some problems and concerns, however. Unless chosen carefully, the reliability and security of the IDC may be no better than the business could put together on their own, and this may be hard to ascertain. Some smaller IDCs may not be staffed 24 hours a day, making quick access to your servers difficult.

There are many IDCs in operation, so how does a company pick the right one? There are checklists available to aid in the investigation and comparison of the physical facilities of different IDCs that a firm may consider, and some key points are subsequently summarized. This paper complements those resources and adds to the chance of a more informed selection by allowing a company to compare the offerings of several IDCs through case studies.

The various checklists focus on two different categories of issues that can lead to greater reliability in an IDC. These are 1) the way in which the IDC has been designed and 2) the way in which the IDC is staffed and operated.

Be sure to visit any IDC being considered. Notice how easy it is for you to enter the building, what identification is required, whether you needed an escort, if you were constantly in view of video surveillance systems, and what records of your visit are kept. Ask about how electric power is supplied to the building and about what generators and other back-up systems are in place (and how much capacity they have). Redundant air-conditioning systems are a must in warmer climates (computers and other networking equipment gets rather hot), and check an effective fire detection and suppression system. What does the building look like? Would it likely withstand an earthquake, a tornado, or a flood?

An explanation of the way that data networks are designed should include how many different carriers connect to the building, how redundancy has been included in the network design within the building (there should be *no* single points of failure), and how many different equipment vendors are used (the more there are, the more complexity there is in operations, training, etc., and the greater the likelihood of problems, "finger-pointing," etc.).

Having said all that, more than 80 percent of telecom network outages are caused by operations errors or other "people problems," so be sure to assess how network operations is handled. An effective NOC will have clear and documented procedures for record keeping, trouble tickets, escalation procedures, exception reporting, working on customer equipment, etc. Successful management of an IDC requires careful attention to *configuration* management (e.g., software-version control, test plans, password management), *performance* management (e.g., capacity planning, quality-of-service [QoS] management, fault detection and resolution procedures, help-desk metrics, etc.), and *security* management (e.g., access control, partner and contractor management, intrusion reaction, etc.).

Management of an IDC means much more than just knowing if some piece of equipment is "up or down." The ability of the IDC staff to measure and assess service levels on a per-customer basis is essential to achieve the promised service-level agreements (SLAs). Managing Internet protocol (IP) address assignments, keeping track of network configurations, and not losing site of trouble tickets and alarms often requires the use of a mechanized NOC record keeping and support system. Good manageability tools and qualified personnel supporting the infrastructure translate into lower operations costs (since time is not wasted trying to resolve indications from conflicting management systems) as well as higher customer satisfaction.

If the service provider has more than one IDC, customers can benefit by having data and content at multiple sites, thus providing faster response times and higher availability (due to the partial or complete redundancy of the data). But it also adds complications for the IDC operations staff, including systems and procedures for coordinating the different centers, distributing updates to the proper locations, synchronizing data at different sites, handling downed servers, coping with the added security risks of remote access, etc.

The case studies presented in this paper on different IDCs in Japan often mention that SLAs are available to customers. A SLA can be a powerful tool to reach a common understanding with an IDC about service levels, availability, security, escalation procedures, etc. Many SLAs include provisions for some sort of refund or penalty payment if agreed service levels are not met. But it is also worth remembering that an SLA is somewhat like a life insurance policy, that is, you should never want to collect on it. Most SLA payments wouldn't cover the lost revenue or loss of customer goodwill that a prolonged outage would cause.

When choosing an IDC, it is always useful to ask how the customer will know what sort of performance levels the IDC is achieving. Regular reports from the IDC are a good sign, since a service provider that tends to want to hide this kind of information usually doesn't have service levels of which they are proud.

The Japan Business Environment

Business firms in Japan are mainly either very large or very small. Most of the very large ones are well known internationally, such as Sony, NEC, Mitsubishi, Honda, Toyota, Nissan, etc. Of course, not well known internationally are the hundreds of thousands of small "mom and pop" businesses and stores, but they constitute a large part of the overall economy.

The telecommunications industry in Japan changed from the classical monopoly environment, with NTT as the only provider, to a fully competitive market, with close to 10,000 service providers licensed by 2001. NTT, with government ownership now dropped to less than 50 percent, has been divided into several specialist companies (e.g., NTT Communications, handling long-distance and international traffic; NTT DoCoMo, handling wireless services; NTT East, providing local telephone services in the eastern part of Japan; NTT-ME, set up to offer Internet and "mutimedia" services; etc.). Principal competitors to NTT are KDDI, which grew out of the old international telecom monopoly company, and Japan Telecom, a new carrier that initially built its facilities along the rights of way of one of its parent companies, Japan Railways.

Taken together, these two factors greatly influenced the development of the IDC business in Japan, since there are many smaller companies that may not have large information technology (IT) staffs as prospective customers and many new service providers eager to find revenues in meeting new service needs.

IDC Developments in Japan

The first IDC opened in Japan several years ago, and by mid-2001, almost 100 companies had entered into the IDC business. Only a few larger companies, however, operate most of the data centers. The major Japanese telecom carriers are, of course, IDC operators, but some large system integrators and some global IDC specialist companies are as well. Some leading IDC operators in Japan are shown in *Table 1*.

At the end of 2000, Goldman Sachs Investment Research estimated there was a total of 95,000 square meters (slightly more than 1 million square feet) of IDC floor space available in Japan—enough, at average configurations, to accommodate about 210,000 Web servers. The same study found that only several hundred servers were actually in use in these centers, thus leading to many IDC suppliers with unused capacity pursuing the small but growing number of hosting customers.

While a few IDC operators have only a single data center, two or three data centers is more typical, and the larger operators have additional centers under construction.

It is believed that a Japanese IDC, to be successful, must include four key factors. The IDC provider must first provide a secure hosting facility. The second, and related, factor is interconnection with the Internet backbone to provide

TABLE 1

Some Leading IDC Operators in Japan

Japan Telecom Companies	Global Telecom Companies
NTT	Genuity
KDDI	WorldCom/Digex
Japan Telecom	Cable & Wireless/Digital Island
Internet Initiative Japan	Equant/GlobalOne
Biglobe	Level 3
System Integrators	**Other IDC Operators**
Fujitsu	Toppan Printing Company
NEC	Dai Nihon Printing
Hitachi	ClayFish Venture Capital
Toshiba	Chubu Telecommunications
CRC	

high-speed and high-volume data connectivity, especially to sites outside of Japan. Third on the list of success factors is a network and operations design (e.g., redundancies) to provide highly reliable and fast response serving of data. The last factor is a range of value-added services aimed at helping the business user to be successful at e-business.

An organization to represent IDC operators and promote this business model was founded in October 2000. It had grown to more than 150 companies by mid-2001. Some founding members include NTT, Sony, Oracle, Cisco Japan, Fuji, Sun Microsystems, Cable & Wireless, and GlobalOne. Called iDC, the organization runs advertisements and conducts seminars to educate potential users on the advantages of outsourcing Web servers and other business applications.

Although there are some differences in pricing between one Japanese IDC and another, the operators have mainly chosen to compete on the services that they offer, how they are packaged, what options are available, etc. Typical IDC monthly prices in Japan in late 2001, for various service options, are outlined in *Table 2*.

Japan IDC Case Studies

In this section, we present case studies of six IDCs now doing business in Japan. (There are other IDC services, but those with the most information available about their offerings and early experiences were selected for this paper.)

1. Digital Island Japan

Digital Island Japan is a subsidiary of Digital Island, headquartered in San Francisco, California. Cable & Wireless acquired Digital Island during 2001, but the Digital Island brand continues to be used. Its name reflects the company's original founding in Hawaii several years ago. Digital Island has a dedicated fiber-optic network connecting 35 countries and has IDCs located in the United States, Europe, and Hong Kong, in addition to Japan. Digital Island has grown from its founding in 1996 to a global business today housing more than 2,550 servers.

Digital Island is a specialist company devoted to IDC–type services. While basic Web hosting and co-location services are available, a major focus is on services for high-volume,

TABLE 2

Service	Monthly Charge (Yen)	Approx. U.S.$ Equivalent
Rental of rack space (1/4 rack)*	50,000	420
Rental of rack space (full rack)*	175,000	1,450
Shared server	4,000	35
Dedicated server	40,000	350
Shared Ethernet** connectivity	15,000	125
Dedicated Ethernet connectivity	500,000	4,200

**Includes limited technical support, e.g., visual inspections or rebooting of customer's equipment*
***10 Mbps; faster connections (e.g., 100 Mbps Fast Ethernet) may optionally be available*

high-performance content-delivery applications and e-business. For example, one service, called Footprint‰, is a content-delivery technology aimed at streaming media and music delivery. The present network can deliver data simultaneously to 300,000 users and is being expanded even further. It is particularly targeted to the financial market (real-time market data), the entertainment industry (especially music), the publishing industry (news), and the software industry (software downloads).

Services currently offered are shown in *Table 3*. Pricing generally consists of a monthly charge that varies with the amount of equipment provided by Digital Island and the responsibilities taken on by their personnel, plus a "data charge" calculated on the number of gigabytes of data that were served to the network during the month. Negotiated prices apply to any custom services requested, and volume discounts are available.

Digital Island offers SLAs to their customers. Typical components include network availability (e.g., 99.98%), network packet loss (e.g., less than 1%), latency (e.g., 80 milliseconds or less for Asia), and server availability (e.g., 99.8%).

2. NTT-ME

NTT-ME is a part of the NTT group and is focused on business applications. NTT-ME is directly connected to the XePhion2000, a gigabit-class high-capacity backbone network. NTT-ME utilizes the highly reliable equipment and facilities made available through NTT's know-how to build communications sites and networks of the highest standards. Their staff (which numbers more than 18,000 IT professionals) has advanced technical knowledge and can address a wide variety of customer broadband data transmission and hosting needs. For example, customers may optionally sign up for additional security and firewall services or for load balancing across multiple servers. NTT-ME also has a wide range of data storage options for situations when the client's data exceeds the amount of disk storage included with the hosting service packages. NTT-ME also offers an unusual service for IDCs, namely the complete hosting and support of Oracle business applications. NTT-ME has a partnership and technology-sharing arrangement with InterNAP in the United States, which facilitates the handling of the business of multinational companies.

In addition to basic Internet connectivity options, NTT-ME also can provide Internet protocol–virtual private networks (IP–VPNs), especially for clients of their business application software hosting services.

Customer satisfaction is important to NTT-ME. In addition to comprehensive SLAs, NTT-ME has partnered with several Japanese insurance companies to offer an unusual option: "Digital Business Insurance." These policies can fully cover all business losses (including lost revenue) that might occur under catastrophic circumstances, whereas typical SLA "penalties" are much less, perhaps a refund of a portion of the charges paid. A customer-support center and NOC operates 24 hours a day, 7 days a week.

NTT-ME has evolved from a pure IDC service provider to one offering not only hosting and related services, but also application service provider (ASP) services, particularly those related to Oracle applications and groupware, for which NTT-ME is the only IDC–based provider in Japan. These applications include a complete integrated package of Oracle applications, providing enterprise-resource

TABLE 3

Service Currently Offered

Service Type	Service Name	Features	Remarks
Server Hosting	Trusted Host™	Basic hosting of customer's server	Digital Island provides network connectivity equipment
	Extended Host™	Includes load balancing between servers and "hands-on" service functions	On-line access to server performance data
	Total Host™	Includes server and management up to operating-system level	
	Private Host™	Floor space and power only; Fast Ethernet connection	User supplies servers, routers, etc.
Streaming Media	Footprint™	Network-edge multiple-site caching (e.g., at ISPs) of content	Used for static data
	Footprint™ On-Demand	Same; for video clips & music	All media player types OK
	Footprint™ Live	Same; for real-time images	Options include image encoding
Localization	TraceWare™	Identifies location of requester and serves localized content	By country or region

management (ERP), supply-chain management (SCM), and customer-relationship management (CRM) functionality. They also include the "Intra-Mart" groupware package for use within companies to promote improved efficiency and information sharing. NTT-ME can offer a comprehensive and complete service, one bringing great value to smaller firms that need to concentrate their efforts on their core business and outsource the operations and management of business applications as well as the housing of their servers.

Although NTT is "the" telephone company in Japan, the NTT-ME subsidiary was a bit late to the IDC market, and in late-2000 held only about a 4 percent market-share, according to a survey by *Nikkei Communications* magazine.

3. KDDI

KDDI is a fairly new company, formed in 2000 by the merger of KDD, the traditional Japanese international telephone carrier, and DDI, a competitive long-distance and cellular operator started in the 1990s. Toyota, one of the original DDI shareholders, still has a small shareholding. When the Japanese market moved to a fully competitive mode, KDD was able to enter domestic markets, and DDI was then able to offer international services. An extensive set of data and Internet services rounds out the portfolio offered in Japan. A joint venture with Singapore Telecom provides services to business customers throughout the Asia-Pacific region.

The IDC focus of KDDI is large-scale e-business, although KDDI emphasizes that even small office/home office (SOHO) accounts are welcome. Under the brand name "dot-square," KDDI draws upon years of experience as a telecom carrier operating numerous data centers for billing and other purposes. KDDI continues to expand, with new data centers added around Japan in 2000 and a large new IDC planned for launch in Tokyo during 2002. All of the KDDI data center's feature redundant power systems, over-engineering air-conditioning equipment, and 24-hour monitoring by the on-site security staff.

Accordingly, KDDI stresses the robustness and capacity of its backbone network and its connectivity to Internet providers in other countries. KDDI's backbone network reaches customers' local-area networks (LANs) through direct connection via leased lines, frame-relay circuits, or IP–VPN encrypted tunnels across the Internet. SLAs are available for all services, and comprehensive performance reports are regularly provided to all clients.

The KDDI dot-square service offers a wide selection of service options to meet the unique needs of every size of customer. For the smaller customers, a basic hosting service is available, using redundant servers and circuits within the data center. Medium-sized customers, including ASPs and Internet service providers (ISPs), can utilize dedicated servers and rack space for routers and other equipment. These racks can be open or equipped with locking doors. Enclosed cages are available for larger customers or those desiring a greater degree of security for their equipment. The exact offerings vary somewhat depending on the size of the IDC but are similar in all. On-site staff in each center can perform "lamp checks" or other simple tasks at the customer's request.

Different Internet connectivity options are available for each hosting service, providing direct connections not only to the highest-capacity Japanese backbone, but also to the Japanese interchange points (JPIX and NSPIXP2) and to major U.S. ISPs.

KDDI offers a variety of operations and professional services, from its own staff and through partners, including in other countries. This can range from routine tasks such as mounting tapes and coordinating the work of contractors to major project management, network engineering, and software development.

According to a late-2000 survey by *Nikkei Communications* magazine, KDDI led the IDC market in Japan with an approximate 10 percent market-share.

4. CRC Institute

The CRC Institute has a large IDC located at Otemachi, near Tokyo. CRC has a proven track record in outsourcing and providing professional services to its clients, and the IDC services are a natural complement. With more than 10 years of experience in operating data centers in Yokohama and Kobe, the CRC Institute has the expertise and well-trained staff that customers expect from one of the pioneers of computer outsourcing in Japan. Their motto is "Comprehensive Solutions and Full Services."

An example of the unique services of the CRC IDC is the Internet security outsourcing service (iSOS), whose need has become apparent with recent hacking events. The iSOS service includes an "unauthorized access detection" capability—a form of what's generally known in the industry as an intrusion detection system, or IDS. It also has a proactive element called "security inspection," which has CRC security experts check the customer system periodically for security risks and vulnerabilities, and recommend improvements. A managed firewall service (called the CRC "firewall outsourcing service") is available, along with a "virus-protection service," which provides users with the latest antiviral software and assistance.

Of course, the CRC IDC services include 24-hour operations monitoring and site security (including comprehensive video surveillance), with various options that can be selected depending on individual customer need. The IDC itself is the latest design, featuring many earthquake-resistant aspects developed from the Kobe earthquake experiences. Power is supplied to the IDC from multiple substations and serves the building in a double loop feeding system. The UPS and on-site generators provide constant power, even during momentary outages or extended periods (e.g., legal inspections). The building air-conditional systems are redundant as well, and the equipment rooms and under-floor areas are served by gas fire-extinguishing units for quick detection and initial extinguishing of a fire for minimal damage.

Customers generally supply their own servers, routers, and other equipment, taking advantage of the extensive site support and network (and server) monitoring capabilities of the CRC IDC. A wide choice of rack, cage, and private-room options are available. Network connectivity is assured to be of the highest quality and performance due to the fact that seven different domestic and international network carriers have brought their facilities into the Ohtemachi building.

The CRC Otemachi IDC is furnished with various conference rooms and other facilities that clients may use for meetings with their customers, presentations, training sessions, etc.

Summary and Conclusions

This paper has overviewed the many benefits that a company can obtain by using the services of an IDC to host, and perhaps manage, their Web servers and Internet connectivity. Due to budget considerations and the difficulties of hiring a suitably trained staff, for many smaller companies, using an IDC service is the only way that they can have a successful presence on the Web. For larger companies, using an IDC (rather than an in-house data center) allows internal IT resources to be devoted to business applications and other projects more aligned with the core business. Regardless of the size of the user, selecting the right IDC is critical for success, and this paper has offered suggestions on some of the important criteria to use.

The development of the IDC market in Japan was profiled, and market data and typical prices presented. Case studies of several service providers offering IDC services in Japan have been used to highlight the types of offerings available, the differences in the way in which service providers support users, and how the different offerings are presented in the marketplace. The case studies covered two large carriers: one U.S.–based multinational service provider and one smaller local firm.

The four case studies, although all for IDCs located in Japan, represent offerings typical of those in the industry in many countries (with perhaps pricing being the greatest variable country-to-country). Along with the more general tips, they offer useful insight to any enterprise or other organization seeking IDC services.

DSL across the Globe

Patrick Kiernan
Director, Market Management
Spirent Communications

While digital subscriber line (DSL) issues in the United States have been discussed at length, the status of DSL in the rest of the world remains less clear. Yet it is important to be aware of global DSL issues for several reasons. Vendors may want to consider the opportunities that might arise in international expansion. Service providers will find the environment elsewhere amazingly similar and can learn lessons from foreign providers' experiences. Moreover, service providers are expanding into Europe, South America, Asia, and Australia.

What lessons does the DSL experience elsewhere provide for these vendors and service providers? After some brief observations about DSL deployment worldwide, this paper will briefly cover the status of deployments in Asia and Europe to draw some useful conclusions about the issues that have an impact on successful DSL rollout. It will then offer some ideas for solutions to the problems.

DSL Worldwide

It might be surprising to know that the United States does not have the largest DSL subscriber base in the world, and it might be even more surprising to learn that Korea holds that distinction. Korea has more subscribers than the United States, and because the actual growth rates for the two are comparable, this difference is likely to continue. Overall, Asia is a larger market than North America. Together, North America and Asia have accounted for most of the volume of DSL growth worldwide. What Europe and Latin America have lacked in volume up to this point, however, will be made up for by the fact that the compound growth rate over the next five years in those two areas of the world will be much larger than the rates in Asia and the United States. This situation is clearly the result of early entry into the DSL market in Asia and North America.

Deployments in Asia

The earliest deployment of DSL was in Singapore in 1997, so the history of DSL deployment begins in Asia (see *Figure 1*). That first deployment was followed by deployments in Taiwan and Hong Kong, both in 1998. Both of those deployments offered very broad DSL coverage. Korea entered the market next, and the service really took off from there. Indeed, although it was once the largest deployment outside the United States, as *Figure 1* indicates, it has now taken over the lead.

Thus Asia is home to the most successful DSL deployment to date. In both Korea and Taiwan actual DSL deployment has gone far beyond even the aggressive industry forecasts, and it continues to accelerate. The key driver in the Asian market has been high-speed Internet connections for gaming and video on demand. Yet rollouts in Japan and China remain important unknowns.

Japan is something of a wild card in DSL deployment. It has a high standard of living, and its people are very interested in the latest technologies. So it was expected that the Japanese would be very attracted to broadband offerings, and a big push was anticipated in 2001. It has not happened yet, however, because of a wide range of problems, including pricing, regulatory, competitive, and business-management issues. The Japanese national telecommunications company has made a huge investment in fiber to the home, a competitive technology, and pricing, infrastructure, and regulation make it difficult to bring in a second carrier to offer DSL.

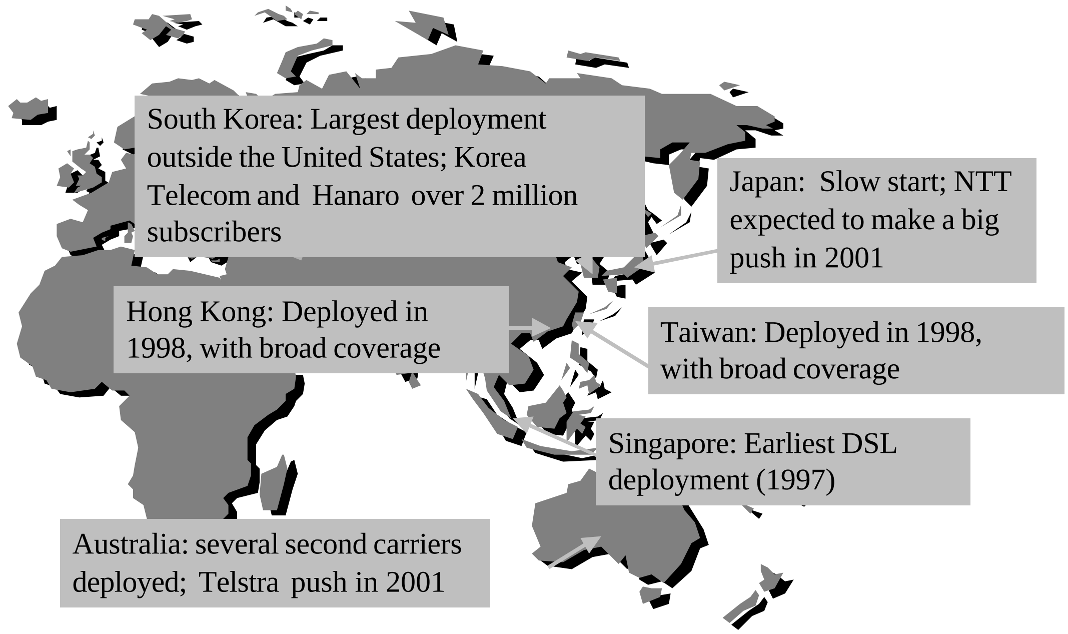
The second-carrier approach, by the way, has proven successful elsewhere. In Australia, the incumbent carrier had not offered DSL aggressively. Because the telecommunications market there has been heavily deregulated, five or six competitive carriers were able to meet market demand for DSL successfully.

The Chinese market is another Asian wild card. The potential market is huge, offering almost boundless opportunities. The issues here are not related specifically to the telecom industry; instead, issues relating to government regulation of culture are making expansion difficult. Fundamental questions about whether a billion people will have free access to information are at the basis of delays in deploying DSL. The answers to those questions will determine whether DSL will be a skyrocketing success story in China or whether another era of repression will prevent it from taking off. Another factor in the situation is the decision to hold the 2008 Olympics in Beijing. The Olympics will increase opportunities for freedom in China and prompt development of the telecom infrastructure.

Thus China and Japan offer major potential markets for broadband services, but whether the potential will be realized remains an unresolved issue.

FIGURE 1

Deployments in Asia



Deployments in Europe

Europe was somewhat slower in rolling out DSL—all the major incumbent local exchange carriers (ILEC) began to offer it in 1999 or 2000, slightly behind the rest of the global market. As in Australia, Europe has a significant amount of second-carrier activity. Regulatory issues throughout Europe, however, make it unclear whether those carriers will survive.

Generally speaking, the addressable market in Europe is larger as a percentage of households passed than in the United States. The European providers benefit from two key market characteristics: good coverage by carriers and very short loops. Central offices (CO) tend to be very small because something between a remote terminal and a full CO, called a controlled-environment vault, is deployed in many places. Use of this type of facility enables many carriers to enter the market with a small footprint. But they still have to be able to do a good job of providing coverage.

Another European characteristic is the impact of the European Union's requirement for local-loop unbundling. This requirement should introduce more competition and drive demand. Finally, scaling networks remains an issue in Europe.

Issues Affecting Successful DSL Rollout

Regulatory Issues

Despite European Union doctrines requiring local-loop unbundling, competitive local exchange carriers (CLEC) in Europe are complaining about the delay tactics ILECs are using to slow access to CO infrastructure. In the United Kingdom, for example, British Telecom is not complying, and competitors are pulling out of the market there as a result. In other instances, although the ILEC may be complying with local unbundling regulations, in fact the market is not open. In Germany, competitive carriers cannot afford to build a footprint or put equipment in a CO. In France, competitive carriers cannot enter only the COs in the area they want to serve; they must have a presence in all 3,000 COs, making it price prohibitive for a competitive carrier to establish a footprint. Despite regulations, then, it is not always practical to roll out DSL service.

Loop and Data Network Problems

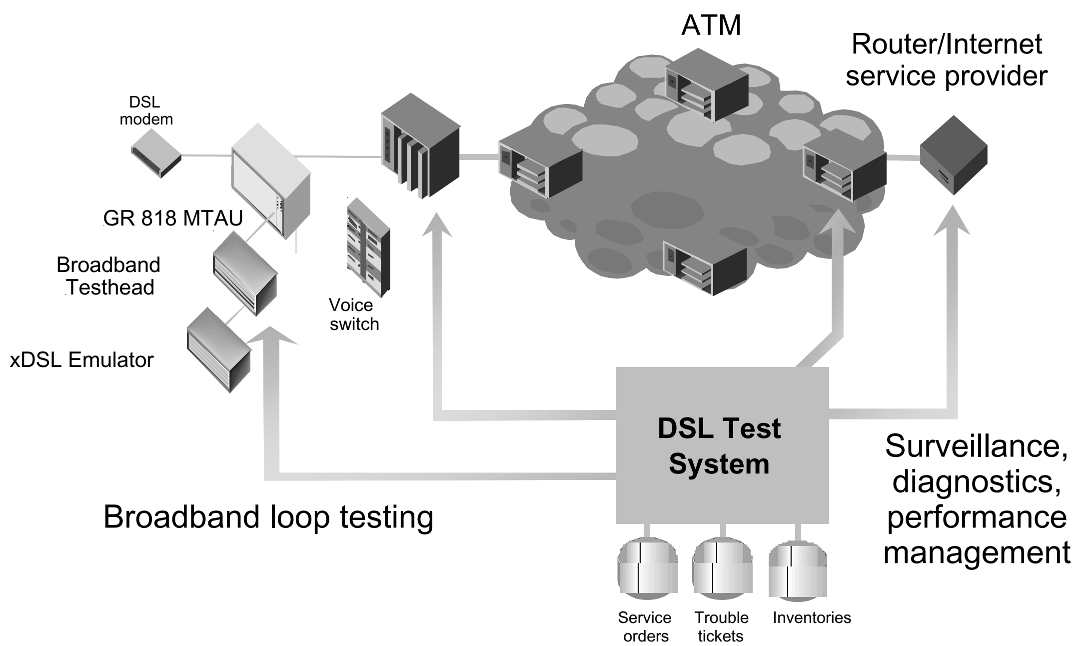
DSL maintenance testing provides some interesting challenges, especially in Europe (see *Figure 2*). About 25 percent of the European physical plant is built on aluminum, not copper, which makes quality an issue. Another issue has emerged in the United Kingdom. British Telecom (BT) just lowered the price for wholesale DSL, thus eliminating the business case for competitive carriers to deploy a network. Competitive carriers become totally reliant on BT for every aspect of DSL, including testing. If BT does not test well, the competitive carrier does not know what is happening in its market. Many CLECs must purchase their own test systems, adding a level of expense, because they cannot trust BT testing. Other problems emerge from relying on the ILEC network. Not all problems reside on the loop; many of them reside on the data network, and the CLEC must have the tools to localize faults that exist in the data network. If the CLEC does not have access, it will not have that capability. Moreover, the ILEC is always in a better cost position than the CLEC.

Scaling

Scaling raises other issues. In Europe current operational procedures are completed manually, and telecommunications

FIGURE 2

Loop- and Data-Network Problems



unions for the workers responsible for those procedures are backed by the government. It is difficult to change the manual processes, which are resulting in increasing backlog and thereby placing a cap on growth. An associated problem is a shortage of high-quality, well-trained technicians, making it even more difficult to carry out the required manual processes.

If growth is to occur, costs must be managed. Truck rolls must be reduced, the business must grow faster than the head count, and time to revenue must be shortened.

Solutions

The solutions to the issues that have affected DSL rollout abroad can be summed up in four points: (1) good pre-qualification tools to expand the addressable market; (2) self-installation; (3) remote testing; and (4) flow-through operations support systems. These lessons, learned from international DSL implementations, are important for DSL in the United States as well.

The Strategic and Financial Justifications for Convergence

Mike Kisch
Marketing Communications Manager, Enterprise Voice and Video Business Unit
Cisco Systems

Bill Erdman
Director of Marketing, Enterprise Voice and Video Business Unit
Cisco Systems

The intent of this white paper is to assist senior managers in defining the information technology (IT) and networking directions of their companies and to provide the necessary strategic and financial justification to make effective decisions regarding voice, data, and video convergence.

The term *convergence*, also known as multiservice networking, refers to the integration of data, voice, and video solutions onto a single, Internet protocol (IP)–based network. The technologies and tools for companies to converge their networks exist now as evidenced by a recent META Group study that found that 26 percent of Global 2000 enterprises are already in the process of migrating to a converged network (see *Figure 1*).

Convergence has progressed to the point that most organizations should seriously evaluate its role in the future of their networks. A converged network can play a critical part in helping a company identify new ways to generate revenue, reduce operational costs, increase organizational flexibility, and generate a sustainable competitive advantage. Many of the new business applications that are now deployed on converged networks provide immediate ways to increase personal and workgroup productivity while enhancing customer care and responsiveness. Convergence can also accelerate business cycles and help enterprises to realize the benefits of their IT investments faster.

As an IT investment, convergence is unique because of its ability to impact the entire organization. Whether it is workforce optimization, e-commerce, supply-chain management, or customer-relationship management (CRM) initiatives, a converged network provides the necessary foundation to decrease implementation time and maximize an organization's investment in new technologies. This is especially important given that the costs to implement a packaged software solution is usually two to three times the cost of the actual software. Convergence also allows organizations to challenge many of the traditional assumptions regarding labor, facilities, and capital investment by providing the tools to empower the organization to mobilize its workforce and centralize its infrastructure and network management. However, the far-reaching implications of convergence often make it a difficult concept for organizations to understand and evaluate.

Moving to a converged network can substantially reduce an organization's total cost of ownership (TCO) for its network and reduce the ongoing costs required to maintain and upgrade the network. Also, by simplifying the administration of the network, an organization's IT staff can focus more on strategic initiatives that can generate demonstrable business benefits. While the hard cost savings are enough to justify migrating to a converged network, the less easily quantifiable "soft" benefits provide the most compelling argument for why an organization should begin migrating to a converged network.

For organizations to understand the reasons to migrate to converged networks, they must understand the impact upon not only a company's cost structure, but also how convergence can help their businesses more quickly and more effectively reach their overall goals.

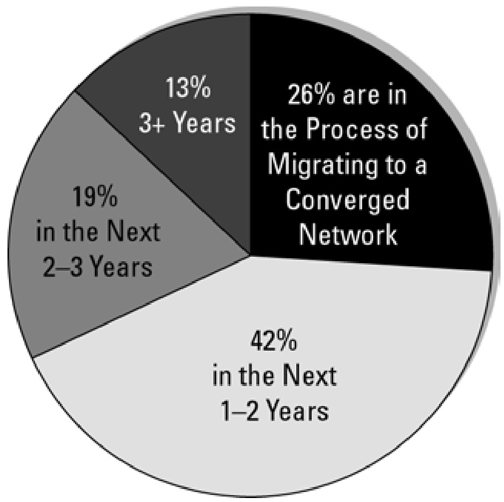
Situational Analysis

IT projects are now faced with a greater degree of scrutiny than ever before. Recent economic fluctuations have made it that much more important for IT managers to justify the strategic and financial value of proposed IT investments. However, regardless of the economic environment, organizations must continue to invest in IT projects that support specific business goals and can produce quick returns. A well-planned IT strategy will allow a business to emerge from adverse market conditions in a better position to take advantage of new opportunities.

As IT has gained greater acceptance as a strategic component of running a business, the parties involved in making the decision have expanded to include business and financial managers who want greater strategic and financial justification of why they should invest the organization's capital. Business and financial managers want to understand how these investments will help them to realize their business goals of generating more revenue, reducing operational costs, and creating a sustainable competitive advantage in

FIGURE 1

Rate of Convergence—Global 2000 Enterprises



the hopes of either boosting or creating value for shareholders. They also want to understand how an investment in IT can accelerate the pace of an organization and increase organizational flexibility. According to Forrester Research, 68 percent of global enterprises believe that their network is a source of competitive advantage for their business.

Much has been written about convergence. As a result, it is often difficult to separate the hype from the reality. While most agree that converging to a single IP–based network is inevitable, there are divergent opinions as to when this will happen. A recent survey by the META Group of Global 2000 enterprises suggests that many companies are well on their way to evolving their networks. In fact, 73 percent of Global 2000 enterprises are already migrating to a converged network or are planning to do so within the next one to two years. This statistic supports the notion that the technology to converge disparate voice, data, and video networks has transitioned from the early adopter to early majority stage in the technology life cycle. Early adopters of IP telephony have proven that voice over an IP network is reliable, even across shared low-bandwidth circuits. Sending voice over the wide-area network (WAN) was one of the initial drivers behind migrating to a converged network. While recent decreases in public switched telephone network (PSTN) tariffs have closed the gap slightly, there still exist savings for large multinational companies that generate substantial costs for international calls. Initial deployments of IP telephony have ranged from several hundred phones all the way up to 25,000, highlighting the scalability of a converged network.

IT decision makers are faced with the task of creating a vision for the future of the network that will help their organizations to achieve their business objectives. At the same time, organizations must also identify the correct stage in the technology life cycle at which the best benefits can be realized while incurring the least risk. The technology life cycle plays a critical role in the investment decision and is often the most difficult aspect of evaluating an IT investment. Many organizations will not invest in a new technology until it has been proven and commoditized. This approach reduces the risk associated with the IT initiative, but even more significantly reduces the potential benefits. Assuming that an IT investment must be a key source of an organization's competitive advantage to be justified, this is only true if the technology is adopted and integrated faster and better than the competition.

The critical drivers that should lead an organization to begin evaluating converging their networks are the hard cost savings related to infrastructure, staffing, and facilities, as well as the improvements in productivity and customer care. There are, however, several key transitional events that can accelerate the evaluation and adoption process, as well as the financial payback:

1. Building a new office or moving to a new location
2. End of lease for private branch exchange (PBX) or support contract
3. Necessary upgrades for data network
4. Lack of expansion capacity of current voice network

In addition to these events, convergence makes particular sense for organizations that are rapidly changing in size and location by opening new branch or regional offices. Adding further urgency to the development of a convergence strategy is the exponential growth of data traffic relative to total network traffic. Data traffic is now growing 10 times faster than voice traffic and will surpass total voice traffic in 2001. As a result, most enterprises will need to place more of a focus on and make significant investments in new data infrastructure over the near term to meet network demands. As they evaluate new data equipment purchases, they should also ensure that the networking equipment could support not only data, but also voice and video.

Scope of the Analysis

Enough empirical evidence now exists to truly evaluate the financial and strategic implications of convergence. This analysis is intended to be an accurate comparison between the currently separate data, voice, and video networks and a converged network. Until now, the comparison most commonly made has been between a converged network carrying voice and the PBX. This is not an accurate comparison, given the greater functionality of a converged network, and is equivalent to comparing the personal computer (PC) to a typewriter. Both the PC and the typewriter are capable of word processing, but word processing is all the typewriter can do, while the PC increases productivity exponentially, enhances customer care, and distributes knowledge throughout the enterprise. An organization needs to evaluate the costs and benefits of their currently separate networks (voice, data, and video) with those of the converged network. Only then will the true benefits of convergence come to light. The majority of the benefits in this analysis focus on hard cost savings derived in the areas of equipment, staffing, and facilities. In addition, the analysis considers business benefits related to the deployment of new applications that can improve productivity and enhance customer care. When performing a cost/benefit analysis, it is very difficult to quantify these soft benefits. As a result, the return on investment (ROI) may significantly understate the true business value of convergence.

The Future of the Network

The future of the corporate network is impossible for anyone to predict. What can be reasonably expected is that the network will continue to become a more critical source of a company's competitive advantage. According to a recent survey, 92 percent of IT professionals believe that future IT initiatives need to support specific business goals. These goals include reducing the cost of doing business (58 percent), increasing business productivity (55 percent), and improving customer service (53 percent) (see *Figure 2*).

The ability of an organization to leverage IT investments that accelerate its business processes, take better care of its customers, and maximize the output of their physical and human capital will play a large role in determining who will continue to be successful. The demands that are placed on the network will also rapidly increase. According to Forrester Research, 77 percent of companies expect their Internet bandwidth usage to increase by more than 60 percent during the next two years. Such dramatic increases make it almost impossible to effectively plan capacity expansion with today's current network model. These increases in bandwidth usage will be driven by an increase in new users, a shift toward richer forms of communication that incorporate audio and video, and an even greater focus on e-commerce initiatives. Some of these e-commerce initiatives will be focused on increasing the current one percent browser-to-buyer conversion rate through the use of multimedia on-line collaboration tools that seamlessly integrate voice, video, and data and are designed to provide the customer a more satisfying on-line experience.

The IT investment process will also change as greater pressure is placed on IT decision makers to financially justify any new IT investment. An IT investment should no longer be approved unless it can help a company quickly generate new revenue streams, reduce operational costs, or create a sustainable competitive advantage (superior customer service or faster speed to market). This need for IT initiatives to rapidly contribute to the company's strategic business goals highlights a critical limitation of the existing network model. Separate voice, video, and data networks require separate sets of infrastructure, multiple teams of administrators, and constant concurrent maintenance. These networks have evolved separately, driven by isolated communication requirements for voice and data. As a result, these separate networks are extremely complex. According to Forrester Research, 90 percent of businesses see this complexity continuing to increase because of more difficult-to-manage components, more users, and more network links.

Many of the IP–based, converged applications discussed in this analysis can also be deployed over separate voice, video, and data networks. The primary difference is the ease and speed in which these applications can be deployed, maintained, and integrated into the network infrastructure. One of the primary benefits of IP is that it offers a transmission protocol in which data and voice communications can be combined together in an integrated fashion, reducing network complexity and providing an enriched user experience. This inherent complexity highlights one of the primary limitations of the existing multiple-network model. It is a difficult and costly process to integrate new applications and technologies. A good example is unified messaging (UM). UM has existed for more than five years and was originally developed for separate voice, video, and data networks. Initially, it showed great promise, but has since failed to achieve its user adoption projections. No one disputes that UM has the potential to increase employee productivity and reduce IT support and administration costs. Unfortunately, the cost and time necessary to integrate UM into disparate networks often overshadow the benefits. Another relevant example is computer telephony integration (CTI). CTI was developed to bridge the gap between the data and voice networks and initially showed a lot of promise. However, it proved to be so complex and expensive to implement that it could be financially justified only in a call-center setting. A converged network significantly reduces this cost of integration and promotes the deployment of applications at the department and individual levels.

Business Impact of Convergence

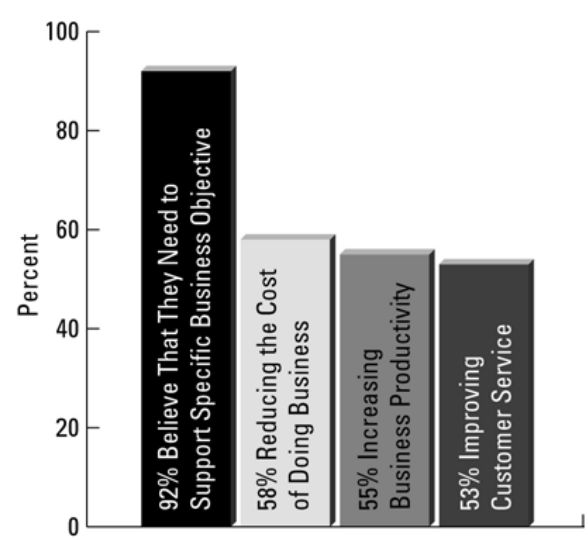
Convergence can lower an enterprise's total cost of network ownership through the elimination of multiple sets of infrastructure, simplified administration/maintenance, and consolidation of IT staffs. However, the real benefits are driven by the new services and applications that are more easily deployable on a converged network than on three separate networks. For the purposes of simplifying this analysis, these business benefits have been grouped into four benefit categories, Business Empowerment, Personal Productivity, Workgroup Productivity, and Customer Care.

Business Empowerment

Convergence can empower a business to reduce infrastructure, staffing, and facilities costs. It can also increase organizational speed (integration of new acquisitions or offices, and deployment of new applications) and flexibility (ability to quickly react to changes in the market).

FIGURE 2

Objectives of IT Investment



Reduction in Network Infrastructure Costs

As voice, video, and data networks continue to evolve to meet the pressures placed upon them, they grow significantly more complex and expensive because organizations must scale up three separate networks. A converged network can do the following:

- Reduce investment in multiple network infrastructures by converging to a single IP–based network. An organization will no longer need to invest in a dedicated device such as a PBX or maintain a separate integrated services digital network (ISDN) for its videoconferencing needs. The migration to single network will significantly reduce the complexity of an organization's network infrastructure, leading to easier administration, increased flexibility, and greater scalability.
- Lower system-expansion costs by deploying a single network, enabling scalability to meet new demands placed on the network by new users and new bandwidth-intensive applications. The resulting single point of administration and decreased reliance on outsourced services will also reduce ongoing network-maintenance costs.
- Centralize application hosting and call processing without sacrificing the user experience at the branch office. This allows remote offices to be offered the same applications as the main branch without having to invest in their own infrastructure and software. This will also provide the central office (CO) a greater degree of cost control over what is added to the network, ensuring better systems integration and security.
- Reduce the number of wiring drops per user by 33 to 50 percent in a new facility, which results in a fast payback for a new investment in converged network technology.
- Significantly reduce the costs associated with integrating new services and applications. For example, UM in a multiple network environment is burdened by the need to tie into proprietary devices, such as the PBX, that have their own unique protocols. This can lead to delays in implementation and therefore delays in ROI. In a converged network, UM can also help a company reduce the number of distinct directories that it needs to maintain by integrating voice, e-mail, and fax into a single lightweight directory aAccess protocol (LDAP) directory. This is another significant source of short-term savings, because it is estimated that some IT groups spend approximately 25 percent of their time per year maintaining and updating the many directories in their networks.
- Lower hardware-connection costs within an organization by adopting an IP–based network. For instance, to connect an existing voice-mail server to a PBX requires a channelized T1 line with 1.5 megabits of bandwidth that can support 24 users and costs approximately U.S.$6,000. In a converged IP–based network running 100 megabit Ethernet with a UM solution, a single server can support a similar number of sessions at a cost of only U.S.$600. In other words, for 1/10th the cost, an organization is able to increase its performance 100x.

Reduction in Staffing and Administration Costs

A recent survey by CIO determined that 49 percent of businesses believe that an IT skills crisis exists. As a result, companies are having to rapidly increase salaries to retain qualified IT staffers while increasing training budgets by more than 25 percent to teach them the necessary skills to manage the growing complexity of the corporate network. A converged network can reduce IT staffing costs and simplify network administration by doing the following:

- Consolidating IT staff skills sets. A converged network based on IP reduces the need for network specialists to manage specific technologies, such the PBX, thereby allowing an IT organization to hire a more generalized skill set with a common knowledge base and be better able to handle growth of the network or departures of key IT personnel.
- A converged network will allow an organization to perform more critical IT functions internally as opposed to having to outsource them providing them greater control over their network and faster response time to their users.
- A converged network will allow organizations the ability to manage much larger user communities with smaller staffs. New converged networks support centralized application hosting and call processing, thereby reducing the need to have dedicated IT staff at each individual work site.
- Moves, additions, and changes account for as much as 14 percent of an annual IT department's budget. Each move is estimated to cost an organization between U.S.$75 and U.S.$135. The average company moves its employees approximately once per year. The potential cost savings by allowing employees to move and install their own phones can be significant for companies of all sizes.

A converged networking model is also much more capable of supporting today's increasingly mobile workforce. This is especially important for salespeople, consultants, telecommuters, or computer technicians who spend much of their time traveling from location to location but are unable to have access to the same network capabilities that they have in their office. During the past several years, enterprise mobility has become a commodity as a result of the adoption of dynamic host control protocol (DHCP). IP phones can effectively leverage this technology, resulting in cost savings and increased employee productivity.

Reduction in Facilities Costs

A single converged network can also help a company to optimize its use of existing facilities by providing a more flexible foundation to serve the needs of its users.

- Most companies have employees who are constantly on the road and rarely use their offices. Unfortunately, other employees cannot use these unoccupied office spaces, because their phone extensions do not travel with them. The practice of hot-desking, or hoteling, has been in existence for almost a decade and originally promised significant savings and greater productivity from investments in real estate and facilities. However, many organizations found that the cost to adapt their current networks to accommodate mobile employees and the associated inconveniences outweighed the benefits. A converged network with IP phones enables employees to freely move about the

office to available slots, allowing companies to assign more workers to shared workspaces and maximize their ROI in facilities.
- Convergence also allows companies that are rapidly expanding or contracting because of mergers or divestitures to quickly integrate new sites into corporate networks.

Convergence can significantly reduce a company's TCO of their network. But to fully understand these cost savings, IT executives must modify their evaluation processes to give convergence its fair due. An organization contemplating migrating to a converged network must also understand how a single network can improve its ability to scale for the future and quickly react to the dynamically changing needs of the business. Specific types of change can include the deployment of new applications and services designed to improve business processes or enhance customer care, the addition of new users to the network, and the integration of new hardware solutions. A single converged network also simplifies the ongoing network-design and evaluation process, allowing an organization to speed up the implementation of new technologies. It is difficult to assess the monetary value of these last several intangible benefits, but all IT managers understand the importance of having a network that can empower change and innovation rather than impede it.

Enhance Personal Productivity

Perhaps the most significant benefit of a converged network is the array of applications that can be quickly integrated into the network and deployed. These applications can enable organizations to increase employee productivity by streamlining administrative tasks, allowing them to focus on activities that create new revenue streams or generate cost savings. As mentioned before, one of the primary drivers of convergence is its ability to provide a flexible foundation to easily integrate all types of new applications and services. Improving personal productivity can also be a key driver in reducing operational costs, because it can help an organization maximize the output of its existing labor force without the need to hire new people. This is equally important during downturns, when there are often hiring freezes, and during upturns, when the competition for employees can drive salaries sky high.

The power of the networked world is in its ability to allow people to more rapidly communicate through multiple delivery mechanisms. Voice-mail, e-mail, and fax have greatly enhanced the ability to communicate across an organization and with customers. However, it has also created a staggering amount of inefficiency in the enterprise. Employees now spend an average of 2.5 hours per day listening, reading, and responding to voice-mail, e-mail, and faxes (see *Figure 3*). Identifying ways to help employees to more efficiently manage these communication methods will be the source of significant productivity improvements.

Unified Messaging

A study done by The Radicati Group, Inc. found that UM can generate 25 to 40 minutes of additional productivity per employee per day and can reduce IT support and administrative costs by 70 percent. UM provides users the ability to access and immediately respond to voice, fax, and e-mail messages from any phone or PC within the enterprise, reducing the time associated with accessing multiple devices. In contrast to today's voice, fax, and data-messaging systems, in which content must be manually copied or scanned to be passed between different system types, UM on a converged network supports a universal inbox that can contain all three types of messages. Employees can access voice-mail, e-mail, and faxes while traveling, and then will be able to reply or forward to the appropriate person (see *Figure 4*). As mentioned earlier, UM has existed for more than five years and has demonstrated tangible productivity benefits. Yet it is still a relatively undiscovered technology because of the difficulty to integrate the software into a multiple-network environment. A converged network provides the necessary platform to make UM a reality for many organizations.

Personal Communications Assistants

Because employees typically have multiple contact points, it is becoming increasingly difficult to know the appropriate number to call at a given time. As a result, "phone tag" is rapidly increasing, leading to missed calls and a frequent inability to contact a critical resource in times of need. In addition, it is often necessary for workers to prioritize who can contact them at a given time. Personal communications assistants on a converged network resolve these problems by providing employees tools to forward critical calls to their most appropriate number, to screen and prioritize incoming calls, and to easily set up audioconferencing bridges without the assistance of an outside party (see *Figure 5*). Some personal communications assistants also have speech-recognition capabilities that allow users to dial by name. Today's personal communication assistants also allow employees to customize call-screening and forwarding features through a graphical user interface (GUI) without having to request assistance from someone in the IT department.

FIGURE 3

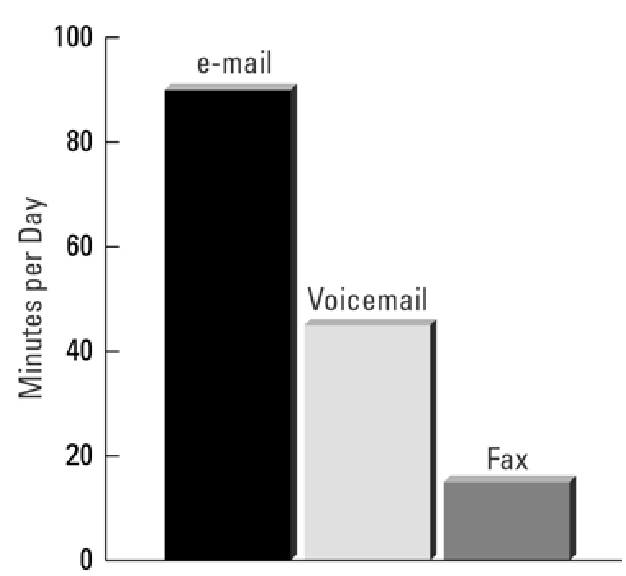


FIGURE 4

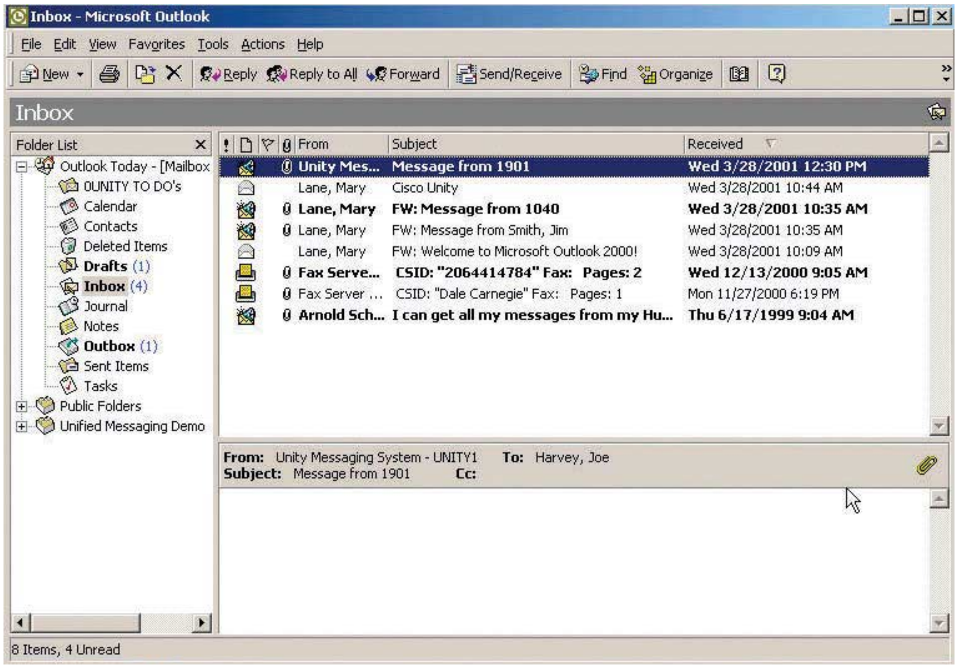
Unified Messaging



IP Video Solutions

Videoconferencing has also been in existence for many years but has never gained widespread adoption, largely because of the cost of having to acquire and maintain a completely separate network to handle video. As a result, when companies did invest in the technology, it was often only for use by a select group of individuals. A converged network has the ability to finally put the power of videoconferencing in the hands of everybody by providing companies a more cost-effective and more easily deployable model. The primary benefits of videoconferencing are its ability to save on travel costs, to minimize lost employee productivity due to travel, and to provide a richer form of communication among people at different locations. Similar to UM, it has been held back by the limitations of the traditional network model. In a converged IP network with QoS, an organization can provide videoconferencing and video on demand (VOD) capabilities to the desktop. New uses for this technology could include distance learning, whereby employees can access video content at their own leisure, as opposed to having to travel to a central training facility, and easier dissemination of critical business communications, such as quarterly board-meeting updates. Finally, IP video solutions have the power to further enable the mobile workforce by providing remote employees a real-time face-to-face interaction with their office-bound colleagues.

IP Phones and IP Soft Phones

IP–based phones are intelligent communications devices capable of supporting many new features that can also increase personal productivity. Many of these new IP phones use extensible markup language (XML)–based applications to allow the user to view employee directories, daily calendars, e-mail messages, and voice-mail using pixel-based liquid crystal displays (LCDs). The advent of the XML programming language allows organizations to easily download critical information and customized applications to a user's phone. An IP phone can provide users a potentially faster alternative to the computer to access simple bits of information that will speed up their work processes. Opportunities for this type of technology will develop on an industry-by-industry basis as organizations identify ways to deliver customized information to their employees or customers.

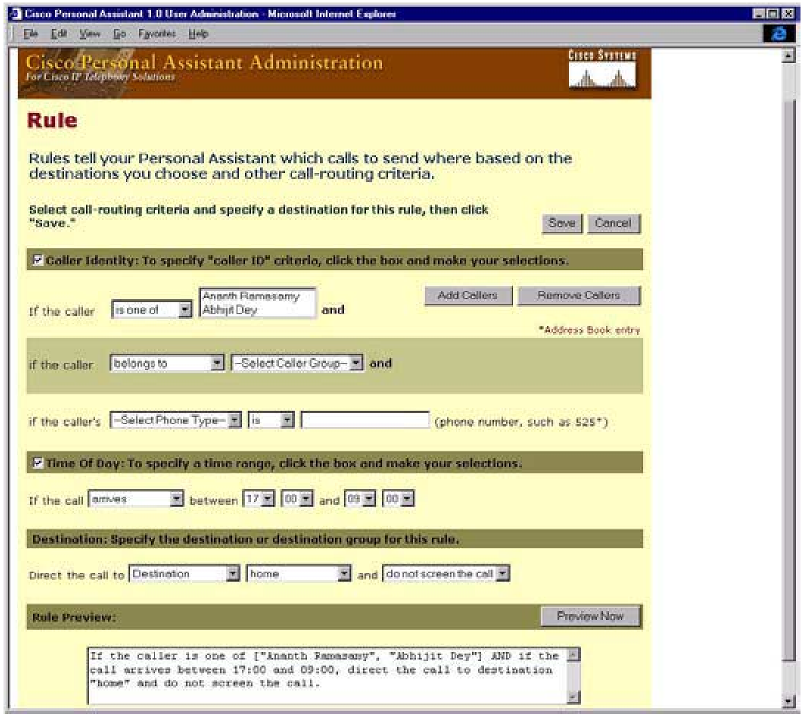
New PC communications applications currently allow users to eliminate their hard phone and use their PC for voice calls. A simple-to-use interface eliminates the need for two devices and allows the user to easily set up conference calls with the touch of a mouse. In addition, because an IP soft phone can travel with the user, telecommuters with high-speed access will be able to take their phone extension home with them and receive calls just as they would in the office. A converged network and the applications enabled by it can significantly improve the performance of employees by providing them the tools that they need to work smarter and faster.

Improve Workgroup Productivity

Even in today's information society, most knowledge still resides in the heads of a company's employees. Companies looking to the future are trying to identify methods to tap this individual specific knowledge and share it with the entire enterprise. As the workforce becomes more mobile, this problem will continue to increase. A converged network offers a platform that allows the deployment of applications and services that are intended to allow an easier dissemination of this knowledge across the organization. Several existing applications can play a key role in this endeavor, as are described in the following sections.

FIGURE 5

Personal Communications Assistant



IP Video Solutions
Videoconferencing has always had tremendous potential to improve knowledge sharing across an organization. But, as mentioned before, only a small percentage of people within an organization were allowed to use it because it was expensive and usually located in only one conference room. For videoconferencing to be a viable method to distribute knowledge, it has to be available to all employees. Under the convergence model, videoconferencing will be transmitted as IP packets and will be able to utilize the same network as does voice and data traffic. This will allow a much wider usage of the technology in the organization. Multiple groups of employees separated by thousands of miles will have the ability to collaborate on projects and share their knowledge, thereby increasing the productivity of the entire team, shortening the decision-making process, and hopefully accelerating the organization's time to market. VOD also offers the ability to provide geographically dispersed users access to an expert's knowledge through distance-learning programs.

Collaboration Tools
Collaboration applications that combine voice and video interaction with information sharing will play a key roll in improving knowledge management by facilitating easier access and the exchange of critical corporate information. This ability to share knowledge across an organization will allow a business to more quickly recognize problems and generate solutions or competitive responses. Current features include application sharing, whereby two users are able to read through a document together to agree on the correct content. Additional applications of the technology could include on-line editing of video content, walking a remote group of people through a presentation, or sharing a white board to brainstorm ideas while in multiple locations. The convergence of voice, video, and data onto a single network helps to make the obvious benefits of collaboration tools a reality.

Enhanced Customer Care/Responsiveness
As evidenced by the boom in CRM, it is obvious that most companies finally understand the value of keeping their current customers happy. An oft-cited statistic that continues to resonate is that it is 5x to 10x more expensive to acquire a new customer than it is to retain an existing one. Many of the recently deceased business to consumer (B2C) companies learned that lesson the hard way as they poured outrageous amounts of money into campaigns that were intended to turn browsers into buyers but often failed in their ability to build a loyal customer base. Most people also recognize that superior customer care and responsiveness is a primary driver of competitive advantage. Every industry has an example of one company that excels based upon its ability to satisfy the customer better than its competition.

Superior customer care has been a particularly vexing issue for companies who are in the process of major e-commerce initiatives. How can a company create an on-line environment that can provide a comparable level of service to a physical store staffed by real people? Converged networks provide organizations a fully integrated voice, video, and data infrastructure designed to provide their customers a richer on-line experience.

Multimedia Contact Centers
Converged networks can provide an enterprise the opportunity to create a truly multimedia call center. In the past,

call agents have only been able to interact with customers via the phone. Customers would at times be frustrated because they were unable to see the person to which they were talking and, oftentimes, they were forced to provide simple account data multiple times before their problem could be resolved. A multimedia contact center will allow an organization to put a face with the voice, and it will allow easier access to data critical to dealing with the customer's problem as fast as possible. The converging of data, voice, and video onto a single network will also provide the Web browser the option of click-to-dial functionality, where they can click a button while on the Web site and be put in contact with a customer-service agent. Furthermore, the easy access to customer data can lead to cross-sell and up-sell opportunities for an organization.

The enhanced mobility features of a converged network will allow call agents to be located remotely. This can reduce labor cost and increase employee quality by allowing the organization to recruit on a regional or national basis rather than within one specific market. It can also reduce the investment in call-center facilities, and the flexibility provided to employees could potentially boost employee morale.

Collaboration Tools

Collaboration applications and their ability to directly affect the customer's user experience are one of the most compelling reasons to justify migration to a converged network. With more than two-thirds of all on-line shopping carts never making it through checkout, there is an obvious disconnect between the level of service that customers receive and the level of service that they require to be successfully converted from a browser into a buyer. This disconnect cost North American businesses more than $1.6 billion in e-commerce revenue last year. And, according to Jupiter Research, more than 90 percent of on-line shoppers want some form of on-line human interaction. Collaboration software running over a converged network will allow the customer-service agent to look at the same page on the Web site as the customer, to make recommendations and product comparisons, to instantly transfer relevant documents to the user's desktop, and to walk them through the checkout process. As customers continue to demand a level of service similar to that which they receive in a physical store, tools such as on-line collaboration can provide the customer a customized on-line experience that eliminates many of the dehumanizing qualities of using the Internet to shop or seek help for a problem.

Contact-center applications and on-line collaborative tools offer the most obvious customer-care benefits. However, UM and personal communications assistants can also improve customer service by providing customers quicker response times to their inquiries. For instance, if a customer urgently needs to reach their account manager, personal communications assistant software allows that call to be routed to the salesperson's current location rather than his or her voice-mail box. Similarly, UM reduces the time required to access and read or listen to voice-mail, e-mail, and faxes. This, in turn, can reduce the time that it takes to respond to a customer.

Migrating to a converged network and the applications enabled by it can not only offer an organization short-term reductions in its TCO, but also can generate substantial long-term benefits, such as increased personal and workgroup productivity, enhanced customer care, and increased organizational flexibility. In other words, it has the potential to be a source of strategic value rather than just a cost center.

Issues That Arise When Migrating to a Converged Network

This analysis has explored the benefits of migrating to a converged network. However, there are also potential issues that could slow adoption of this technology. According to a recent study by the META Group, the primary obstacles impeding organizations from migrating to converged networks are perceptions about voice quality, system reliability, interoperability with legacy systems, and cost.

Latency, jitter, and echo were early problems that plagued IP telephony. These were largely caused by a lack of QoS in the network. A converged network must be able to separate each traffic type and handle it according to its unique requirements. For example, data traffic is not time-sensitive—it travels in bursts and requires accurate delivery. However, voice—and to a certain extent, video traffic—is very time-sensitive. Adding voice packets to a bursty IP environment requires QoS to the desktop. An organization needs to understand what QoS is and how important it can be to ensure proper network performance for voice, in addition to data and video. Traffic classification and marking, queuing, and data-packet fragmentation and interleaving techniques are available now to guarantee voice quality. Planning a QoS strategy before deployment saves time and money and eliminates frustrated users. Most IP telephony vendors can now deliver toll-quality voice. However, to ensure this high quality, networks need end-to end QoS policy management in all routers and switches. Even if an organization is not fully committed to a convergence strategy now, it makes sense that all of its new data equipment can handle voice and video, because this will ease the path to eventual migration.

Reliability is also a critical concern of companies that are contemplating the convergence of their networks. Universal experience with traditional analog or digital phones is that, upon picking up the receiver, the user receives a dial tone 99.999 percent of the time. It is often assumed that when merging voice onto a data network, it will become unreliable. However, the PBX is inherently no more reliable than a data network; what makes it more reliable is that organizations recognize that voice is mission critical and therefore usually invest in the necessary redundancy and power back-up systems. Many IP telephony vendors have built similar levels of redundancy into their systems via call-processing server clusters, redundant routers and switches, and uninterruptible power supply (UPS) systems. With the correct design considerations and best practices, converged networks running IP telephony can achieve a comparable level of reliability to the traditional voice network. The added benefit of building redundancy into a converged network is that organizations can also improve the reliability of their data and video traffic. Another early problem with IP telephony was that the phones ceased to function when the network lost power. In response, most IP telephony vendors have developed in-line power solutions to ensure that users still have voice service during a power loss.

Most organizations have made significant investments in their existing voice, video, and data networks. They are understandably concerned about their ability to protect their investments while migrating these separate networks to a converged networking model. Therefore, a low-risk migration path is required from the old world to the new world. Most converged networking vendors have created products to ease this transition and ensure that new equipment can integrate with the existing infrastructure. In the longer term, a converged network will most likely make additional technology purchases more interoperable, because it will be based on open standards and will be one network as opposed to separate voice, video, and data networks. As in any technology investment, especially one with such far-reaching implications as convergence, an initial investment in the technology will be required to migrate to a converged network. For some organizations that are opening new offices, retiring PBXs, or already planning to make significant investments in data-networking equipment, the financial decision is relatively easy. For companies that have older data-networking equipment, the up-front cost of migrating to a converged network will likely be steeper. For these organizations, it is recommended that they begin to prepare their data network to handle voice and video before they make a substantial investment in IP telephony equipment and applications.

Summary and Conclusions

Convincing an executive committee to invest in new technology in these lean economic times can be a daunting challenge. The IT initiative must support core business strategies, yet must also provide quick returns to meet an organization's short-term financial focus. Migrating to a converged network can deliver both. Its ability to empower an organization to reduce infrastructure, staffing, and facilities costs can produce a quick ROI, while its greater flexibility and scalability allows a company to more quickly react to change. Finally, the ability to more easily integrate new end-user applications allows a business to improve personal and workgroup productivity and enhance customer care. All of these benefits can directly contribute to a business' competitive advantage, whether that advantage is based on speed to market, superior customer service, or being the low-cost producer.

To prepare for migration to a converged network, companies must understand all of the relevant factors to ensure a high probability of success. It is important to understand your existing PBX vendor's future architectural plans for your current voice network and how that vendor plans to provide viable migration paths to IP. Convergence can potentially take many forms, but some strategies are further developed than others. Also, to make migration to convergence easier, all organizations need to assess their current data networks to determine how well prepared they are to run voice and video over the same lines.

Lastly, IT managers must begin to evaluate convergence on its own terms rather than as merely a replacement for the traditional PBX. This will be a gradual process for some, but companies that immediately grasp the benefits of convergence will create networks that effect change and innovation rather than impede them. And if there is any doubt about the future of converged voice, video, and data networks, just look around the office and count how many typewriters you see.

The Consumer Relationship Is King: Thoughts on the 21st Century Content and Media Company

Michael Kline
Senior Manager
Deloitte Consulting

Overview: The Consumer Relationship Is King

"It's good to be the king!" (Louis XVI [Mel Brooks], History of the World Part I*)*

As content and media companies contemplate the strategies they need to forge their digital futures, one thing is clear: The rules of competition in the content and media industries are going to change. The impact of the transition from analog to digital content creation, aggregation, and distribution will be significant enough to require a new competitive framework to describe the ways companies should respond to this transition.

The purpose of this paper is to present our thinking on what that competitive/strategic framework looks like and what the implications are for content and media companies today. We intend this framework to address the concerns of the various players in the content and media value chain, from content creators to content aggregators to content distributors.

Here are some of the highlights of the framework.

- In the analog world, competition occurred along two dimensions: content and distribution. Content companies bulked up to ensure access to favorable distribution, and distribution companies bulked up to ensure favorable access to content.
- In the digital world, competition will occur along a third dimension: personalization. The battle for scale and advantage will increasingly occur along this axis.
- Personalization is a measure of the depth of knowledge a company has about the preferences of its customers and that company's ability to deliver customized products and services to its customers, based on that knowledge.
- For a number of reasons, we believe that today's personalization efforts will succeed, whereas those in the past—"mass customization", "one-to-one", et al.—were either prematurely introduced or inadequately implemented.
- Businesses historically powered by content and distribution assets will, over time, be increasingly powered by personalization assets, and value will flow disproportionately to those asset holders.
- Aggregation of consumers, as well as the information associated with those consumers, will create equal if not greater leverage in the supply chain than the aggregation of content.
- A new breed of company—the entertainment services provider—will emerge.
- Privacy will be a major issue for companies competing along the personalization axis.
- In light of these changes, content and media companies will need to develop competencies in personalization that cut across all aspects of their organizations.
- In particular, content creators need to begin moving from selling products to assembling packages of content and content-related interactive applications that enable them to capture end-user information and to pre-empt content distribution companies from capturing the value of complementary products.
- In the short to medium term, content owners will be king, as many content and media companies try to establish direct consumer relationships by paying large sums for content. In the longer term, consumer-relationship managers will be king, and the most successful content and media companies will have a superior understanding of the consumer and the ability to

deliver the consumer what she or he wants, to where she or he wants it, and when.

- While personalization will play a major role in the future, it is unclear who the leading consumer-relationship managers will be, and there are several different possible scenarios to describe the future evolution of content and media businesses. What is clear is that strategic, technological, and organizational flexibility will be required in order to respond to the various possible futures and to communicate to investors about the strategies employed amid this uncertainty.

The first section of the paper, "The Content and Media Competitive Landscape: The Analog View," describes the historical competitive framework that has characterized competitive behavior in these industries over the past decade. The second section, "The Content and Media Competitive Landscape: From Analog to Digital," examines the forces that are changing that competitive framework and that, in our opinion, require content and media companies to adopt a new framework to compete effectively going forward. The third section, "Personalization: The Third Dimension of Competition," outlines our thoughts on the new dimension of competition for content and media companies: personalization. The fourth section, "Strategic Uncertainty: The Possible Futures for Content and Media Companies," presents three different possible scenarios for the future evolution of the content and media industries and suggests the various strategies different companies will use to compete moving forward. The last section, "Owning the Consumer Relationship: Challenges for the 21st Century Content and Media Company," considers the organizational, technological, and strategic implications personalization will have for content and media companies.

The Content and Media Competitive Landscape: The Analog View

"We're going to need a bigger boat." (Chief Martin Bridy [Roy Scheider], Jaws*)*

The delivery of content to consumers has historically occurred along a fairly monolithic value chain made up of license holders, content aggregators, and consumer access/content distribution companies (see *Figure 1*). Competition between different segments of the value chain was less about fighting over end-user ownership and more about establishing leverage in negotiations between those segments. And, for the most part, each player in the value chain tended to focus on different customer groups, enabled by different assets and competencies, and powered by different economic models and motivations.

Content companies acted as venture capitalists, financing the development of original content (and the acquisition of third-party content). Over time, these companies diversified their risk by branching out into many different forms of content (e.g., film, music, publishing, games), all or most of which they sold/syndicated to content aggregators and distributors. Aggregators (e.g., television networks, cable channels, Internet portals) packaged and scheduled the content in order to maximize advertising revenue and, over time, branched out into financing original content creation in order to secure an ongoing supply of content and to establish their signature brands. Content distributors (e.g., cable and satellite companies, retail stores) leveraged heavy brick and mortar infrastructure investments to deliver an ever-increasing supply of channels/titles to end users via direct sales and/or subscriptions.

FIGURE 1

Content and Media —The Analog Chain

	License Holders	Aggregators	Customer Access
Primary Assets	• Licensed to breadth of content • Access capital	• Audience • Advertiser relationships	• Physical distribution assets • Direct customer relationship
Business Model	• Revenue share with distributors • Limited direct sales (clubs, etc.)	• Advertising • Limited subscriptions	• Subscriptions • Direct sales • Advertising
Strategy	• Aggregate breadth of content • Secure access to distribution	• Develop original programming • Aggregate content to secure distribution	• Consolidate distribution • Secure access to content

SOURCE:DELOITTE CONSULTING

In this analog world, with a single path to the end consumer, competition took the form of maintaining parity among the various value-chain participants. By way of analogy, content creators and aggregators, much like the United States and Russia during the Cold War, "bulked up" by acquiring other content creation and aggregation companies to ensure favorable access to consumers and advertisers. At the same time, distribution companies also consolidated in order to ensure favorable access to content (see *Figure 2*). In other words, competition tended to occur along two primary dimensions: content and distribution.

More recently, this wave of horizontal integration has been accompanied by a wave of vertical integration, where companies have made acquisitions to position themselves further along both the content and distribution competitive axes (again, see *Figure 2*). From Disney's acquisition of ABC, Viacom's acquisition of Blockbuster (and later, CBS), and the merger of AOL and Time Warner, the level of vertical integration in content and media companies increased dramatically during the last decade.

Firms did make different bets in terms of the level of vertical integration in which they engaged—e.g., Disney, for the most part, remained out of the "content distribution/consumer access" business in terms of cable and satellite system ownership (though it does have direct relationships via its retail and theme park operations), while AOL Time Warner integrated across the value chain. Likewise, certain firms made acquisitions favoring one revenue source over another—e.g., Viacom (advertising) versus Vivendi (consumer expenditures).

That being said, competition in content and media over the past decade has been, more than anything else, a battle for physical (and global) scale to maintain relative bargaining power in the value chain. Like the Cold War, however, the best outcome in this two-dimensional competitive framework is stalemate. Innovation often takes a back seat, which paves the way for new companies to enter. There is also the question of how much bigger content and media companies can become—partially, for regulatory reasons, but even more because of the diminished operational efficiencies and competitive nimbleness that come with size. But, most important, the advent of digital technologies poses a fundamental threat to the content and media value chain itself.

As we will discuss in the next section, the changes to the value chain that are being brought about by digital distribution technologies will, in our opinion, force content and media companies to re-evaluate how they compete.

The Content and Media Competitive Landscape: From Analog to Digital

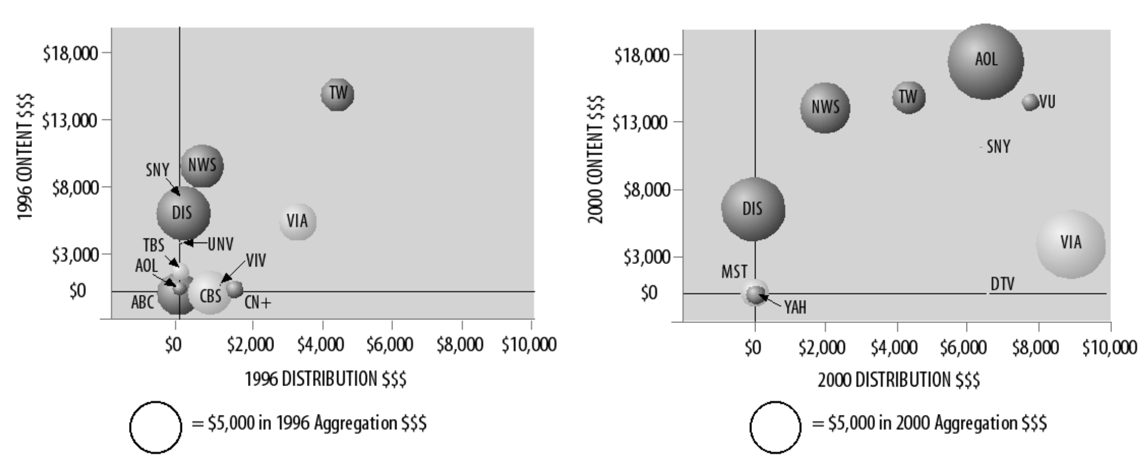
"Size matters not. Look at me. Judge me by my size, do you?" (Yoda [Frank Oz], Star Wars: Episode V—The Empire Strikes Back*)*

The traditional (analog) content and media value chain was characterized by a single path to the end user (or, in the case of filmed content, single, well-defined schedules—or windows—for delivering content to the end user) defined by the largest players in the value chain. "However," as Thomas Middelhoff, the CEO of Bertelsmann, said, "it is my conviction that as content becomes digital, the entire media and entertainment value chain will change."

The digitization of content disrupts the traditional value chain by opening up multiple paths to the consumer of that content—that is, because digital content is no longer tied to the channel for which it is created. In the analog world, for example, music is essentially defined by the channel in which it is sold—i.e., indivisible units called compact discs (CDs) sold in physical retail stores—and, as such, music has only a limited number of ways of reaching consumers. In the digital world, music can be delivered to consumers through a variety of channels (e.g., peer-to-peer, virtual stores, personal

FIGURE 2

The Content and Media Competitive Landscape—The Analog Battle



SOURCE: COMPANY ANNUAL REPORTS, DELOITTE CONSULTING ANALYSIS video recorders [PVRs]) and under a variety of different economic models (e.g., pay per download, monthly subscriptions—perhaps with incentives for contributed content). And while the existing music companies have successfully slowed that transition through legal action and scaled-down digital offerings of their own, the sale and consumption of music will change due to these technologies.

With digital technologies, the linear, analog value chain becomes a networked, digital ecosystem, characterized by many more points of contact with the consumer by many more players. In effect, what digital technologies are facilitating is the convergence of formerly unrelated industries and companies, with the locus of convergence taking place at the individual consumer (and advertiser) level. For example, the $22 billion home-video market is captured today by a limited number of players (e.g., video stores, video distributors, and the license holders). In a world of digital video on demand (VOD) (see *Figure 3*), many companies not historically involved in that revenue stream are positioning themselves to capture part of it. Companies such as TiVo and RealNetworks are attempting to become the networks of the future, and TiVo—at least for now—is able to capture revenue from users without having to share it with the content owners. Even Microsoft's authentication and identification service, Passport, will be angling to control ownership of the consumer's information. In fact, the battle between AOL and Microsoft is more than anything about who controls the primary consumer interface. It is each company's hope that by gaining control of that interface, it will effectively have a platform that content and application providers will have to plug into in order to get access to consumers. The companies will, as a matter of course, charge for that access.

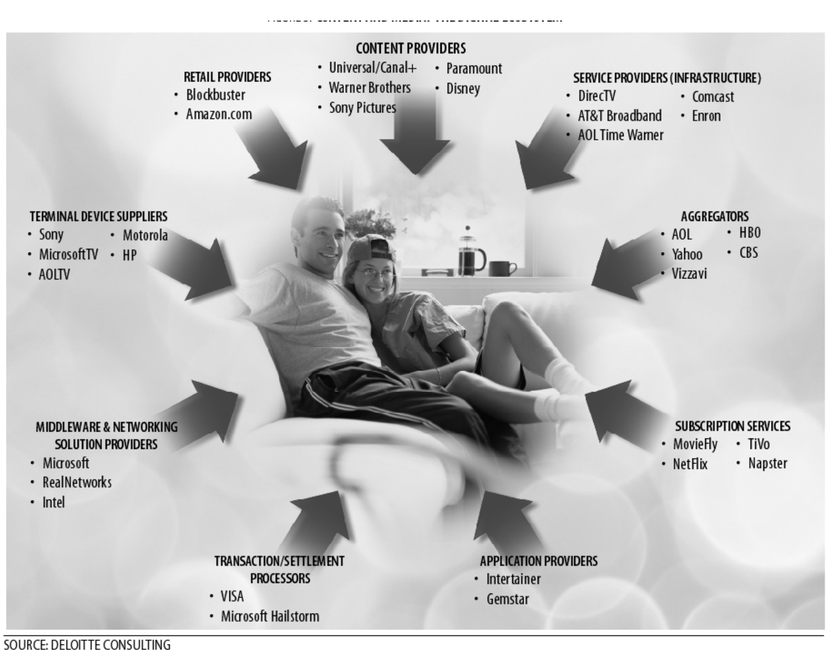
We assert that many new competitors will threaten to disintermediate end-user relationships currently owned by existing value-chain participants by disaggregating content from its historical distribution channels—but, to what extent? Given their current financial state, companies such as TiVo, Intertainer, and RealNetworks are just as likely to fail as succeed. And even more established "new era" companies, such as Yahoo and Gemstar, which have at least captured market value since their beginnings, have not yet demonstrated an ability to capture significant revenues in content- and media-related transactions. In other words, should existing players care?

For content companies, the basic question often has been: If I continue to create compelling content, isn't that enough? (In other words, no matter which distribution channel consumers choose, great content will be needed, and therefore I'll get paid my share.) The answer is: Not necessarily. While compelling content will continue to find an outlet, the increasing amount of user-generated content (e.g., chat, messaging) facilitated by digital technologies does reduce the share of overall content for which traditional content owners will be compensated. This is also at a time when the battle for a consumer's leisure time is already an issue; one need only look at the proliferation of magazine titles, Web sites, and television channels to appreciate the extent of the battle for the end consumer's attention.

In addition, it is less certain what share of the value of content license holders will capture, given the increasing number of potential intermediaries. It is likely that no single content company will be able to own all the content in a particular category, thus there will always be a need for an intermediary to aggregate that content. However, if content

FIGURE 3

Content and Media —The Digital Ecosystem



SOURCE: DELOITTE CONSULTING

companies cannot ultimately control the end-user relationship because of these new intermediaries, then the concern becomes how they will maintain and grow the share of the value that is captured vis à vis those intermediaries.

And, as production costs decline due to cheaper, digital alternatives, and as alternative, cheaper forms of digital distribution emerge, the core value that content companies offer to the content creators they represent (e.g., independent musicians and producers) needs to change. Today, the value that content companies offer to their content suppliers is in securing control over proprietary distribution channels. However, as those channels open up and the costs of production and distribution begin to come down, that value becomes more a function of marketing value, which is driven by the depth of knowledge content companies have of the end consumer's needs. Thus, knowledge about the end consumer will become the new dimension firms will compete along to attract and sign artists and producers.

For content aggregators—especially those dependent on advertising revenues—the proliferation of distribution channels enabled by new digital technologies, such as peer-to-peer and PVR, threatens to fragment the consumer base needed to drive advertiser interest. To illustrate this point, with PVR functionality enabling users to download programs independent of their original schedules, one could argue that TiVo (or DirecTV or AOLTV) becomes the broadcast network. Indeed, in the new digital ecosystem, the identity of your competitors is less clear.

In the broadcast (analog) world, networks were content aggregators that built brands to compete for ratings. In the broadband (digital) world, networks become the infrastructure that delivers content (bits) to consumers. As such, the greatest competition for networks may not be other networks, but instead the network operators through which the network programming passes (especially as these operators integrate TiVo-like functionality into their systems). In fact, those content aggregators that cannot control the distribution of their content or that do not possess a strong brand recognition with the end user may be replaced by their emerging digital counterparts. For aggregators, the threat of losing their relationship to the end consumer poses the even greater threat of losing their advertiser relationships, which account for the majority of their revenues.

For distribution companies, the growth of "open," Internet protocol (IP)–based distribution systems threatens to undermine their primary source of advantage—that is, their virtual monopoly over access to end users because of the incredibly high costs associated with duplicating their distribution infrastructures. Peer-to-peer distribution, for example, has the potential to be a "disruptive technology" that fundamentally changes the economics of content distribution. Peer-to-peer decentralizes distribution and is one of the ways content companies, content aggregators, and emerging digital distribution companies can open up what has been to date a closed-end system.

In such an open system, value will not necessarily flow to those with the greatest capital investment. Instead, companies may take advantage of the viral nature of the peer-to-peer medium (by offering, for example, innovative incentives to consumers for distributing and contributing content). These companies will focus on building their end-user relationships as opposed to their physical asset bases, and thus may change the way content is distributed. At a minimum, for cable and satellite companies—not to mention brick-and-mortar retailers—the possibility that wireline and wireless telephone operators and network resellers will siphon off their most profitable customers will force them to develop new ways of differentiating themselves to their consumer base.

All of this is not to suggest that the future content and media ecosystem will no longer consist of content creators, content aggregators, and distributors. Nor is it to suggest that scale no longer matters or that acquisitions will not take place—in fact, quite the contrary, given the recent indications from the Federal Communications Commission (FCC) that many existing ownership limitations will be relaxed. Rather, what will change is the relative value captured by each of the participants, as will the way that scale is defined. Physical scale will, to a certain extent, be necessary to maintain leverage in negotiations with ever-larger suppliers and buyers. But, with many of the larger media conglomerates approaching that size and with an explosion of content that only serves to exacerbate the conflict over a consumer's leisure time (the issue is not trying to find more content to push at consumers, but rather getting consumers to notice your content), then it follows that the nature of advantage will originate from other capabilities and assets.

"Traditionally," Thomas Middelhoff continued, "media companies said, 'We must control distribution.' In the future, corporations must establish direct access to consumers through multichannel on-line and off-line distribution strategies."

We believe that the move from analog to digital requires a new competitive framework, one that focuses on who owns the consumer relationship. And, we believe that the battle for owning that consumer relationship will not simply be through increased content and distribution asset ownership, but will instead occur along a third dimension: personalization.

Personalization: The Third Dimension of Competition

"Did you hear the one about the guy who was too poor to get personalized plates so he changed his name to J3L2404?" (Marge Gunderson [Frances McDormand], Fargo*)*

If traditional competition occurred along two dimensions, future competition in content and media will occur along a third dimension—a dimension we are calling personalization (see *Figure 4*).

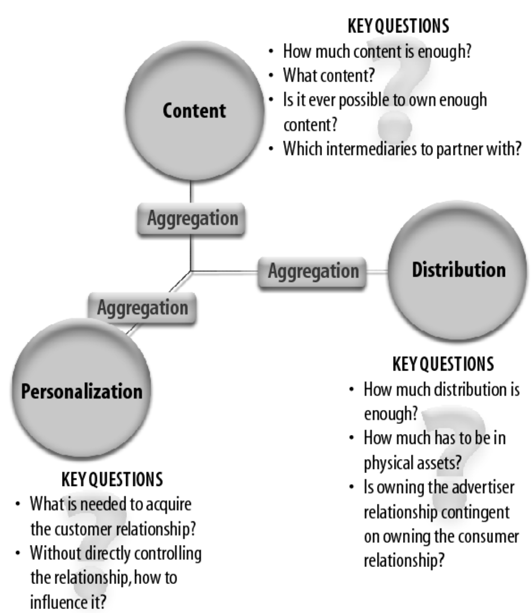
What is it? Personalization is a measure of the depth of knowledge a company has about the preferences of its customers and that company's ability to deliver customized products and services to its customers based on that knowledge. While personalization is about having a broad range of customer contact points—across media, devices, and platforms—it is more than simply having a direct relationship to a consumer. Personalization may be enabled by owning physical assets, but it does not flow directly from their ownership. Nor is it simply a question of building a database with superior analytical tools to process that data, though that is a component. Companies need to develop technologies, business processes, and organizational structures to truly compete along this dimension. And they need to do so within the privacy guidelines that will be established in the coming years.

Why is it emerging? As described in the previous section, the digitization of content and the emergence of peer-to-peer file-sharing networks have created a new way for companies to compete against established content and distribution companies. The growth of alternative last-mile solutions and the adoption of open communications standards are changing the rules as well. While Napster's rapid acquisition of more than 50 million users can be explained to a great extent by its giving away content for free, one of the messages of its success should not be ignored—i.e., that new distribution mechanisms that deliver to consumers exactly what they want, when they want it, can dramatically impact existing distribution systems. In addition, with a preponderance of content alternatives and an ever-shrinking quantity of leisure time, consumers will favor companies that can simplify their lives and that are more attuned to their schedules and preferences.

What do content and media companies get from it? In a phrase: superior economic leverage. There is a geometric return associated with each additional user or each additional product sold to an existing consumer in companies that have successfully transformed themselves into personalization engines. Each time a user purchases an item on Amazon.com[1], for example, that information generates multiple, targeted marketing opportunities—not just to that user (e.g., notification when that author writes another book), but also to all other users with similar profiles (e.g., notifications based on their prior history that a new book may be of interest to them).

FIGURE 4

The Content and Media Competitive Landscape—The Three Dimensions of Competition in the Digital Age



SOURCE: DELOITTE CONSULTING

In another example, Lands' End created a "My Personal Shopper" personalization engine on its site, and people who used that service bought on the site 80 percent more often, with an average order value that was 10 percent higher than orders made through other channels. And, in early VOD trials, monthly subscriber churn was reduced from more than three percent to just less than one percent. While it is still too early to tell what these numbers will be, as VOD becomes more common, the point that users stay with services that provide them what they want, when they want it, is an important one, especially as many content and media companies contemplate moving from single- (product) sale business models to subscription-based models that will be subject to churn.

In addition, personalization enables differential pricing for what is essentially the same product or service. This will allow companies to stress, for example, certain product attributes (e.g., timeliness or convenience) or even to charge different pricing models altogether (e.g., subscriptions, renting, buying, or bundling) based simply on a more sophisticated view of the consumer. The financial benefits of personalization include greater frequency of sales/visits, higher average price per sale, and lower customer acquisition costs as a percentage of sales, reduced churn. And, unlike building scale in physical dimensions, building scale along the personalization dimension can result in a much higher return on assets.

How can companies get it? Personalization requires more than technology—companies need to be completely oriented toward personalization to compete along this axis. In addition to the technology investments in relational databases, data-analysis tools, call-center applications, customer-relationship management (CRM) software, and so on, companies must also invest in the people and processes needed to gather and analyze information about user preferences. This is especially relevant for companies that have not strongly focused on the end user before, which is the case with many content and media companies that sell through distributors. Companies without direct access to consumer information will need to negotiate with those companies that do have access. While that is likely to be the most contentious part of the negotiations, the benefits achieved by delivering the right product at the right time should leave enough value for both parties to share.

How will companies use it to compete? In converging industries, where many companies, both old and new, are trying to position themselves to own the consumer relationship, consumer loyalty is up for grabs. Companies will use their personalization assets to build and strengthen their consumer relationships; this correspondingly raises switching costs for those consumers. As switching costs rise, the physical-scale equation changes—increased consumer leverage through personalization reduces the relative value imparted by physical assets, namely content and distribution assets.

For content companies, the threat of personalization is the risk of reduced leverage with other members of the value chain. Content aggregators and distributors will use their newfound leverage with consumers to negotiate more favorable terms with their content suppliers. As companies such as DirecTV, for example, know more and more about a particular user's preferences, that user may not be moved to switch even if a content company's channel is dropped or if a local channel is not carried.

For content aggregators, the threat of personalization is the risk of being cut out of the equation. We have already discussed how PVR technology threatens traditional advertising revenue, especially for programming that is not "live." This will force networks to pay ever-increasing rates for live programming, such as sports and news. To a great extent, we have already seen such a rise in license fees. However, if content aggregators do not develop a deep relationship with their audience, they run the risk of not being able to pay as much for those licenses as companies that do, even if those companies reach fewer people. Even if a distributor reaches only half the audience that a network might, it may see greater returns on the advertising it sells, and thus be able to pay more for licenses. This is because a distributor will be providing targeted advertising, which generates much higher costs-per-thousand (CPMs) than broadcast advertising. (And, in this example, reaching half the audience would require twice the CPM—a multiple that personalization has been shown to have.)

For distribution companies, the threat of personalization is the risk of losing their primary consumer relationship and stranding their significant physical asset base. For example, while existing cable and satellite companies may have an inherent advantage over their competition by virtue of their being the primary source for video programming because consumers are simply used to subscribing to their services, alternative sources of video subscription services that deliver personalized content may be able to draw certain consumers away. This is possible even if those services suffer, at least initially, from either reduced content (e.g., due to licenses being locked up) or greater inconvenience (e.g., due to users having to download programming to their PCs). By understanding what certain customer segments want and are willing to pay for, these alternative access companies can win share from those companies that treat—and charge—their customers the same. In other words, physical infrastructures built for mass-market distribution have the potential to lose out to lower-cost architectures tailored to specific customer segments.

What does it all mean? In the short term, content companies will be king, as many players, in an effort to build primary relationships with consumers, pay large sums for content. In the longer term, however, consumer-relationship managers will be king, and the most successful content and media companies will have a superior understanding of the consumer and the ability to deliver what she or he wants, to where she or he wants it, and when. For a discussion of who those relationship managers might be, please see the next section, "Strategic Uncertainty: The Possible Futures for Content and Media."

Why now (or haven't we heard this before)? Before moving on, however, it is worth discussing why companies need to be thinking about this today. For some time, we have heard people talking about how there would not be 500 channels, but rather only one ("my channel"). And, the concept of mass customization, while not synonymous with personalization, gained favor in the early 1990s, only to fall out of favor as companies realized that the costs of customization far outweighed the benefits.

Indeed, personalization is not free. There are always costs associated with implementing it, not the least of which is the loss of basic economies of scale that are achieved through mass production. In the case of digital music, on-line radio broadcasters need to pay additional royalties for allowing consumers to develop personalized play lists, the theory being that a more personal level of connection with the consumer will eventually lead to additional revenues from that consumer, improved word of mouth, and other benefits. Personalization does have to provide real value that makes enough of a difference to the consumer, and that is a lot more difficult—and expensive—than a lot of people thought it would be.

So, what has changed? First, technological developments have made personalization more feasible. The PVR, for instance, allows for the simple creation of a single, personalized channel, and advances in CRM systems provide the needed infrastructure to support personalized service offerings.

Second, during the past decade, media have proliferated dramatically—there are thousands of new magazines (more than 16,000 consumer titles), hundreds of new television channels, and thousands of Web sites—causing an even greater need for a company to filter out content that is not relevant to a consumer.

Third, there has been a change in consumer behavior itself. A new generation of consumers that were raised on interaction with content providers and personalization of their Web sites demonstrates consumers' increased comfort level with personalized services.

Fourth, much of the growth in the past decade was achieved through acquisitions. Many of the content and media companies, in their current form, are experiencing slower growth—cable penetration has, for the most part, peaked; dial-up Internet access is slowing down; domestic music sales have actually declined; the number of movie tickets sold is fairly flat—and there is a question about just how much more these companies can use acquisitions, at least domestically, to grow their markets. What's clear is that companies need to develop new ways to find growth.

Fifth, the AOL and Time Warner merger speaks to a new type of company, one focused on the subscriber and with interactive/personalization capabilities at its core.

While all of this suggests some fundamental changes in the way companies will be competing going forward, it is worth making the point that competing along the personalization axis requires an explicit, well-executed strategy. Past attempts at "mass customization" failed not so much because the basic concept was flawed, but because companies did not analyze what type of customization was valued by their customers. Personalization for personalization's sake will indeed lead to higher costs without any associated benefits. Companies need to pursue the type and level of personalization that is precisely right for their customers, and this can only be gauged through thorough and ongoing customer analysis.

Strategic Uncertainty: The Possible Futures for Content and Media Companies

"I don't know the future. I didn't come to tell you how this is going to end. I came here to tell you how it's going to begin." (Neo [Keanu Reeves], The Matrix*)*

While we believe personalization will play a major role in the future, the tremendous amount of regulatory, technological, and end-user uncertainty makes it unclear who the leading consumer-relationship managers will be. We have defined three scenarios that, in our opinion, describe the possible future evolutions of the content and media businesses. As part of any such exercise, we will attempt to describe the underlying factors and events that need to occur to make that scenario happen (see *Figure 5*). After describing each scenario, we will discuss the possible strategies that different content and media companies might use to influence the evolution to their advantage.

1. My Studio

This scenario describes a world where content companies and content aggregators—and their personalization assets—capture the majority of the value. Here, the stranglehold that existing closed-end distribution systems have over consumer access is broken. This implies that the deployment of alternative last-mile solutions into the home occurs, that open standards are developed to tie the various components in the digital living room together, and that regulatory agencies push for accelerated broadband deployment as well as for must-carry provisions from existing distribution companies. Given these events, distribution assets become increasingly commoditized, and content companies have the opportunity to develop more direct relationships with the end consumer.

2. My Walled Garden

This scenario describes a world in which closed distribution systems—and their personalization assets—capture the majority of the value. In other words, "proprietary" broadband access rules the day, given the slow deployment of alternative distribution channels due to inferior economics and difficult-to-change end-user behavior, a passive regulatory regime, and minimal standardization of technologies. In this scenario, assuming the distribution companies simultaneously leverage their position to strengthen their end-user relationships, certain content companies and aggregators may be marginalized and suffer in terms of negotiating power versus these distributors. And, as more and more functionality—including, for instance, PVR and messaging—gets built into these closed-end networks, the role of traditional content aggregators that do not have either a strong brand or access to unique content will be threatened.

3. My Entertainment Services Provider

This scenario describes a world in which pure relationship managers capture the majority of the value. In other words, companies that have amassed the largest database of consumer behavior and built the capabilities to leverage that data into personalized content and media offerings will not only exist, but will capture greater value than pure content and distribution companies. (Of course, the question of how these companies acquire those end-user relationships without the physical assets to begin with merits discussion. The way Amazon.com has positioned itself and the way

SOURCE: DELOITTE CONSULTING

RealNetworks is positioning itself suggest the opportunity for software-based—as opposed to physical asset–based—companies to play a significant role in the value chain. In addition, one can also assume that a distribution or content company, once it has developed a sufficient number of high-quality end-user relationships can, over time, divest their physical assets to focus on their highest performing, lowest capital-intensive assets.) In situations where the entertainment service provider cannot develop that end-user relationship, it can make its engine available to third parties (via a private-label arrangement) but still participate in the revenue, especially as its broader database facilitates up-selling and cross-selling for its partners.

This scenario requires broadband ubiquity enabled by alternative access technologies; channel, content, and device proliferation; and "must carry" and "must license" provisions from regulatory bodies to ensure supply from distribution and content companies. While this scenario is not likely to occur in the immediate future, the very real possibility of access commoditization as well as the reality that no single content company will ever be able to assemble all of the content under its umbrella do suggest the possibility of a future where a standalone entertainment services provider will emerge.

It is important to note that the likelihood of each scenario actually occurring will vary by content type and that, in fact, what is likely to happen will be a fragmentation in the evolution of different content and media businesses. For example, while video content looks to be delivered through the "walled garden" of existing distribution systems (at least in the short to medium term), music content is already finding alternative distribution outlets that suggest different outcomes. The scenario-planning exercise described needs to be more rigorously applied to specific content categories, though it does point to certain lessons that will apply across categories and suggests the issues that content and media companies need to start considering in order to control their futures.

That said, what are the strategic implications for the various content and media companies, and where should they be focusing their efforts to steer the evolution to their advantage? Given the number of new companies entering the digital content and media space, the rapid degree of technological change, and the highly uncertain response of end consumers—i.e., given the likelihood that the different scenarios each have a probability of occurring—highly flexible strategic planning will be required. That means, for instance, the use of real (strategic) options to hedge and the constant monitoring of when those strategic options are in or out of the money. Often, it also means going down several parallel paths—each of which has implications for what the optimal organizational structures and buy-versus-ally strategies might be.

While strategic flexibility will be the overarching guiding principle for these companies—at least for the next several years—there are specific actions that each segment of the content and media value chain can begin taking.

For content companies and content aggregators, the principal strategic challenge will be to commoditize distribution assets or, at a minimum, to maintain leverage with the distribution companies. That means amassing a breadth of unique content and investing in their brands, though the level at which branding occurs—at the individual program level or the network level, for example—will be an interesting issue for content companies. If content and media companies do see a world of open delivery systems, then investing in distribution assets may not be the best deployment of capital, which can be better invested in brand and content development.

Leverage with distribution companies can also take the form of allying with or even acquiring major suppliers to the distributors. News Corp.'s ownership of Gemstar, for example, is a point of leverage it can use with domestic cable and satellite operators despite its relatively light position in domestic distribution assets (although a successful acquisition of DirecTV will certainly change that). Pushing open standards is another mechanism to combat the power of distribution companies, although the question of which standards is an issue. Peer-to-peer standards as well as open standards for set-top box manufacturing—to push them into retail outlets—are ways to open the door into closed-end distribution systems.

In terms of moving along the personalization axis, content companies will need to start investing in personalization technologies and platforms, if for no other reason than to take an option on their future success. AOL Time Warner's recent investment in Amazon.com is a step in that direction, as is Vivendi's acquisition of MP3.com. Other possible events include partnerships with and/or acquisitions of Yahoo! and RealNetworks, with Vivendi and Sony as the potentially interested parties, given their relative lack of presence in networks and branded content aggregation assets.

While content creators (e.g., film studios, record companies) and content aggregators (e.g., networks, cable channels) face similar challenges, they each face additional challenges unique to their position in the value chain. For content creators, a major challenge will be how to develop direct relationships with the end consumer, given that aggregators and intermediaries (e.g., bookstores, video stores, movie theaters—and their digital equivalents) will continue to play a role in offering a breadth of selection from content companies.

The additional challenge, as we have discussed, is that digital distribution for the first time divorces the content from the distribution channel, a pairing that content companies use today to generate most of their money (e.g., CDs sold as units in retail stores). Where content companies can establish those direct relationships, they should—although managing channel conflict will be an issue. Where they cannot, the key will be making sure that their content does not get divorced from the complementary revenue streams associated with that content.

In other words, instead of pushing units to their distribution partners and not receiving the end-user information, content companies need to start thinking about the packages of content they can assemble and then distribute. For example, music companies need to sell more than just a CD (or its digital equivalent) into the channel. With the core music file that gets distributed, a music company could also package-in links to its Web site, an interactive game, a chat session with the musicians, a concert-tracking and ticket-purchasing application, and various sweepstake and marketing offers, all of which enable the content company to capture end-user information and to pre-empt content distribution companies from capturing the value of complementary products and services.

For content aggregators, on the other hand, there is the opportunity to become an entertainment services provider, managing consumer profiles to deliver personalized content across the disparate closed-end distribution systems—i.e., to the device and through the channel specified by the consumer for that particular category of content. Given device proliferation, as well as the increasing number of services that consumers are expected to subscribe to, there is an opportunity for a company to aggregate those services for the end user, thereby utilizing superior personalization assets to bypass the existing advantage of closed-end distribution assets.

For existing content distributors (namely, cable and satellite companies), the consumer relationship, to a certain extent, is theirs to lose (although cable and satellite companies will continue to battle for market-share).

In the short term, content distribution companies will continue to consolidate their positions in closed-end systems through acquisitions as well as through the development of proprietary standards. In addition, these companies will acquire limited content in order to maintain a position of leverage over their content suppliers. DirecTV's growth was tied to its purchase of exclusive rights to sports programming, and one can envision a similar acquisition to initiate control over interactive media applications.

DirecTV or Echostar might buy a company such as Electronic Arts, given that games distribution will increasingly be through digital channels, and then develop proprietary gaming applications that encourage users to sign up with them. At some point, owning a few prized content assets will enable these companies, with their direct user relationships, to improve their position vis à vis standalone content providers.

In the longer term, the challenge for these companies will be to move from being passive deliverers of billing statements to active managers of their consumer relationships. Or, to put it another way, a satellite company such as DirecTV needs to think less about being a "satellite company" and more about being an "entertainment services provider," delivering content to consumers based on their unique insight into their consumers' preferences. This may actually mean managing the delivery of content over systems not necessarily owned by the company, such as delivery over wireless networks to cell phones or even IP networks to personal computers (PCs). As part of this transformation, these companies will need to invest in personalization technologies and platforms, with DirecTV's investment in TiVo being one example.

We may even see mergers between brick-and-mortar companies—companies that, despite being very much at risk from digital distribution technologies, possess very strong consumer databases —and their digital equivalents. Blockbuster's partnership with DirecTV to sell subscriptions is an example of the potential mutual benefits stemming from this type of relationship, though the real benefit to a company such as DirecTV might be in Blockbuster's infrastructure for managing consumer information and for marketing to consumers.

For new content distributors such as wireline and wireless telephone companies, there is the double challenge of penetrating the market owned by the existing distributors while simultaneously avoiding the commoditization of their infrastructures to common carrier status by content companies.

One of the biggest issues here is educating consumers that there are alternatives for them when it comes to content and media suppliers. The most probable strategy for these companies will be to pursue one or two specific content and media categories that lend themselves to these alternative distribution channels. While there is much talk about IP–delivered VOD services, they most likely comprise one of the categories that will not be delivered through IP in the near term. Games and music are the most likely categories for new content distributors to pursue.

Like their cable and satellite brethren, these companies may need to make a targeted content acquisition or partnership in order to drive interest in their services. Once consumers begin changing their behavior with regard to the consumption of entertainment, then these companies can start bundling in additional content categories.

The major advantage new content distributors will have over their competitors is the ability to build more flexible architectures than existing distributors' mass-market, broadcast infrastructures. So, while a full array of video programming may be difficult to assemble for these companies, they may be able to target the segments of customers that would prefer a lower monthly television bill because they only watch a very small and focused portion of the programming.

Like the content companies, new content distributors need to find ways to open up closed-end distribution systems. Open standards are one way of accomplishing this. It is our opinion that peer-to-peer technologies give new content distributors (as well as the content companies themselves) the ability to fundamentally alter the economics and dynamics of existing content distribution. And it is, potentially, the new content distributors (wireless and wireline companies) that can lend legitimacy to the peer-to-peer movement.

Owning the Consumer Relationship: Challenges for the 21st Century Content and Media Company

"Are you ready to surf, Lance?" (Lt. Colonel Bill Kilgore [Robert Duvall], Apocalypse Now*)*

While the possible futures are uncertain and while the ways in which companies plan for the future world of personalization will be different, what is certain is that content and media companies will need to develop competencies in personalization that cut across all aspects of their organization. As discussed earlier, personalization requires that companies undergo a complete reorientation and rethinking of the way they do business.

Distribution companies need to move from thinking of themselves as simply pipe companies sending bills to their customers and more as the managers of their individual subscribers' entertainment experiences. Content aggregators need to define, in very explicit terms, what their brand means to their audience, or the new networks will steal their audience. And content owners need to think less about selling products into the distribution channel and more about delivering cross-category experiences, both indirectly and directly, to the end consumer.

The transformation will be a wholesale one for many companies—in particular, for those that have very little interaction with the end consumer today—thus affecting all aspects of the organization. The following are the areas of consideration—and questions to ask—for companies looking to own the consumer relationship.

- ***Strategic Scope:*** The nature of scale will change as the third dimension of personalization is added to the competitive equation, as will the extent to which companies need to be vertically integrated to compete.
  - What assets are needed in order to compete along the personalization axis?
  - How many assets are still needed along the content and distribution axes to ensure adequate access to consumers and to information flows about their behavior?
  - At what point can physical assets be shed (i.e., at what point do physical assets have their highest potential value but lowest future value)?
- ***Customer Strategy:*** Competition will increasingly take place at the segment—even individual—level, and customer strategy will need to follow.
  - Which customer segments are most vulnerable to companies offering personalized services?
  - How are customer segments even defined in industries undergoing convergence (e.g., the digital living room)?
  - What offers should be made to those newly defined customer segments?
- ***Pricing Strategy:*** Many companies will move to dynamic, real-time pricing models based on specific consumer behavior in order to differentiate themselves.
  - At what level are pricing decisions now made (e.g., at the individual or segment level)?
  - How do you move to a dynamic pricing model, where pricing occurs in real time (or near real time)?
  - How do you get dynamic pricing accepted by consumers?
- ***Organizational Structure:*** Companies will need to migrate from product-based silos to flexible structures organized around the consumer.
  - What is the appropriate balance between centralized and decentralized control in companies competing to own the consumer?
  - How do compensation systems need to change in order to reward cross-selling and sharing of consumer information?
- ***Financial Systems:*** Companies will need to move from tracking individual properties/products in their financial systems to tracking individual consumers.
  - What is the lifetime value of a customer?
- ***Billing Systems:*** Companies whose billing is based on unit-based pricing will need to migrate to systems based more on usage- and subscription-based pricing. Companies whose billing is at the household level will need to consider billing at the individual level.
  - What part of billing (if any) can be outsourced, given this fundamental change?
- ***Customer Care:*** Companies trying to build direct consumer relationships will need to build supporting customer-care infrastructures that are integrated across the various customer contact points (Web, call-center, retail, etc.).
  - To what extent can the customer-care infrastructure be leveraged into sales and marketing functions?
- ***Technology Architecture and Other Systems:*** Companies will orient their systems around the individual. Database architectures that are not relational in nature will need to become so. Digital asset management systems need to be less about managing units and more about assembling packages.
  - What architecture protects the company's assets, ensures consumer privacy, and flexibly responds to technological change?
  - What does rights management mean when the Internet transcends traditional territory definitions?
  - What does digital asset management mean, as content companies move from products to packages?

The biggest challenge for companies will be making these wholesale changes as they continue to operate their businesses, especially because many of these new investments will grow at the expense of some of these companies' existing revenue streams. For example, maintaining the satisfaction levels of existing channel partners while pursuing direct consumer relationships will be a major challenge—and one that some companies will simply choose not to assume.

Internally, balancing the rewards for individual group performance against the rewards for an integrated end consumer focus will prove equally challenging. And, of course, if the rate of transformation exceeds the rate at which these new markets develop, then overall shareholder performance will decline.

Indeed, these are not trivial challenges. However, they are challenges that must be met to compete along this third dimension of personalization and to win in this new, digital era.

Are you ready to surf the personalization wave?

Notes

1. *A note on Amazon.com:* While it certainly could be argued that Amazon.com does not have the financial success to be used to support this point, we feel that the company's financial difficulties are less a function of a flawed personalization strategy than a function of an overly aggressive content strategy—i.e., offering too many categories, often in areas that have very different logistics and support costs from the core offerings. Staying focused on books, videos, music, and video games—which all contain similar distribution logistics—and then licensing the personalization engine to other retailers of other merchandise would have enabled Amazon.com to capture the advantages of the data it collected, without all the associated costs. From that base in content and media-related products, Amazon.com could have used its resources to move into video rentals, music-on-demand subscription services, and the like—all powered by its strong personalization capabilities—and ultimately shown better financial performance.

Summary of Strategic Trends in the U.S. Telecommunications Industry

Joseph S. Kraemer
Director
Law and Economics Consulting Group (LECG)

Introduction

Strategic Trends presents perspectives shared by a wide range of industry participants on what has occurred, is occurring, and, most importantly, can be expected to occur in the telecommunications industry. This paper has two objectives: (1) bring some degree of consensus out of the confusing strategic situation of late 2001 and (2) provide input to the strategic planning processes of companies struggling to survive the current downturn and then thrive during the recovery.

Strategic Trends constitutes a joint effort. More than 50 senior industry executives and providers of professional services (e.g., bankers, attorneys, consultants) contributed to the final version.

The method employed was a modified Delphi in which industry experts react to a hypothetical "future" with a mix of agreement, criticism, and alternative explanations and interpretations. Opinions were not attributable to individuals and represent personal views, not "official" corporate positions. Given that the participating experts have decision authority in their organizations, it is probable that they will act in accordance with their perceptions/beliefs, thereby creating the classic "self-fulfilling prophecy." Therefore, whether you as an individual agree or disagree with the consensus, you can expect that the strategic and tactical plans of participating industry stakeholders will reflect the consensus view of *Strategic Trends* or a close variation thereof.

Strategic Trends began as a late August 2001 e-mail brainstorming session among three consulting firms. Clients of those firms were then asked to comment. More and more input has occurred as versions of the document have been forwarded throughout the industry, posted on Web sites, and presented at industry forums.

Within two weeks of the tragedy, decision-makers began to react to the events of September 11, 2001, and its aftermath. Several issue areas in this version reflect post–September 11 abandonment/modification/reinforcement of previously held views. Such changes in perspective reflect both (1) the commercial consequences to telecommunications companies of "exogenous" economic/political/social events that originate outside the industry and (2) the fragility of the current economic outlook that is vulnerable to such unanticipated events.

The paper is organized as a series of issue areas. These issues are those that are most significant to the future of the industry in 2002 and beyond.

Recovery No Sooner Than 2003

In the <u>best case</u> scenario there will be no material recovery in the telecommunications industry until at least the summer of 2003.[1] The delay in recovery means that the slump will be longer and deeper than the late 2001 conventional wisdom.

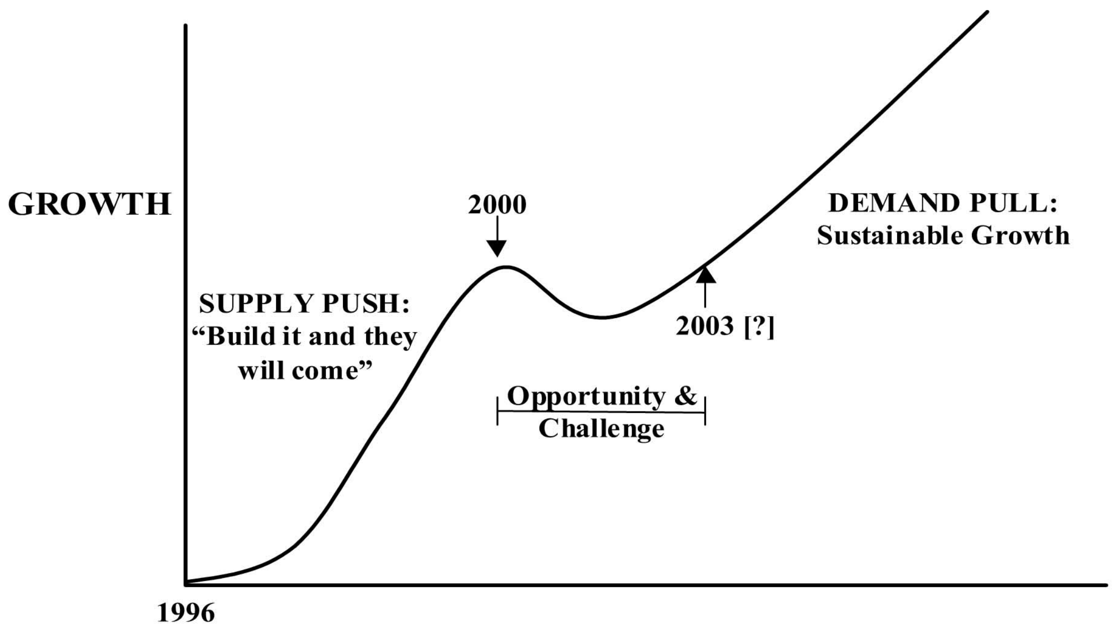
The telecommunications industry will *lag*, *not lead*, the recovery of the U.S. economy. The lag will be two to three quarters (i.e., for the industry to recover in mid-2003, the economy must experience a sustained recovery before the end of 2002). The period from now until the recovery will be one of "triage" during which dead and dying businesses will be identified and closed out so as to maximize the remaining opportunities for the survivors. The triage process began in late 2000 and will continue at least through 2002.

Aggressive and well-managed companies will recover sooner. These companies will take advantage of the industry situation to improve their competitive position through both internal growth and acquisitions. In effect, aggressive managers will out-hustle and out-maneuver weaker, less-well-managed competitors.

"Supply Push" dominated the 1996–2000 period, when aggregate network capacity came on-line far in excess of near-term demand. The next growth period (2003 [?] and beyond) will be characterized increasingly by "Demand Pull" as (1) customers sort out the applications that they require and the amounts that they will pay and as (2) younger and more "wired" generations (born 1970 and after) start households and increase their discretionary income. *The management challenge is to take maximum advantage of the opportunities present as the industry consolidates and retrenches* (see *Figure 1*).

FIGURE 1

Back-to-Back Growth Curves



The Future Consolidation of the Industry

The carrier segment of the telecommunications industry is consolidating with an eventual (circa 2004–2005) configuration similar to the airline industry—three or four majors, a few regionals, and some niche players. Accordingly, the distinction between "local" and "long distance" will disappear. Telephone service (including local and long distance) will be delivered by vertically integrated suppliers.

The total number of licensed wireline carriers in the United States will decrease by 75 percent between year-end 2000 and year-end 2003. In contrast to the chaos of the last 18 months, markets will stabilize. There will be many fewer carriers to offer price, product, or service competition. However, customers will have confidence that their carriers of choice will remain in business and deliver services in accordance with contracts (i.e., be viable in the long term).

The September 11 attacks reinforce the need for robust, interconnected networks that have a high probability of survival in the event of natural or man-made disaster. That argues for a consolidated base of carriers operating with agreed-upon disaster protocols.

Financially stressed carriers will have a debt load that is a burden. Therefore, acquisition of such a carrier (on an asset value basis) may be financially viable only after the carrier files for bankruptcy or restructures in a way so as to disadvantage existing debt and equity holders.

Consolidation will not be easy, particularly for smaller carriers. If one carrier acquires another, then the result is more customers on separate networks that may not be technically capable of integration at the physical and logical layers. In the short run, this works against achieving economies of scale. In most cases, the post-transaction period continues for 12 to 24 months. During that time, the risk is that the acquirer's management loses market focus and becomes distracted by organizational design and personnel issues.

Consolidation in North America will increase the pressure to create continental-sized carriers in Europe. Such European consolidations are more likely to receive European Commission (E.C.) regulatory approval subsequent to the creation of mega-carriers in North America.

Carriers will attempt diversification at the same time as consolidation. Carriers will stress investment and "strategic partnerships" outside their core businesses. They will continue to experiment with diversification into content and e-commerce applications. However, although some will be very successful, most will fail. Diversification is a high-risk strategy principally because the distinctive competencies associated with the content and e-commerce businesses are so different from the skill set that makes carriers successful.

The RBOCs as Survivors

Of all the participants across all of the segments in the industry, the regional Bell operating companies (RBOCs) are the most likely to survive and thrive. In fact, the most visible sign of the industry recovery will be an improvement in RBOC financial performance.

The RBOCs will dominate North America and most likely absorb *at least* the traditional long-distance businesses of AT&T, WorldCom, and Sprint. The local infrastructure developed over the last decade by AT&T and MCI would also be included.[2]

RBOC executives and other observers forecast that RBOC versus RBOC competition will accelerate and intensify as (1) industry consolidation takes place and as (2) the RBOCs transform themselves into national and global full-service providers. *This is a very controversial position with which non–RBOC commentators disagree*. Instead, the dissenters argue that there are no economic incentives for inter–RBOC competition. Therefore, these dissenters argue further that the RBOCs will structure their regions as "fortress hubs" and not compete in their core businesses or geographies (known as the "polite oligopoly" scenario).

In addition to inter–RBOC rivalry, the primary sources of competition for the RBOCs will be (1) surviving competitive local-exchange carriers (CLECs) operating as regional or niche service providers, (2) mobile wireless companies, and (3) cable multiple-system operators (MSOs) in residential and small-business markets. The RBOCs remain vulnerable to a video/Internet access/telephony service bundle sold by the MSOs.[3] However, a critical unknown is the extent to which the MSOs can and will finance and manage the deployment, marketing, sale, and provisioning of such a service bundle.[4]

The Evolution of the CLECs

The first phase of the CLEC era ended with a bang that is still reverberating through the capital markets. Lost in the noise of so many failures is the fact that a strong demand remains for an alternative local service provider to the incumbent LEC.[5] *Surviving CLECs will be predominately facilities-based[6] and serve small and medium-sized business customers. The survivors will function as regional or niche providers, not as "integrated communications providers" on a national basis.*

To be viable CLECs must (1) have access to operating capital, (2) achieve a minimum level of scale economics, (3) develop a high-loyalty/low-churn customer base, and (4) follow a very focused business plan. One viable CLEC model is an independent telephone company extending service into an adjacent RBOC's service area.

The first phase of the CLEC industry was characterized by (1) too much cheap capital, (2) very bad business plans, (3) poor management, (4) RBOC unpreparedness, and (5) inappropriate regulatory theories and actions. The most visible legacies of the first phase are bankruptcies, litigation, and the collapse of investor community confidence.[7] Regulatory/legislative intervention to "save the CLECs" (e.g., divide the RBOCs into separate wholesale and retail businesses) will distract management (of both the RBOCs and the CLECs), confuse investors, and, potentially, become a major cause of delay in overall industry recovery.

Suppliers (e.g., network equipment manufacturers and professional services firms) built unneeded capacity to serve the collapsing CLEC industry. The suppliers themselves must now, in turn, consolidate and shrink. Recovery for suppliers will *lag* recovery for carriers by one year or more (i.e., if carriers recover in mid-2003, suppliers will recover in mid-2004).

Broadband Progress

High-speed Internet access penetration of U.S. households may have almost doubled in 2001. However, final year-end data will show that high-speed Internet access adoption by residential and small-business customers fell below the original 2001 forecast.

The original industry consensus forecast was 11 million residential and small-business connections by year-end 2001.[8] Consensus estimates are between 9.0 and 10.0 million as of December 31, 2001. The expectation is that the growth for 2002 and 2003 will also be below industry expectations. The primary causes of the shortfall appear to be (1) price sensitivity under conditions of economic uncertainty and (2) a lack of ubiquitous digital subscriber line (DSL)–based solutions in urban and suburban areas.

Analysts distinguish "availability" from "take rate."[9] Cable and telephone companies in combination claim that high-speed access *is available* in urban and suburban areas and that the *take-rate shortfall* results from a lack of content and applications that appeal to consumers and small businesses. Conversely, companies in the content/applications businesses argue that high-speed access availability is either overstated or overpriced, or both.

The near-term demand for high-speed access will be driven by existing content and applications. Over the longer-term, new content and applications will be created as one of the results of the increased base of potential customers with high-speed access. *The synergistic effect is that of a "virtuous circle," with access and content/applications reinforcing each other in a positive direction.*

The pace of high-speed Internet access rollout is more than an esoteric discussion, because the conventional wisdom is that acceleration of high-speed access will affect the economy favorably. The stimulus will occur because of (1) the spending stimulus associated with the capital expenditures to build the networks and (2) the benefits of expanded business-to-consumer (B2C) electronic commerce. Beneficiaries of broadband include the local network companies (cable operators as well as LECs), along with a myriad of others including network equipment vendors, personal computer (PC) makers, chip manufacturers, software companies, and media companies such as America Online (AOL)–Time Warner. In addition, there are thousands of companies for which the Internet is a low-cost distribution channel. Secondary effects would be experienced by the suppliers to these companies.

Regulators and policy makers debate increasingly whether slow adoption is (1) a market failure that requires intervention, (2) typical at this point in time in the rollout of a potential mass-market service, or (3) a situation that requires a federal "industrial policy" regardless of whether or not the market has failed. The outcome of the debate will affect the nature and extent of government intervention.[10]

The current dispute as to whether RBOCs must unbundle newly constructed fiber networks for sale to competitors will slow down the near-term deployment of telephone network–based high-speed access capabilities. This will have two effects:

(1) Cable-based systems will become the method of choice for high-speed access.
(2) Deployment of fiber by the telephone companies to the neighborhood, curb, or home will be delayed materially.

In the event that terrorist activities force quarantine restrictions on personnel movements due to biological or chemical attack, dispersed work sites (including homes) with high-speed access will be required.

The Critical Nature of Video

The ultimate bandwidth-eating "killer application" will be video. Video applications will include the following:

(1) Entertainment video downloaded from the Internet as well as received over cable or satellite system
(2) Business video, including videoconferencing (potentially from nontraditional work sites such as homes) and corporate training (real-time class room and user-initiated downloads)
(3) Distance learning for formal education (K-12th grade, post secondary, and advanced) and personal improvement
(4) Web-based video content used for everything from selling automobiles to on-line classified advertising
(5) Video attachments to personal and corporate messages (including "instant messaging")
(6) Video telephony, which has a high approval rating from upscale demographic segments born after 1970

Video compression techniques will continue to improve, which will reduce transmission bandwidth for a given task. However, the net effect of compression techniques versus application growth will still require substantial low-cost bandwidth. Such bandwidth will come from "lighting" the unlit fiber-based systems now in excess supply. These fiber systems have been, or will be, sold to carriers that will buy and book them at a cost basis that will provide a positive return on investment (ROI).

The increasing prevalence of video-based content constitutes a technology and market-driven discontinuity that facilitates entry by nontraditional companies, such as AOL and Microsoft, into the communications business. In a video world, the traditional carriers are disadvantaged relative to new entrants. To the extent the embedded network infrastructure is not video-capable, then it becomes transformed from an asset to a liability.

Transport technologies will include wired and wireless systems, the latter being both terrestrial and satellite-based. Carriers such as incumbent local-exchange carriers (ILECs) that are not video-capable will operate at a competitive disadvantage.

Slower Than Expected Wireless Data

The U.S. adoption curve for wireless data services will be much slower than the experience with DoCoMo's wireless Internet service in Japan. The situation in the United States is complicated by extreme uncertainty as to the value and availability of wireless data spectrum.

Desirable spectrum is occupied currently by a combination of (1) television broadcasters, (2) federal government agencies (including the Department of Defense [DOD]), and (3) local school districts. All three present difficult technical and political issues that must be resolved prior to spectrum becoming available.[11]

Adoption and implementation of wireless data applications by businesses are accelerating. Business use of wireless data lacks the visibility it deserves due to media focus on consumer applications. However, over the long term, business data applications will be limited unless additional spectrum becomes available.

Wireless carriers must choose between alternative wireless data business models: (1) the *Traditional Model*, in which carriers provide an open platform and receive revenue primarily from traffic carried and some value added services (e.g., billing) or (2) the *Transactions Model*, in which carriers share in the revenue stream of content providers (i.e., the equivalent of an LEC sharing the revenue of Yahoo! or AOL on the wired network). The risk of the Traditional Model is that the revenue stream, gross margin, and earning before interest, taxes, depreciation, and amortization (EBITDA) may not generate a sufficiently robust ROI to justify the use of scarce capital. The risk of the Transactions Model is that carrier revenue demands and proprietary requirements will delay or stifle the development of the applications necessary to drive the wireless data business.

Wireless carriers may elect to share network facilities. This will reduce up-front capital requirements but restrict downstream competition to price (rather than technical features or coverage).

Network Construction Curtailed

The "surge era"[12] in carrier network construction has ended. The "network" in the United States (as completed or funded *and* under construction currently) is more than adequate to meet demand forecasts through the middle of this decade. The deployment of next-generation carrier network technology will be delayed until the existing surplus of current generation technology is absorbed.[13]

CAPEX will be curtailed back to approximate pre-1996 levels (on an inflation-adjusted basis). "Build it, and they will come" has gone.

The drop is most obvious in inter-city networks that are overbuilt. Construction will continue for intra-city fiber networks, but only for customer-specific builds with assured demand under signed contract.[14] The focus now will be on achieving the carrier's ROI that was contained in the business plans that justified the original network investment. (This may not be easy, since many of these business plans relied upon excessively optimistic scenarios and associated financial forecasts.)

There will be substantial emphasis during the 2003–2005 period on rolling out "home networks" that are essentially local-area networks (LANs) for upper-income households.[15] Such networks will be video-capable and are expected to increase demand for "last-mile" high-speed access service from cable and/or telephone companies.

Prices for transport and switching will continue to move toward the *cost* of the most efficient provider. Public policy will support this price movement despite the economic stress on many carriers with high embedded costs.

Extreme uncertainty exists currently as to baseline/equilibrium prices for telecommunications services. Short-term contracts tend to be the rule currently, since large buyers are avoiding long-term commitments. The short-term (next six to 12 months) combination of (1) excess supply and (2) repressed/tentative demand reinforces mid-2003 as the earliest recovery possible. Consequently, carriers will emphasize efficient, low-cost operations and scale economies that, in combination, will generate high margins and positive EBITDA.

Economics dictate migration onto a single packet network for voice, data, image, and video. In the long-term, maintaining two parallel networks—circuit-switched for voice and packet-switched for data—is excessively expensive.

Internet protocol (IP) telephony is more economical due to lower hardware/software costs and the greater efficiency of packet transmission. Combined capital and operating cost savings are estimated to be in the range of 30 percent to 50 percent. However, given the embedded network infrastructure, in the short run, many carriers plan to use Class-5 circuit switches for voice and to offload data to packet networks.

Large businesses will build packet-based extranets and intranets in which voice will be integrated and quality of service (QoS) assured. In addition, corporate users believe increasingly that packetized voice connections are more likely to survive disasters like September 11.

There is much less consensus on packetized voice for small and medium-sized businesses and residences. Some industry sources argue the following:

(1) Based on price advantage, small and medium-sized businesses will purchase packetized voice and Internet access over DSL as a less expensive alternative to purchasing multiple voice and data lines.

(2) Residential customers will buy a package of video, Internet access and packet voice services from a cable-television company. As a competitive response to cable, LECs will sell a comparable package.

The lack of consensus on small and medium-sized businesses and residential customers reflects the cost to migrate the embedded circuit-based network technology, the lack of agreement on QoS standards in public networks, and the absence of an RBOC champion for packetized voice.[16]

R&D Cutback Adverse in the Long Term

In order to conserve cash and survive, network-technology companies (in particular) and the industry (in general) decreased research and development (R&D) expenditures in 2001, will continue to do so in 2002, and may not increase such expenditures until 2003 or later. This will affect adversely the commercialization pipeline for new products and services during the 2003–2005 period (and potentially beyond). The cut back on R&D will affect disproportionately the future of small, independent technology companies that often combined seed money from established companies with other sources of capital.

Radical innovations that on average take 10 years between concept and market will be delayed or terminated prematurely. The full significance of this situation cannot be forecasted with precision, but its initial impact will occur in the last half of this decade.

The venture capital (VC) community's reluctance to fund the telecommunications-related technology sector reinforces the R&D shortfall effect. The VCs see (1) a declining demand for the technology and (2) no viable exit strategy once the capital is committed.[17]

Companies not involved currently in telecommunications directly (e.g., Microsoft) are *increasing* R&D expenditures. Such increases may provide competitive advantage in the event of entry.

To Regulate or Not To Regulate

The current situation could trigger a movement for more regulation, re-regulation, and/or legislative intervention. Such a movement will increase uncertainty and slow, if not stop, the industry's recovery process.

It is popular now for state and federal regulators to endorse "market-based solutions" in which regulators restrict their role to (1) ensuring a level playing field and (2) addressing areas where the market has failed. Given current market conditions, regulators have begun to identify "market failures" that potentially require some form of intervention. Examples of such alleged "failures" include the following

(1) A perceived "lack" of local competition as demonstrated by the financial failures of many CLECs
(2) The "low take rate" by small businesses and residences for "broadband" services
(3) "Underserved" rural and/or low income areas that do not have parity pricing and/or service availability with urban areas
(4) The apparent lack of spectrum for third-generation (3G) services
(5) The "excessively long" rollout of broadcast digital television

Regulators are not comfortable with the Schumpeterian concept that the current period is one of "creative destruction" in which the shakeout-consolidation process is natural and a prerequisite to moving the telecommunications industry from one growth cycle to another. In effect, the failure of many CLECs, structural consolidation, and "slow" adoption of "broadband" by consumers are interpreted by many regulators and legislators as the trigger for increased or re-regulation.[18]

The Global Perspective

Success in the United States constitutes a prerequisite for a foreign carrier to be considered "global" and therefore credible to home country and U.S. corporate customers. However, the potential for further foreign carrier investment in the United States remains highly unlikely in the 2002–2003 period.

Major foreign carriers remain unable to adjust to home-country competition and/or are crippled by the debt loads necessary to meet capital commitments (e.g., for 3G licenses and infrastructure construction). In addition, those that have tried U.S. entry strategies (e.g., BT) have made money on their stock purchases but failed to sustain presence in the U.S. market.

Experience to date shows that minority equity investments made in large U.S. carrier holding companies (e.g., DT in Sprint) do not meet the long-term business requirements of foreign carriers. A potentially more viable strategy consists of portfolio investments in market segments (e.g., wireless or information services) in which the investing carrier has experience and can achieve effective control (e.g., DT in VoiceStream).

"Global carriers" that focus on serving multinational companies can be expected, at a minimum, to provide telecommunications services between, among, and within the countries of "The Triad" (North America, Japan, and Europe). Carriers have attempted one of two global strategies: (1) "on-net" emphasizing end-to-end services using owned-and-operated facilities (e.g., WorldCom) or (2) a "partner" arrangement between or among two or more carriers (e.g., AT&T and BT in Concert).[19]

No carrier or carrier consortium can yet meet all the criteria for global service all of the time everywhere. However, some can meet many of the criteria most of the time somewhere. The critical differentiator is the ability of a carrier to provide price-competitive services *between, among, and within* the Triad countries. This may be accomplished by means of owned/leased facilities and/or the facilities of a partner and/or the facilities of a non-affiliated local carrier.[20]

Given the abundance of competition and the over-capacity of network facilities throughout the Triad, it may be that the real value-add is the identification and selection of local/regional providers and the aggregation of those providers into a network of networks to meet the requirements of specific customers. Consolidation of carriers in Europe and North America will facilitate the network of networks approach. Large business customers may move to self-provision rather than outsource under this model.

Managing for Success

The difference between corporate success and failure will come down to the ability of management to lead their enterprises through the downturn and position them for renewed growth. The telecommunications industry is critical to the U.S. economy and national productivity.[21] Therefore, after the current workout period, telecommunications will grow at least as fast as the overall economy if not faster.

The industry participants that contributed to *Strategic Trends* were asked to be descriptive not prescriptive. However, their comments often included clues and signals as to the strategies senior management would follow. The broad outline of these strategies is subsequently presented.

This is a period of triage in which the industry can be grouped into three tiers:

(1) *Tier I: Companies that are healthy fundamentally.* These should seize the opportunity to gain market-share and position themselves versus weakened competitors.

(2) *Tier II: Less-well-off companies that need to focus on survival and avoid risks.* For example, in the short run, a Tier II may focus regionally and forgo national expansion.

(3) *Tier III: The dead and the dying* that should sell out or fold up in such a way as to least injure their investors, employees, customers, and suppliers. To extend their lives at the cost of damaging the industry's reputation, wasting more capital, and providing an opportunity for re-regulation does the industry a disservice.

At the Tier I companies, management is leading along two dimensions: *the operational and the strategic*. In terms of *operational* matters, these companies emphasize back-to-basics. Core processes are being reviewed to ensure that the metrics are correct and standards are met (e.g., order-entry time, first-call customer problem resolution, mean time to repair [MTTR]). Personnel that cannot meet expectations are being terminated.

Tier I companies are moving to increase share while focusing on churn reduction and customer loyalty programs for the embedded customer base. A few are even seeking out customers that are experiencing short-turn recession-induced business effects to offer them extended payment terms and/or advantageous pricing in anticipation of a strong relationship in better times.

The Tier I companies are also renegotiating contracts and reviewing the number and performance of their sources of purchased goods and services. While not pushing suppliers to the wall, there are opportunities to drive costs out of the supply chain as well as lock down long-term supply relationships.

In the s*trategic* realm, this is the time to make *acquisitions* with asking prices low and going lower. Compared to 1999 and 2000, Tier I companies can acquire customers, assets, or new distribution channels at a fraction of the cost. However, acquisitions need to be planned carefully so as to truly add strategic value. The planning process needs to include post-acquisition implementation actions. Finally, given the over-capacity, poor management, and cash-flow problems in the industry, acquisitions must be selective and limited, or the process could easily destroy value and take management's attention away from the core business.

Tier I companies are leveraging their *internal competitive advantages* (e.g., scale economies to allow price reductions, access to capital to drive new technology deployment, increasing marketing to enhance brand and gain share when advertising prices are very low due to the recession). The key here is to use financial and commercial advantages to take advantage of temporary market aberrations and competitor distress.

After the Tier III companies and the weakest Tier II companies disappear, the industry will be better capitalized and more viable. Most importantly, after the shakeout, the telecommunications industry will be positioned to support a new era in wired and wireless communications. *The era will be all digital, increasingly video-focused, have intriguing new entrants (e.g., AOL and Microsoft), and be focused on anywhere, any-time connectivity supplied by a limited number of consolidated, well-financed major players.*

Notes

1. "Recovery" may be measured by such factors as increases in the rate of growth of revenue, operating income, cashflow, and capital expenditures (CAPEX) at the industry, segment, and/or company levels. Improved performance of industry stock indices will confirm a turnaround.
2. Local infrastructure in an acquiring RBOCs home region would be divested to meet antitrust requirements.
3. Market research shows a potential penetration level of up to 30 percent of urban households and 8 to 10 percent of businesses with 500 or fewer employees.
4. Preliminary comments by Comcast management at the announcement of the acquisition of AT&T Broadband indicate that the successor company will market and sell a video/Internet access/telephony service bundle aggressively.
5. While ILECs appear to have prevailed in voice-centric competition with the CLECs, they may have been victorious in the wrong war as (1) voice traffic migrates to wireless and (2) wireline competition becomes data-centric.
6. "Predominately facilities-based" includes the operating model in which a CLEC leases local-exchange carrier (LEC) unbundled loops on a long-term or short-term basis, depending on the economics of the transaction.
7. Distressed CLEC assets can be purchased for 20¢ or less for each dollar on the CLECs balance sheet.
8. Federal Communications Commission (FCC) statistics show 5.2 million "high-speed" connections (i.e., 200 kbps or better) at year-end 2000, of which 64 percent were cable modems, 31 percent ADSL, and 5 percent other. Based on these numbers, only 4 to 5 percent of U.S. households had high-speed connections at the end of 2000.
9. The official position of the FCC is that availability, not take rate, is the key measure.
10. The range of potential government interventions includes (1) tax subsidies for high-speed access providers and/or homeowners, (2) direct subsidies similar to the Universal Service Fund, (3) removal of restraints such as problems with digital rights management (DRM) and rights-of-way, and (4) government responsibility for construction and operation of networks especially in rural areas.
11. The September 11 attacks and the current war on terrorism make DOD spectrum untouchable in the near term. Potentially, some spectrum may become available through one or more of the following: (1) early migration by broadcasters out of channels 60–69, (2) agreement on the use of NextWave's spectrum, and/or (3) agreement on mobile use of multichannel multipoint distribution system (MMDS) spectrum.
12. The "surge era" refers to the excess of aggregate capital spending on network construction and retrofit that occurred during the 1996–2000 period over the baseline 1991–1995 period in the United States.
13. For example, carriers with embedded circuit -switched networks are disinclined to procure unproven softswitch technology when Class-5 switches have sold recently at less than twenty cents on the dollar.
14. As discussed previously, for small businesses and consumers, the growth rate for broadband access has begun to decline. That limits the pace of network investment in upgrading the local loop.
15. Such home networks may be wired or wireless, hopefully using one standard agreed to by participating companies so as to not confuse consumers with incompatible subsystems that cannot be interconnected. Home network applications include (1) security, (2) entertainment, (3) home automation, (4) PC networking, and (5) intra-home communications with outside-home connectivity.
16. In November 2001, the local Telecommunications Division of Sprint announced a contract with Nortel Networks to transform its network to a packet voice network. The Division has eight million customers across 18 states. This is the first move by an LEC to transform its embedded network to packet-based technology.
17. An initial public offering (IPO) or acquisition constitutes an acceptable exit strategy. Neither option appears realistic currently.
18. In the near term, carriers that trust the market more than the regulatory/legislative process will put relatively more personnel and resources into regulatory reform/neutralization than was the case in the 1996–2000 period.
19. Neither strategy has proven to be superior. The "on-net" approach is very capital intensive, while "partnering" requires constant management and refreshment of inter-company alliances.
20. To be price competitive when requiring facilities from a non-affiliated local carrier, a carrier must negotiate substantial inter-carrier price discounts (i.e., a wholesale rate based usually on minimum volume commitments).
21. In a speech to investment analysts (December 4, 2001), Sprint Chairman and Chief Executive Officer William Esrey commented that telecommunications "constitutes two percent of the $10 trillion U.S. economy" and that he expected telecommunications revenues to increase at a seven percent compound annual growth rate between 2001 and 2005.

Broadband—Hype and Reality

Balaji Kumar
Director, Advanced Network Services
EngineX Networks

Abstract

This paper provides a unique perspective on the state of the broadband industry and its service deployment. It gives a snapshot of the broadband promise made by industry participants and assesses the current state of that promise. In addition, this paper discusses some strategies on what it will take for companies to achieve the broadband promise. It also provides some insights, which should help all of the players in the food chain to benefit in terms of profiting from the broadband service deployment.

The Broadband Promise

It all started out with a simple "broadband" promise by the communications industry (service providers, equipment vendors, and others) to end users. The promise was to provide unlimited on-demand bandwidth, a choice of providers, cost-effective services (voice, data, and video) with high reliability and security at real broadband speeds. In the process, industry experts forecasted that broadband with converged services would generate billions of dollars in revenue. According to CIMI Corporation, worldwide network-based service providers are expected to gain incremental revenue streams totaling more than $600 billion during the next ten years. This revenue could translate into huge profits for the providers, while fostering the creation of an array of services benefiting end users. In this environment, end users will have the flexibility in communications, information access, and other services. This will definitely change the way people live and communicate.

To enable this promise, the industry has taken actions in multiple directions—technology, regulatory, and business financing—to accelerate the goal of achieving the broadband promise.

The Broadband Reality

However, the seemingly simple broadband promise has become a nightmare for the communications industry—service providers, equipment vendors, investors, and users alike. There is no question that there is a huge demand for broadband. In fact, according to Cahners In-stat (see *Figure 1*), broadband access (a primary indication of broadband demand) is expected to penetrate 32 million households (30 percent of U.S. households) by 2004.

Many believe that broadband has arrived because there is a huge demand. However, the underlying reality paints a very different scenario.

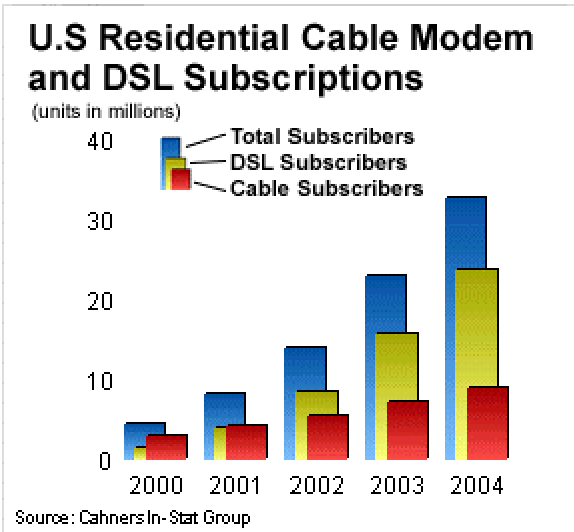
The whole industry is collapsing due to the cumulative effect of competitors failing to deliver the technology or service as committed and the inability to meet regulatory mandates and access requirements, which are together compounded by the Internet's current state-of-technology. This has stunted the growth of business models that profit from broadband delivery. The problem that hinders the growth of broadband falls into five categories:

1. Business Model
2. Technology
3. People
4. Finance
5. Services

Business Model
A sound business model is the basis for any business—there is no exception granted to broadband. This means a model with which a business can sell products or services that customers are willing to pay for and, in the process, generate revenue and be profitable over time. The service-provider industry, which is pursuing the broadband opportunity, consists of the incumbent local-exchange carriers (ILECs)—carriers that spun-off from AT&T since divesture in 1984—and new entrants leveraging existing and new technology for more efficient service delivery. The business mindset and the requirement for these segments are completely different. The incumbents think long term for return on investment (ROI) because they are not in a hurry to fill customer needs or demand. Their mindset is that "the user will buy it when we build it." New entrants, on the other hand, have a short ROI mindset, usually driven by the time frame and expectations of their investors. The new entrants that raise capital from the public have to show that they are different from others and use technology as an excuse to differentiate their value proposition—at least they did so when market valuations were reaching new heights daily. Examples of such companies are Teligent, Winstar, Covad, Rhythms, and Northpoint. Because these players used technology as the pitch, it forced the equipment vendors to pitch product and services that providers were demanding. The reality was that these technologies—which were the basis for the companies' business models and very reason for being—were either premature or incomplete, or did not fit into the

FIGURE 1

Broadband Subscription



providers' service offerings to their customers. In addition, the costs to develop these technologies far exceeded the revenue they could generate for the providers.

Thus, the industry began with a model that was built on technology that had not been validated in terms of user needs or applicability of the technology to the pressing business needs of service providers. But, the industry's hype and buzz about broadband in the heady, gold-rush era (pre-bust) meant that the fundamentals with respect to building a business were ignored.

Technology

Technology was actually the driving force behind the broadband promise. It brought down the barriers with respect to cost, speed, and time to market and allowed more competition to the industry. With the prospect that the communications industry could radically change everything about broadband delivery, many companies joined the cause.

However, too much of anything is always a sign of disaster. There is more technology available in the communication industry than anyone can handle. There is asymmetric digital subscriber line (ADSL), high–bit rate DSL (HDSL), very-high–data rate DSL (VDSL), G.shdsl, local multipoint distribution system (LMDS), multichannel multipoint distribution system (MMDS), wireless application protocol (WAP), asynchronous transfer mode (ATM), and Internet protocol (IP), to name a few. In a majority of cases, these technologies compete against one another without any unique value from the end user's point of view.

In addition, those with financial incentives in the industry—bankers, media, and instant experts—hyped the technology beyond its capabilities. Anyone who visited a trade show and could spell one of the alphabet soups was considered an expert. When this kind of expert controls the capital or influences people who control the capital, the chain reaction becomes uncontrollable. One technology would be anointed, and that year all the investment would follow into the sector that develops that technology or to the provider that provides the services using that technology. The most recent trend in 2000 was the broadband wireless MMDS. This is the last of the broadband technology, which has its limitations as any other previous broadband technologies, such as DSL, cable, and LMDS. It was expected to solve all of the previous problems and achieve the broadband promise. What the innocent fails to understand is that wireless technology is one piece of the puzzle in delivering the service to the user, and it is in no way a "be-all, end-all" solution.

People (Management)

It does not matter how credible the business model or how high the market demand is for the service/product or the technology. It is the experience and credibility of the people behind it that makes the difference.

The industry had promised users what they could deliver based on the hype, and the users did not have the skill set or understanding to differentiate reality from hype. The challenge now faced by management is a combination of traditional thinking with a new business model (aggressive unproven model) or developing a new technology, or simply the raft of start-up environment challenges. In addition, difficulty in hiring regulatory and financial people with limited knowledge of technology (or the telecom industry) further complicates the situation. The bottom line is that many management teams are not capable of understanding the end-to-end issues pertinent to successfully executing something so complex, especially when there is no precedent.

Today, the road is littered with numerous examples of what not to do. What is less prevalent are examples of companies with a track record for doing it right. There is no best practice to follow. In addition, human nature is to learn from mistakes and not to avoid problems beforehand by logic.

Therefore, the challenges with respect to people capable of delivering the broadband promise are far from resolved.

Finance

Because the broadband technology is new to the industry (less than 15 years) and the communications business is a capital-intensive one, the new players require huge amounts of capital to build either a product or a network to provide uniform service to end users. It also requires the time to develop the product/service and a competent team to deliver the vision, as well as patience to monitor the progress using valid benchmarks to measure progress.

The financial community does not understand the broadband environment and expects the project to be completed in half the time with half of the cost. The folly of this unrealistic set of expectations is painfully clear in the case of the demise of the telecom sector. Broadband Office, Covad, Rhythms, Northpoint, Teligent, and numerous satellite-based companies raised millions, if not billions, of dollars with business models that depended on unproven technology. In addition to this, the industry was developing products without any understanding of customer needs or addressing the issue of affordability. Thus, the industry spent millions without having any tangible return to investors. The inevitable bubble bust surprised the experts tracking the sector—but they really should not have been surprised if they had applied critical thinking in their company/industry analysis.

Services
One of the biggest promises of broadband was to deliver a wide variety of services—such as voice, data, and video—at high-speeds and at a fraction of the cost compared to the existing solution.

The reality is that the services were provided using unbundled network elements (UNEs) whose total cost of providing the service exceeded the price charged for the services. The high cost was incurred due to the services being delivered using a "stove-pipe model" (i.e., a vertical integrated system and process to cater to a specific service offering, as in the case of today's telephone service). This forced the providers to provide either a limited set of services or unmanaged services for which the users were not willing to pay any premiums, which would have helped the providers cover the cost of the infrastructure build-out.

Moreover, competitive pressure and regulatory complexities have made the service offering an expensive solution such that only companies with high capital and a larger customer base could survive and keep providing service at low or no margin.

Figure 2 shows a typical broadband environment for a service offering. Here, the majority of the broadband (services such as voice, on-demand high-speed access to information) is delivered using a variety of access technologies such as DSL and T1 with dedicated links via ATM/IP to the appropriate backbone provider with no bandwidth guarantee or security or quality of service (QoS).

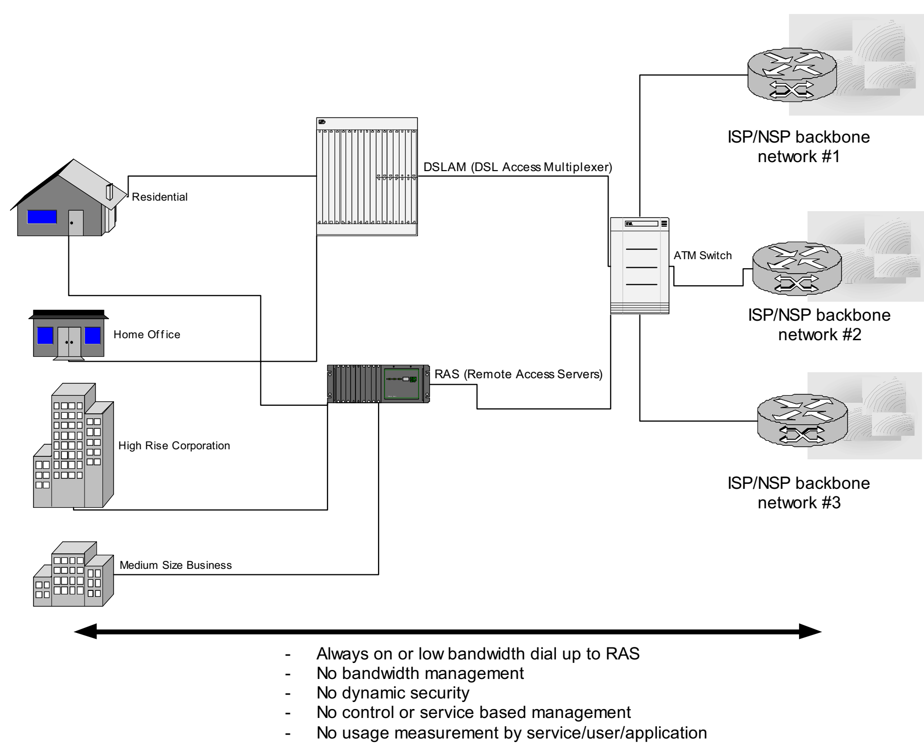
The customer who subscribes to network services gets Layer-2/Layer-3 transport service from point A to point B. The customer pays the provider a flat fee for the use of this transport to access anything. (The customer pays irrespective of the use of the transport.)

Thus, the provider gets a flat fee irrespective of the bandwidth used by the customer. The provider is in no position to leverage the unused capacity to generate additional revenue. This is because the provider does not control the bandwidth use or sell service-level agreements (SLAs). The providers do provide SLA–based services today by offering dedicated private lines or by charging based on the content, service, or application used or accessed on a demand basis.

Because of the various network configurations and technologies used, providers are unable to provide advanced services. One of the reasons for the voice network being very successful is that the provider has complete control of the services delivered over the network and is thus able to charge or give away services from time to time based on

FIGURE 2

Today's Broadband Environment



demand and usage. This enables value-added services, such as caller ID, fax, and dial-up options, to be charged for at a reasonable cost while being profitable to the provider.

Target Environment for Fulfilling the Broadband Promise

The previous section discussed the current reality of the broadband environment, where there are numerous challenges in achieving the promise envisioned. Even though it is not an impossible task, companies are still a long way from achieving it.

In this section, we will discuss the same categories mentioned earlier with the appropriate strategies that can be pursued in order to fulfill the broadband promise.

Business Model

Irrespective of the type of business, there are certain expectations by the investors with respect to ROI. The private investors, who invest in the new players, have a very high expectation with respect to short-duration ROI. In the quest for capital, new players responded by building business models that met the investors' unrealistic expectations. This, in recent years, has ended in disaster. A typical rule of thumb for a broadband service-provider business model focused on convergent services is payback within five years with at least 5 percent penetration or take-rate for a given serving area, assuming that there is sufficient automation from day one to keep the cost down. If the business model deviates from this rule of thumb, it would be wise to validate the assumptions and capability of the team in executing the model. For instance, service providers that plan to provide the services need to validate these services with the currently used technology (mature technology is low risk), alternatives for providing the same services, take-rate assumptions, coverage, customer willingness to pay for the service, etc. It is necessary for these parameters to be validated with sufficient scrutiny. This litmus test should indicate that a model is built to withstand even the worst times.

Technology

One of the primary challenges faced by the industry is building a business model around a technology. For instance, Teligent and Winstar were classified as broadband wireless, whereas Covad, Northpoint, Rhythms were classified as DSL players, even though they were targeting the same business and service offering. The obvious reason was that the investment community was dazzled by the technology promises without any basic business sense.

The basic recommendation is that the business should not be driven by technology. Instead, the business should be market-driven based on customer needs and requirements and not based on the promises made by technology capabilities. Thus, the service offering should meet customer needs such as price, QoS, better customer services, and wide range of service set. Technology should be an enabler for these service offerings.

In addition, in the case of unproven technology in the field, the first rule of thumb is to avoid it. If one is willing to take the risk, then the technology should be validated in various controlled environments before being rolled out to the customer. Part of the validation should be an end-to-end fit of the technology as a solution in the provider environment along with other existing systems. This enables the provider to see the real cost savings and benefit for the company and its customers. One such general focus should be automation, which reduces the manual intervention as much as possible.

Nevertheless, this is more easily said than done. Due to the pressure from investors and the promises made by the management team, new players in the industry have tried to short cut these efforts, with predictably dismal results. Only the large incumbent players with built-in support could sustain such inefficiencies.

People

This is the most complex area to address and is the one that makes or breaks a company's ability to execute on its vision to provide broadband successfully. It is management's challenge to build a team with the right abilities and attitude to execute the vision. The basic objective of any team should be defined clearly so that everyone on board has realistic business goals that can be achieved or executed. If the business goals are based on promises that are not realistic, then the team will be demoralized or try to cut corners to meet the objective.

It is necessary to have a team that is level headed and experienced, with a proven track record for thinking out of the box, using some logic, and setting realistic goals and expectations.

Finance

One fundamental rule to impress upon investors interested in the broadband arena is that there is no quick return on their investment. Long-term commitment is needed for emerging technology. The focus should be on solutions, and the role of technology should be as an enabler with respect to the automation of end-to-end service delivery with respect to systems and processes. Equally important, the investor should invest in a credible team to execute the vision.

Services

As mentioned earlier, the services should be driven by the market demand and to meet customer needs. Some of the basic customer needs are low cost, ability to track and measure services; and multiple services (voice, data, video) using a common infrastructure.

Figure 3 shows a target broadband network environment that meets the basic customer requirement with respect to the flexible, cost-effective delivery of services such as voice, data, and video. In this environment, the customer negotiates dynamically with the provider regarding requirements, such as services (voice, data or video); expected bandwidth; and expected QoS. In this architecture, the provider will connect to a service switch in the network and negotiate the network parameters, and provide the necessary access to information or services that the customer needs. This architecture also enables a provider to track and measure the services being offered. This will enable the provider to charge or bill appropriately for the various services delivered to the end user. This architecture is very similar to the voice (narrowband) network but much more complex.

Summary

This paper has examined the state of the broadband industry and its service deployment compared to the promise of broadband. The broadband promise was to provide unlimited on-demand bandwidth, choice of providers, and cost-effective services (voice, data, and video) with high reliability at real broadband speeds. In the process, the industry would generate billions of dollars of revenue with converged services.

What started as a simple promise has become a nightmare for the communication industry—service providers, equipment vendors, investors, and end users. The challenges range from developing appropriate business models, building reasonable assumptions about the nature of the technology solution, the need to hire experienced and talented people, setting reasonable and measurable goals that can be articulated to the investors funding the companies, and, last but not the least, the services offered. Failure to meet these challenges has brought broadband to its current reality.

In general, there are no best practices to follow at present, but there are some high-level litmus tests that can be done vis à vis the business model, technology used, staffing, investor objectives, and services offered. Some are generic; others are specific to broadband environment. Any amount of progress in these areas will help the industry to progress toward its promise.

The Business Case for Moving Voice and Data Concentration to the Edge

John Maddison
Director, Product Marketing
VINA Technologies

Carriers have long known how to capture revenue by deploying voice and data services in metro access networks. But to do so profitably remains a formidable and perhaps even growing challenge. As recent revelations of red ink and shrinking margins make painfully clear, providers have especially struggled to make money when they extended bundled services to small and medium-sized businesses (SMBs)—a vast and underserved market. Earnings have often eluded the sector's participants because they lacked the technology to optimize their existing infrastructures and to connect customers affordably.

To maximize the productivity of their networks and to control the cost of adding new accounts, years ago carriers adopted the tactic of concentrating their voice and data. The first type of concentration relied on digital loop carriers (DLCs), while the second took advantage of digital access and cross-connect systems (DACSs). Most of the companies aimed to concentrate their voice by 4:1 and their data by 3:1. Both ratios reflected the statistically proven theory that only a fourth of the voice subscribers and just a third of the data subscribers need access to a network at the same time. Meanwhile, a different kind of concentration was going on in central offices (COs), where carriers were increasingly clustering their DLCs and DACSs. With the instruments of their voice and data concentration confined to a relatively few large sites, the providers hoped to shrink their spending for capital equipment and thus aid their bottom lines.

But a funny thing happened on the way to profitability. The emphasis on centralization never produced its expected savings. In fact, the cost of connecting customers to networks steadily rose. To make matters worse, the increase coincided with an explosion in demand for bandwidth and with a resulting growth in required capacity per connection.

What went wrong? For one thing, the decision to make COs the focus for concentrating services unwittingly compounded carriers' requirements for T3 or larger trunks, each often leasing for at least four figures per month. Then, too, the attempted solution never adequately accounted for the proliferation of the DACSs and DLCs that proved necessary to support the providers' CO–based Class-5 switches and high-capacity routers. Moreover, despite concerted efforts to centralize the concentration of voice and data, some of the DACSs and DLCs wound up in co-locations or local serving offices anyways. To the extent that they did so, the devices hurt incumbent vendors by aggravating their shortage of unused racks and hampered competitive providers by inflating both their capital and recurring spending, including their fees for leased space. From both an operational and a capital perspective, therefore, the original paradigm for concentrating broadband communications backfired. Since then, the cost of connecting customers to metro access networks has continually climbed without showing any sign of ending.

Growing financial pressures are increasingly prompting carriers to consider alternative approaches for bringing new end users on-line. One proposed solution that shows particular promise consists partly of transplanting time division multiplexing (TDM) DACSs, GR303 DLCs, and frame-relay switches from COs to co-locations and thus placing the products as closely as possible to customer premises. The proposal further involves combining the devices under one cover or even on the same card to form a new kind of system that for the first time concentrates voice and data simultaneously. Some industry analysts have recently taken to referring to the invention as an integrated multiservice access platform (IMAP).

In different respects, both parts of the contemplated innovation hold the potential to help carriers substantially decrease their spending and improve their earnings. Transferring DACSs, DLCs, and frame-relay switches—and therefore the concentration of voice and data—to the edge of metro access networks would reduce operational expenses by optimizing backhaul capacity and lowering demands for T3 or bigger trunks. At the same time, integrating all three hardware modules to produce an IMAP would slash capital spending by replacing them with one multifunctional unit that precludes their purchase as discrete footprints. The integration of formerly separate boxes would also bring the additional benefit of saving room in racks and minimizing monthly bills to lease space in co-locations.

In short, the combination of extensive integration and decentralized concentration promises dramatically diminished capital and operating expenditures and greatly expanded opportunities for profitably adding customers to carriers' networks. Confirmation of the breakthrough comes from early adopters of newly introduced IMAPs, as the rest of this white paper shows. The following three brief case histories present a compelling business case for repositioning the concentration of telecommunications traffic from COs to a multifunctional platform at the network's edge. As the report additionally illustrates, the emerging model's overwhelming benefits apply to competitive and incumbent vendors alike and to both voice and data services.

Example #1: A Newcomer Saves Big by Concentrating Its Voice

At one large competitive carrier, IMAPs cut capital and operational spending over two years by more than $31 million.

Delivering voice and data services in 32 geographic markets, the carrier serves SMBs that average 10 lines for phones and six for connection to the Internet. Integrated access devices (IADs) in each of the end customers' premises converge the parallel telecommunications signals onto a single T1 link that leads to one of the company's 750 co-locations. Before acquiring its IMAP, the carrier equipped every co-location with three M13 multiplexers, each accepting up to 28 incoming T1s and aggregating them to a T3 trunk. Otherwise, the company centralized its telecommunications gear as much as possible in the hope of squeezing costs through economies of scale. Toward that end, each of the provider's COs housed a DACS that steered the T3's voice traffic over 28 T1s to a coresident Class-5 switch and the data across 18 T1s to a coexisting router. The Class-5 switch and the router then respectively forwarded their transmissions to the public switched telephone network (PSTN) and to a frame-relay network.

Under the pre–IMAP regime, limitations in the M13s' capacity forced their owner to install a new multiplexer after every 28th customer. The resulting proliferation of M13s in the company's co-locations inflated expenditures for capital hardware. Worse still, each additional multiplexer also raised the carrier's recurring costs by necessitating another T3 backhaul connection, leasing for $2,500 per month.

To restrain its expenses, the company replaced its existing DACSs and M13s with IMAPs in all its co-locations and configured each platform so that 68 of its 96 T1 ports serve customers. The remaining 28 ports act as backhaul connections. Because such a configuration allows for nearly 2.5 times more customer-facing broadband links than an M13, the carrier can now do away with all three of the multiplexers that previously operated in each of its co-locations. At $3,000 each, the three eliminated M13s mean a reduction of $9,000 per co-location in outlays of capital equipment and a saving of $6.8 million across the company's entire network of 750 sites.

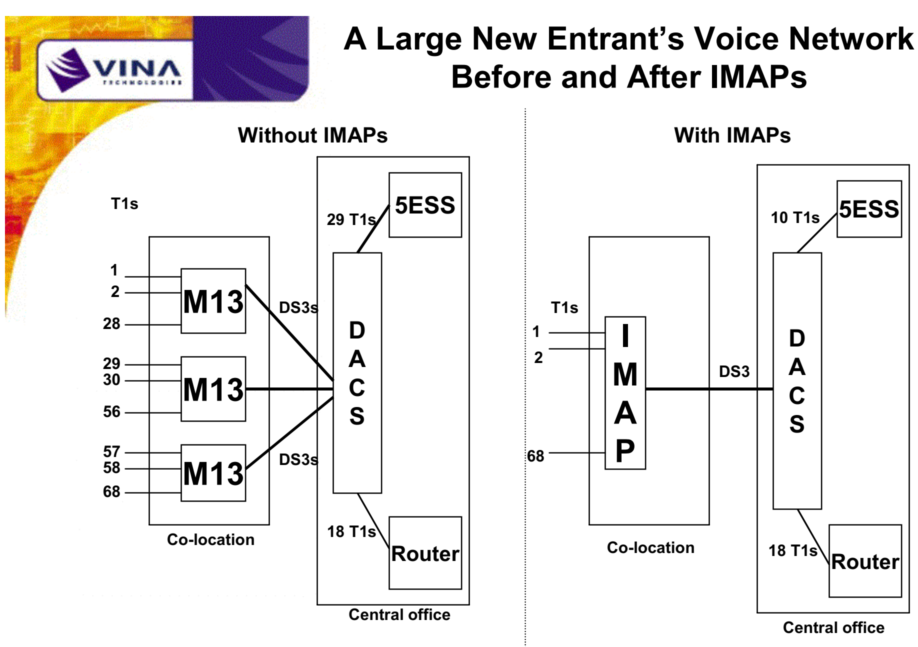
By relying on the IMAP's ability to concentrate voice signals, the carrier similarly lowers its requirements for backhaul trunks from three T3s per co-location to just one. The removal of two links, each leasing for $2,500 monthly, at all 750 co-locations whittles the provider's backhaul costs by nearly $1.9 million per month or $45 million over two years.

For every eliminated T3, the company also conserves a port in its CO–based DACSs. So two retired backhaul trunks at each of the 750 co-locations translates to 1,500 saved DACS ports at $1,000 per unit, and thus further decreases the carrier's capital spending by $1.5 million.

An additional six-figure drop in capital expenditures results from the IMAP's ability to optimize the usage of ports in the

FIGURE 1

An IMAP Simplifies a Start-Up Carrier's Network and Cuts Its Costs



service provider's Class-5 switches. Using the GR303 protocol, the platform concentrates the carrier's voice traffic by threefold and thereby enables it to trim the number of T1s between the switches and their supporting DACS from 28 to 10. The conservation of 18 T1 connections, equivalent to 440 digital signal (DS)–0 ports in Class-5 switches at $100 per port, saves the provider an extra $44,000 at each of its COs and $1.4 million for all 32 of them.

The decline in outlays for switches brings the company's gross drop in payments for capital and recurring expense items to $52.4 million over two years. Included in the total are savings of $1.5 million for DACS ports, $45 million for leased backhaul lines, and $4.5 million for M13s. After accounting for the IMAPs' aggregate cost of roughly $23.3 million, the provider observed a two-year net decline in spending of $31.4 million. By allowing the carrier to slash its installed T3 trunks, Class-5 switches, and DACS ports, the platforms also triple the useful life of the company's voice network.

Example #2: Carrier Saves in Converged Voice and Data Networks

Roughly 20 percent of the services that a small northeastern competitive carrier delivers to 208 SMBs consist of voice alone; the remaining 80 percent combine telephony with data. The customers average 10 lines for voice plus six for access to the Internet and converge their traffic with the help of an IAD onto a single T1 connection.

Either way, before the provider switched to IMAPs, each of the resulting 208 T1s went to one of the provider's 30 co-locations, where a DACS accepted the traffic and directed its voice component to a nearby DLC and its data to a frame-relay switch. After being concentrated four to one by the DLC, the voice transmissions proceeded to as many as three co-resident M13 multiplexers that aggregated the incoming T1s to T3s. The data, meanwhile, passed through the frame-relay switch without benefit of concentration and, like the voice, continued to the M13s. From there, both kinds of signals emerged from the co-locations and traveled over three backhaul trunks to a CO, where a Class-5 switch routed the voice to a PSTN. At the same time, the data moved first through the CO's core router, then to a frame-relay network.

Because of its past absence of a cost-effective means for concentrating data, the carrier found itself forced to maintain more extensive backhaul connections than it deemed optimal. In fact, to support its 208 incoming links from SMBs, the provider needed three backhaul T3s, collectively equivalent to 22 T1s for the concentrated voice and 42 for data, at each of its co-locations. Leasing monthly for a unit charge of $1,800, the links cost the carrier more than $1.94 million per year in recurring fees across its entire network.

Another source of unacceptably high operational expenses involved the company's monthly payments for leased space in its co-locations. To accommodate its broad assortment of single-purpose devices—such as DACSs, DLCs, and data switches—the carrier had to pay for two seven-foot racks per co-locations. Each rack leased for $800 per month to produce an annual network-wide bill of $570,600 for all 30 sites.

For most carriers, heavy spending for leased space in co-locations usually implies large outlays for capital equipment, and the subject of this case history proved to be no exception to the rule. To support its existing base of customers, the provider needed to equip each of its co-locations with four DACSs and DLCs and with enough ports in frame-relay switches for 998 DS–0s. The DACSs and DLCs averaged $36,720 in price, while the switches went for $23 per DS–0, equivalent to nearly $23,000 for every co-location. Moreover, the carrier required a minimum of three M13s at $3,500 per unit in each co-location to serve its end users' needs. The necessary number of multiplexers reflected their limited capacity of just 28 T1 connections per unit.

Concerned that its legacy infrastructure and associated overhead were fast spiraling out of control, the carrier started in early 2001 to consider a fundamentally new strategy for deploying converged services in metro access networks. The rethinking ultimately led the company to reconnect its customers' 208 in-bound T1s to IMAPs in each of its co-locations. Installation of the platforms signaled at least

FIGURE 2

Summary of an IMAP's Benefits for a Start-Up Carrier's Voice Network

A New Entrant Cuts Its Capital and Operational Costs by Using IMAPs for Voice

Asset	Saved Units	Unit Price	Sites	$ Savings
M13s	3	$3,000	750 co-los	$6,800,000
DACS ports	2	$1,000	750 co-los	$1,500,000
DS–0 ports	440	$100	32 markets	$1,408,000
All cap. equip.				$9,708,000
T3 trunks	1	$2,500/month x 24	750 co-los	$45,000,000
Gross CAPEX/OPEX				$54,708,000
IMAPs				–$23,250,000
Net CAPEX/OPEX				$31,458,000

two major advances in the provider's network infrastructure. First, the IMAPs' integrated DACSs and DLCs made their discrete counterparts in the company's existing leased space functionally redundant, thereby prompting their replacement. Second, the IMAPs corrected a previous glaring weakness in the carrier's technology—the omission of data concentration. Thanks to the platform's built-in frame-relay switches, the provider gained the newfound ability to concentrate its data by a factor of three.

In the wake of recent improvements, the carrier's network-bound transmissions now take the following revised path: After accepting traffic from SMBs, each of the IMAP's service modules processes voice and data respectively in its integrated GR303 DLC and frame-relay switch. While GR303 replicates the fourfold voice concentration that the provider practiced before, the switch concentrates its data 3:1. Both components of the solution then forward their respective loads to T3s that connect the co-locations to a CO.

By expanding the carrier's existing concentration of voice to include data, the IMAP shaves from 64 to 40 each co-location's required number of leased backhaul T1s for both services. This expansion also reduces the need for T3s from three to two. Of the 40 current T1s, only 16 correspond to data, a form of traffic that formerly demanded 42. The retirement of one T3 at each of the provider's co-locations translates to a monthly slice in recurring expenses of $1,800 per site and to a network-wide decline of $640,800 each year. Threefold concentration of data also lowers the company's requirements for ports in data switches from 998 DS–0s to 371 per co-location. At $23 per DS–0 in 30 facilities, the difference yields a total additional savings of more than $430,000.

Even more dramatic than the IMAP's impact on operational spending is its lowering of the carrier's capital outlays and the resulting conservation of the company's precious cash. Because of its multifunctionality, the platform frees the carrier from having to pay a unit price of $36,720 for the four DACSs and DLCs that reside in each of its 30 co-locations. The ensuing decrease in payments for hardware, therefore, totals $146,880 per co-location and more than $4.4 million across the company's full network.

A sharp cutback in the use of data switch ports plus the wholesale retirement of discrete DACSs, DLCs, and multiplexers diminishes the need for leased space in co-locations. In fact, since taking delivery of its IMAPs, the carrier has halved its monthly fees for rented real estate from $1,600 to $800 as its consumption of seven-foot racks has shrunk from two per site to one.

Spread over a whole year, the projected drop in expenditures will total $936,000 for operational items and $5,154,030 for capital hardware. In comparison to previous levels of spending, the two sums respectively save the carrier 61 percent and 31 percent.

Example #3: A Carrier Shrinks Its Capital Cost without Concentration

As the two preceding case histories attest, much of an IMAP's value rests on the product's potential to concentrate voice and data or just voice alone. But even carriers that shun concentration can still benefit mightily from the platform's multifunctionality and the resulting ability to dispense with duplicate hardware and minimize capital procurements. A striking case in point involves a large

FIGURE 3

How an IMAP Transformed a Voice and Data Network

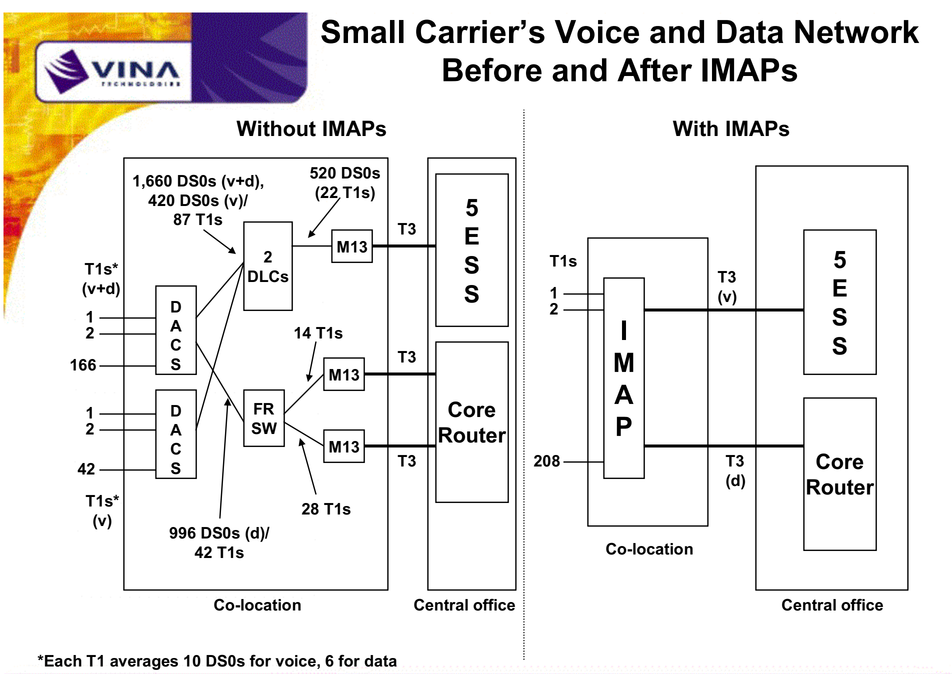


FIGURE 4

Summary of an IMAP's Value Proposition in a Voice and Data Network

A Small Carrier Cuts Its CAPEX and POEX by Using IMAPs for Voice and Data				
Asset	**Saved Units**	**Unit Price**	**Co-locations**	**$ Savings**
M13s	3	$3,500	30	$315,000
DACSs/DLCs	4	$36,720	30	$4,406,400
FR switch ports	627 DS–0s	$23/DS–0	30	$432,630
All cap. equip.				$5,154,030
T3 trunks	1	$1,800/month x 12	30	$648,000
Co-lo racks	1	$800/month x 12	30	$288,000
All OPEX				$936,000
Gross CAPEX/OPEX				$6,090,030
IMAPs				–$3,300,000
Net CAPEX/OPEX				$2,790,030

midwestern provider that differs from both of the earlier subjects in qualifying as an incumbent vendor and in declining to concentrate its traffic. Like its two competitive counterparts, the incumbent had grown increasingly disgruntled with the costliness of its existing model for deploying services and had recognized the need for fundamental change.

In one state with 25 metro markets, each typically comprising 288 SMBs, the carrier delivers a combination of services that demand an average of 12 lines per customer, eight for voice and four for data. An IAD in every served site integrates parallel lines onto one T1 connection that ends in the provider's local serving office. Because every end user corresponds to a different broadband link, the number of arriving T1s totals 288.

Prior to the carrier's purchase of IMAPs, all of the incoming T1 lines connected through a channelized service to 336 channel banks in each of the 25 metro locations. The number of installed channel banks reflected the need to maintain one for each SMB and another 48 to support the average requirement of four data-oriented DS–0s per customer. After reaching the channel banks, the voice and data signals diverged—the former heading to a Class-5 switch for transfer to the PSTN and the latter bound for a DACS en route to the carrier's data network. Half of the fully loaded DACS's

FIGURE 5

A Large Incumbent Carrier Adds an IMAP without Concentrating Its Traffic

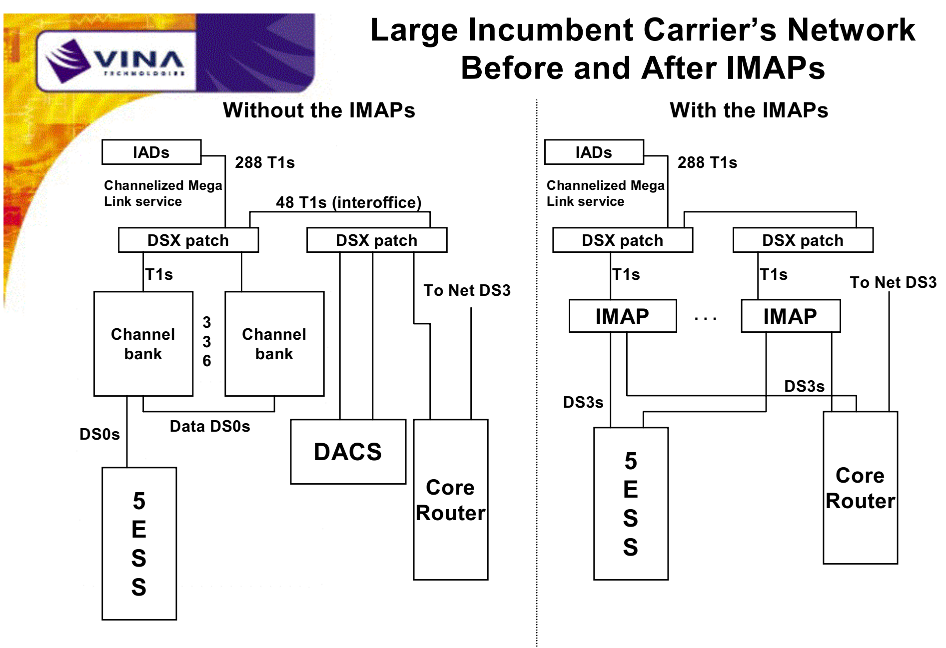

FIGURE 6

Summary of an IMAP's Value Proposition for a Large Incumbent Carrier

An Incumbent Slashes Its Capital Spending by Using IMAP But No Concentration				
Asset	**Saved Units**	**Unit Price**	**Sites**	**$ Savings**
Channel bank	336 per site	$2,000	25	$16,800,000
DACS	1 per site	$20,000	25	$500,000
CAPEX cost				$17,300,000
MBXs			25	–$5,570,750
Net cap. effect				$11,729,250

96 ports were allocated to outgoing T1s from end users. The remaining 48 accommodated T1s that led to the company's data network through an intervening frame-relay switch.

Even under the most generous terms, however, the company faced the intimidating prospect of footing a bill of $2,000 for each of the 336 channel banks in every market. Total amount due per site: $672,000, excluding the additional budgetary bite of $20,000 for the provider's data-handling DACS. In short, the fiscal drain from its capital investments struck the provider as unjustifiably severe.

Convinced that overturning its networking status quo would reap huge dividends, the incumbent removed its installed DACSs and channel banks in favor of a few IMAPs that functionally emulate the devices that they replace. As a result of the change in infrastructure, converged T1 traffic that once traveled to the channel banks now goes instead to IMAPs over the same channelized link. From the new platforms, the voice and data then move as before to a Class-5 switch or to a frame-relay switch without the slightest aid of concentration.

Since the IMAPs' arrival, the carrier's outlays for capital equipment have plummeted almost 68 percent. Most of the plunge results from the platforms' threefold lower cost than the supplanted channel banks: In each metro market, the IMAPs carry a combined price tag of about $223,000—approximately $449,000 less than the channel banks. Credit for the rest of the decline goes to the elimination of DACSs, each costing $20,000 per location. The total savings of more than $469,000 in each of the company's 25 sites comes to roughly $11.7 million. Bear in mind that the windfall proved possible even though the provider never saw fit to concentrate its voice and data, often an IMAP's biggest source of financial benefit.

Summary

By installing IMAPs in their co-locations or local serving offices, the three subjects of the foregoing case histories benefited as in *Figure 7.*

FIGURE 7

Recap of How Three Carriers Gained Financially from Adopting an IMAP

Example	**Key Benefits**
Carrier #1	• Decreased capital expenses by more than $9.7 million over two years • Cut payments for leased backhaul lines by $45 million over two years
Carrier #2	• Reduced its operational costs by 61 percent • Trimmed its capital spending by 31 percent
Carrier #3	• Lopped 68 percent from its CAPEX (assumes channel bank @ $2,000/unit)

E-Business Management: A Practical Perspective

John McConnell
President
McConnell Associates

Introduction

E-business across the Internet continues to grow rapidly, and the challenge of managing these critical services grows even faster. The major challenges to effective management are as follows:

- Delivery chains are more complex, including multiple businesses, different types of service providers, back-end services, and content-delivery networks. It has been difficult to monitor, let alone manage, such a delivery chain.
- New opportunities and markets are being created by digital subscriber line (DSL), cable, wireless, and metropolitan Ethernet access. E-businesses must deliver total availability and superior performance as well as compelling content. Recent stock market activity indicates continued competitive pressures on e-businesses to make money as well as noise.
- The currently accepted tolerance point is eight seconds—the wait time for downloading a Web page or getting desired information—before a customer looks elsewhere. This tolerance will go lower as speed and performance become stronger differentiators. Slow e-business sites will be dropped for competitors that have compelling content with crisp performance.

The lack of management tools designed specifically to deal with e-business and its unique demands is one of the significant challenges. This report examines the e-business management challenge, defines a structure for evaluating various players, and compares some leading management products. An introductory overview sets the stage for a discussion of the segments of the e-business management marketplace.

An E-Business Overview

Segments

E-business has three primary segments: business-to-consumer (B2C), business-to-business (B2B), and Intranets—sometimes known as business-to-employee (B2E). B2C covers customer interactions with an e-business site; they may collect information, order products, and use support services through a Web site. B2C receives the lion's share of media attention, but B2B is where most expenditures have been targeted. B2B incorporates electronic processes, such as supply-chain management or customer-relationship management (CRM), as well as on-line services, such as trading or procurement. B2E supports an organization's internal processes; information is distributed through the Web and employees deal with more tasks on-line.

Many e-business transactions are actually hybrids. For example, a customer ordering a product at a B2C site may trigger B2B processes for verifying credit, preparing shipping notification, and initiating billing. B2E processes may also be activated to track inventory and distribute information about order volumes. An e-business manager needs to track this set of interrelated activities instead of strolling the aisles and noting activity. Traditional management tools are not able to cope with the complexity of most e-business environments.

Service-Level Agreements

E-businesses must have constant availability and superior performance to compete. Most are negotiating service-level agreements (SLAs) with their service providers, business partners, and suppliers to clearly define their expectations and to track delivery against objective service metrics. Service providers, partners, and suppliers also benefit by demonstrating they are delivering high service quality and identifying new opportunities for differentiated, high-margin services.

The Customer Experience

Another essential ingredient for e-business is tracking the customer experience. Compelling content, easy navigation, support, and performance affect the overall experience. A traditional manager had opportunities to interact with customers; e-business customers usually click to a competitor without bothering to complain. E-business management tools must provide insight into the customer's on-line experience.

E-business management solutions must deal not only with complexity, but also with the business that depends upon sophisticated technology.

Managing E-Business: It's the Transactions, Not the Technology

Any business is based on transactions: between a clerk and customer or between a customer and a Web site. For example, an on-line customer may query a Web site for product information, compare product features, select a product, provide billing and shipping information, and consummate the sale. The e-business usually responds with an e-mail confirmation and delivery details. Customers may return to the Web site to track their order, ask further questions, or change the selection.

Technology is the foundation, but it must be managed to optimize business transactions, rather than as an end in itself. For example, a network quality of service (QoS) solution will, at best, address only the network impacts on transactions. Network-management decisions must be guided by e-business goals.

Managing E-Business: It's the Business, Not the Technology

Managing an e-business means delivering meaningful information to the e-business managers, in addition to the technology teams. Business managers want information that allows them to understand what their on-line business is doing and where they need to focus their attention. For example, e-business managers are interested in business-related questions such as the following:

- Has the number of abandoned shopping carts changed after the Web page was improved?
- Are the new banner ads affecting our store traffic?
- What are my competitors doing? How do we compare?
- Are the inventory and shipping systems working effectively? Are we stocked properly? Are deliveries moving smoothly?

The e-business management system collects information from many sources and aggregates it into meaningful metrics for the business managers. It also provides detailed technical information to the technical teams.

An E-Business Management Architecture

Managing e-business transactions is an information and processing-intensive process. Information from many sources must be aggregated and correlated for a complete view of service flows. Large volumes of "raw" operational data must be converted to more meaningful information, such as baselines, revenues, and SLA compliance.

A simple architecture describes the e-business management system and its relationships to the technology infrastructures and their management tools (see *Figure 1*).

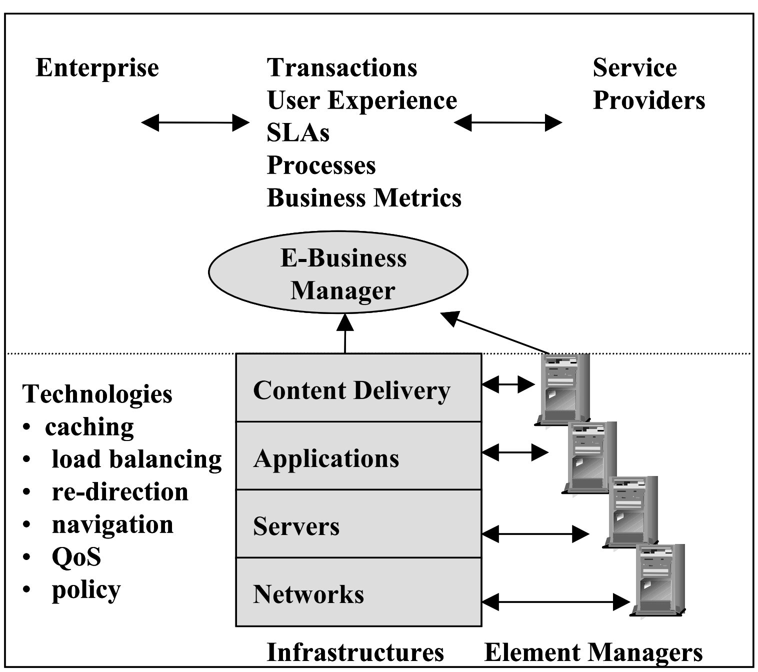
The dashed horizontal line is the boundary between e-business transactions and their supporting technology.

Above the Line: E-Business

The e-business management system deals with business-focused information such as the customer experience, transaction volumes, and supply-chain performance. It allows service providers and enterprises to offer differentiated services with the necessary guarantees. Customers are able to track their hosted e-business services and control their costs and service quality.

FIGURE 1

An E-Business Management Architectural Overview



The e-business management system must also work with the technology-management systems to maintain and improve service delivery. Technology decisions must be informed and driven by their impact on customers, SLAs, and services.

Below the Line: Infrastructures (Segments)
Four technology infrastructures must be managed to provide high-quality transaction flows. Infrastructure elements are typically managed by vendor-specific element-management tools. Specific information from each infrastructure is used to assess its contribution to overall e-business performance.

Content Delivery
The content-delivery infrastructure manages the placement and optimal delivery of content. This model uses the content-delivery infrastructure to delineate services delivered by a service provider. Many of the same tools, such as re-direction and caching, are also used for the server infrastructure.

The complexities of managing content are continual. E-businesses constantly update their content to make it more attractive, to respond to new changes, or to offer special promotions, for instance. Creating and distributing information to the content-delivery infrastructure is a separate discipline from making certain that the content is distributed for fast access with load balancers, caches, or other devices.

Applications
The applications infrastructure is concerned with the functions needed for optimal application performance and service quality. The e-business management system must make certain that applications are operating correctly—starting them, halting them, or moving them to different servers.

The interactions between applications, content management, and monitoring grow more complex as dynamic (personalized) content becomes more common. Personalized, changing content strains the ability of the management system to generate the correct virtual transactions and to check the content when the transaction is completed.

Servers
The server infrastructure is focused on availability and high transaction volumes. Multiple sites and *n*-tier architectures are coupled with caching, re-direction, and load balancing for high-quality e-business services. The e-business management system must track transaction volumes and adjust the number of servers and task distribution accordingly.

Networks
The networks infrastructure spans enterprise and provider facilities and offers differentiated services for e-business transaction flows. E-business management is responsible for end-to-end performance even though external providers provide many of the networking services. Measuring performance and isolating problem areas is a major task.

Time Frames
Real-time monitoring, tracking, and adjustment are critical to maintaining the agreed-upon service quality. However, there are other management functions that occur over longer time intervals. Capacity planning, for example, is necessary for adequate and accurate provisioning. Resource shortages will cripple any site. Information collected by the e-business management system is used to forecast requirements. Other tools assess the impacts of new services or changes to avoid unexpected disruptions.

Defining a structure for discussing e-business management provides the foundation for comparing a range of available management products. The next section looks at specific needs and the capabilities of these products to meet them.

The Marketplace

E-business management is an emerging market, and many players want to position themselves in this new area. Some products are purpose-built for e-business management, while others are being adapted to address new market opportunities. Some target a portion of the problem, while others are growing a complete solution. The products compared in this report are shown in *Table 1*.

The products do not overlap completely, as can be seen. Firehunter, ProactiveInsight, and SiteScope were designed

TABLE 1

Vendor	*Product*	*Focus*	*Background*
Agilent	Firehunter	Full solution	Purpose-built
BMC	SiteAngel	Web application	Applications
Concord	Health	Application, server, network	Reporting
Freshwater	SiteScope	Web application, server	Purpose-built
Mercury Interactive	Topaz	Web application	Load testing
Micromuse	NetCool	Network	Event management
ProactiveNet	ProactiveInsight	Full solution	Purpose-built

for e-business management, while Concord, BMC, and Mercury Interactive entered with products originally designed for other management needs (reporting, application management, and load testing, respectively). SiteAngel is a subscription service, while the others are products.

Comparing products is always partially subjective. For example, user interfaces are evaluated on preferences, making them difficult to assess. A set of attributes was selected for this report to bring a perspective of current capabilities to the discussion.

Criteria

The criteria will be discussed briefly before they are applied to the products. They were selected to cover the important characteristics of a robust e-business management system. Each of the major categories may have several sub-categories. The selected criteria are as follows:

- ***Perspective and Breadth:*** The actual orientation of the product. Does it provide information on the business and customer experience?
- ***Monitoring and Instrumentation:*** Does the product collect information from a rich variety of sources with a choice of instrumentation techniques?
- ***Analysis:*** Does the product provide high-value analysis for tracking SLAs, baselines, and business metrics?
- ***Robustness and Scalability:*** Will the product have high availability and the ability to handle growth economically?

Perspective and Breadth

Perspective and breadth are important overall differentiators. An e-business management system must first of all have an e-business perspective: focusing on managing transactions, presenting business-oriented metrics, and tracking the customer experience.

Managers must be able to see transactions flowing across their e-business environments. They must also be able to correlate their services to the underlying infrastructures so they can understand the impacts of element problems on services, SLAs, and specific customers.

An e-business management system must have the breadth to cover all key infrastructures. End-to-end transaction-performance monitoring is essential. In addition, a solid e-business management solution also monitors the range of underlying services such as domain name servers (DNSs) or lightweight directory access protocol (LDAP).

Monitoring and Instrumentation

An e-business management system must track the behavior of elements, infrastructures, and e-business services. It must continually check for compliance to negotiated service-quality metrics and provide real-time alerts when situations require immediate attention from the management team.

Basic e-business monitoring must include transactions and sub-transactions (for higher granularity). Response time is an important metric, but content checking is becoming essential to insure the integrity of the transaction.

The e-business management system takes advantage of passive and active measurements. Passive measurements track actual activity, such as a desktop agent monitoring transactions with remote servers. Active monitoring generates virtual transactions that the management system uses for building consistent baselines.

Analysis

The collected data must be analyzed and presented to the management team. There are real-time and longer-term analysis tasks. For real-time analysis, data from many sources is organized to track the performance of various services and compare it to the SLAs. Both thresholds and baseline deviations are important indicators of potential problems.

Detecting a potential problem is only the initial step; further analysis is needed to identify the likely cause. This can extend from triage—identifying the infrastructure for deeper analysis—to identifying the element itself. Additional correlation is needed to associate elements with the customers, services, and SLAs that are impacted.

Longer-term analysis functions are needed for identifying usage trends and projecting future resource demands. Capacity planning prevents disruptions, because resources were not in place for growing e-business volumes.

Robustness and Scalability

E-business management systems must have high availability. Using multiple servers provides fault tolerance and failover when failures occur. Data management includes backing up key management information to protect it.

Scalability is also a concern because volumes can grow rapidly. Multiple servers also aid scaling. One of the most important areas is scaling the management staff. Highly automated management tools that discover the information that they need, adapt to changes, and relieve humans of mundane tasks are also needed for scalable solutions.

Results

Scoring

Simple scoring is used to evaluate relative capabilities. Satisfying a criterion earns a maximum score of 10 points; partial satisfaction scores lower. Weighting could be used to make specific criteria more important than others.

Perspective and Breadth

The specific features were as follows:

- Provisioning of e-business metrics
- Visibility of the entire service chain
- Visibility of the four infrastructures
- Measuring the user experience

Table 2 shows the scoring for these first features. It should be noted that differences are already apparent. As shown, several of these products do not address the basic requirements for e-business management. For example, BMC, Mercury Interactive, and Freshwater are not tracking all four of the e-business infrastructures. Customers do not have overall visibility and control of their transactions with a single product.

Some scores were also lowered due to incomplete coverage. ProactiveNet, for instance, only collects information with its own monitoring agents, reducing its visibility into the complete infrastructure.

There are many supporting services that must be monitored. For example, DNS or LDAP have substantial impacts if they are congested or unavailable. Automatically monitoring a wide array of services simplifies operations and provides valuable information (see *Table 3*).

SiteAngel and Topaz are currently focused on Web application and server performance; therefore, they do not monitor many of the underlying services supporting the Web transaction.

Monitoring
E-business management focuses on transactions, in contrast to the usual infrastructure monitoring tasks. Transaction monitoring must approximate the user experience by using virtual transactions—activity generated by the management system for management purposes (see *Table 4*).

Granularity is also a consideration. Complex transactions will activate sub-processes that are also important to measure. For example, if a credit authorization or a shipping/inventory search is slow, the customer satisfaction decreases, although the fault is externally based. E-business managers need the granularity to understand the behavior of their processes.

All products measure overall transaction performance, and most (except for Micromuse) also provide finer granularity. Thresholds can be set for sending alarms to signal the management system when performance degrades. E-business managers want alarms in close to real-time—some of this is dependent upon the agents. SiteAngel, in contrast, only provides periodic reports rather than alarms.

There is more separation when examining the four infrastructures supporting e-business. SiteAngel and SiteScope, in particular, only monitor the performance of the Web application and server, leaving the remaining infrastructures invisible.

SiteScope, Topaz, and SiteAngel are unable to provide business metrics because they measure the response times of only virtual transactions. They do not collect the needed

information to track orders, revenues, or other critical business metrics.

Instrumentation

Active collection builds consistent baselines and provides continuous monitoring. This must be blended with passive instrumentation that collects information from real e-business flows—where the business-oriented metrics are derived.

Pervasive instrumentation is needed in a complex, distributed environment. Placing agents in different locations provides measurements across different parts of the underlying infrastructures. SiteAngel and SiteScope use only a single site to generate virtual transactions (see *Table 5)*. This is limiting because different parts of the networks infrastructure are not tested.

Openness is also a key; there are many information sources available. SiteAngel, SiteScope, and Topaz use only their own agents for information collection. While this may suffice for measuring overall performance, it leaves a substantial portion of the underlying infrastructures unmonitored, forcing customers to employ several monitoring tools and integrate the data themselves.

Intelligent monitoring is also essential: The management system must minimize network, server, and application loads while collecting quality information at the same time. SiteAngel, for example, adjusts the polling interval for greater granularity after a potential problem is detected. Firehunter also automatically baselines and allows for sustained thresholds—tracking an indicated problem for a time interval to determine if it is real or an artifact.

Analysis

The wealth of raw data must be analyzed and organized for effective service tracking, planning, and decision-making (see *Table 6*).

Tracking Compliance
One important feature is tracking compliance with SLAs. All products track simple SLA metrics, such as response time. However, e-business service quality is actually determined by a set of interrelated factors, such as network and content delays or load-balancing efficiency. Firehunter, NetCool, and ProactiveInsight separate from the rest with their compound SLA metrics.

Baselines
All products in this report generate service-performance baselines—indicating the envelope of normal transaction behavior. Content checking is another important distinction: The transaction must complete correctly, with the correct information in the pages. A transaction that completes quickly but does not deliver business value can be deceptive for the management team.

Root-Cause
Analyzing problems—and potential problems—is another critical area. The management team needs fast and accurate information that identifies the causes of degraded transaction performance. Triage is the first level of problem analysis—isolating the problem to one of the four infrastructures. Root-cause analysis identifies specific elements contributing to the problem and overlaps functions provided by element and infrastructure managers. Products such as SiteScope can identify problems but did not earn points because they do not cover all the infrastructures. Concord earns reduced points because they offer only some server analysis through its acquisition of Empire Technologies.

Scaling and Robustness
Management systems must scale easily, accommodating rapid growth and change, conserving scarce staff resources, and delivering bottom-line results (see *Table 7*). Factors considered for scaling include the following:

- ***Intelligent-Agent Management:*** treating agents as a group and modifying them all with a single operation
- ***Intelligent Agents:*** offloading servers and conserving bandwidth by local processing

- ***Multiple Servers:*** scale even further and provide aggregation through hierarchy; fault tolerance is also enhanced with several servers

Fail-over mechanisms are also essential for high availability. ProactiveNet and BMC share an advantage in this area.

Summary

Agilent Firehunter has a narrow lead over ProactiveInsight, and the two enjoy a significant margin from the others considered in this paper. Both leaders showed consistent strength in each category, attesting to their balance and focus on the transactions of e-business (see *Table 8*).

The remainder of the field suffers from incomplete solutions or adapting other tools for e-business management. For example, Concord Health is a powerful reporting package that is adding transaction management through acquisitions such as FirstSense and Empire.

Many of the products covered in this paper are clearly not able to deal with complex e-business management demands. There is considerable activity centered on acquiring the missing parts through mergers and strategic partnerships. Those who are lagging will continue to evolve toward the model of the purpose-built solution. However, integrating a set of independent products is no easy task.

The highest scoring product, Firehunter, illustrates the value of a purpose-built product that addresses the e-business management challenge directly. Service providers, the enterprise, and their customers will all find higher value when they opt for an integrated solution.

"Bandwidth Glut" or Strategies in Need of Repair?

Telecom Supply versus Demand in 2002 and Beyond

Russ McGuire
Chief Strategy Officer
TeleChoice

Mark Heaton
Optical Analyst
TeleChoice

Introduction

For the telecom industry, the "odyssey" of 2001 was nothing more than a relentless, stomach-wrenching drop to the very bottom of the proverbial barrel. In fact, *The Wall Street Journal* reported that the cumulative net earnings of NASDAQ companies between 1995 and the first half of 2000 were completely negated by the net earnings (i.e., losses) for these same companies between the second half of 2000 and the first seven months of 2001. As far as the financial markets are concerned, it is as if the technology boom of 1995 to 2000 never happened.

Many shell-shocked and wide-eyed industry veterans who managed to stumble out of 2001 are now facing the obvious question: What's in store for us in 2002 and beyond? For service providers, particularly on the long-haul front, this question is unfortunately framed by the market's troublesome and persistent theory of a supposed "bandwidth glut" throughout the U.S. market.

Clearly, if carriers hope to turn the tide of pessimism about their success in 2002, it is critical that they loudly, publicly, and without hesitation address the market's perceived "bandwidth glut" head-on. Is this current wave of pessimism warranted? Is the market really facing an oversupply of network capacity in 2002 and beyond? In a word, "no"—and for three pivotal reasons:

1. Installed dark fiber does not equal available capacity (*lit* fibers equal available capacity).
2. It costs far more to "light" fiber than it does to install it.
3. Carriers have no financial incentive to light new fibers without corresponding demand.

When it comes to analyzing supply and demand, the core question for many carriers to understand is precisely *where* in the market current demand levels outstrip supply. Likewise, it is equally critical for carriers to understand exactly which market segments have already been flooded with excess amounts of supply. Combined, these two extremes of the market help to guide informed carriers toward the market's most lucrative investment opportunities and away from situations with costly and difficult competitive dynamics.

TeleChoice has created a modeling tool for understanding the nature of telecom supply and demand and has performed exhaustive research and analysis to populate the model with information about the U.S. long-haul transport market. This tool, the Model for Advanced Capital Planning (MADCAP), has been created primarily to assist carriers in making strategic decisions about when, where, and how to invest capital in their network infrastructure.

TeleChoice has used the MADCAP tool to understand the current transport market and to examine the implications on the industry, using a number of different potential industry scenarios. This document discusses those findings, focusing on the current situation as well as three different potential industry scenarios. The report provides high-level guidance on how carriers and their technology vendors should approach the realities of today's market and how they should manage the opportunities and risks associated with potential industry outcomes.

What Bandwidth Glut?

As previously indicated, TeleChoice's recent analysis of the carrier industry in the U.S. market reveals that there simply is no widespread bandwidth glut. In fact, the analysis finds that more than 63 percent of the fiber routes between top U.S. cities are at or near full capacity. However, before diving too far into the conclusions, it is important to understand exactly what is included in this analysis.

In performing the analysis, TeleChoice developed a comprehensive network model that incorporated and analyzed data from all carriers that have lit capacity along key network routes. The model not only examines physical network assets (e.g., dark fiber), but also, more importantly, the amount of fiber that has been "lit" and is ready for service. Overlaid across this snapshot of route-by-route network capacity (i.e., supply) were the aggregated capacity requirements (i.e., demand) rolled up from individual network applications, again, on a route-by-route basis. The map in *Figure 1* illustrates the results from this overlay analysis of the entire industry's current supply and demand levels.

Once complete, the model pointed to many interesting conclusions, which at the highest level can best be summarized as follows:

- On less than 20 percent of routes analyzed, there is a current oversupply of lit capacity.
- Under a variety of industry growth scenarios, all analyzed routes will require significant capacity upgrades within the next several years.
- Several routes require significant upgrades immediately.
- Based on the volume of single-service traffic, several carriers could benefit immediately from higher density (e.g., 40 gigabits per second [Gbps]) transport systems.

In short, TeleChoice's route-by-route analysis of available capacity across the U.S. market reveals the bandwidth glut to be limited to a few routes but not widespread. There is a relatively healthy balance between current levels of supply and demand on most routes.

Growth Scenarios

Given the empirical evidence collected through the model, three representative growth scenarios have been developed to project supply and demand dynamics for the period 2001 to 2005:

"Doom & Gloom" Growth Scenario

This scenario (see *Figure 2*) assumes that capital markets remain closed to all telecom infrastructure activities, both long haul and local/metro. The impact of this scenario is that demand growth is constrained by the continued bottleneck in the metro and access portions of the network. Demand continues to grow at a healthy rate but not at the potentially explosive rates indicated in the other two scenarios. In this scenario, networks (long haul and local) are still upgraded to stay slightly ahead of demand.

"Free Money" Growth Scenario

This scenario (see *Figure* 3) assumes that capital markets quickly reopen for all telecom infrastructure activities. The impact of this scenario is that the local bottleneck is broken, resulting in tremendous growth in demand. However, long-haul carriers aggressively extend their networks by building new infrastructure into new routes and new territories. In this scenario, supply outpaces even the rapid demand growth in most segments of the network.

"Rational Expansion" Growth Scenario

This scenario (see *Figure 4*) assumes that capital markets are open for local telecom infrastructure activities but are relatively closed for long-haul infrastructure. Because of the investment in the last mile, this scenario results in tremendous demand growth. Long-haul networks must be aggressively upgraded to keep up with this demand growth. However, long-haul carriers stick to success-based growth on their existing routes rather than undertaking large new construction projects. In this scenario, long-haul networks are upgraded to stay slightly ahead of demand.

Regardless of how quickly the market grows, demand (particularly data) is expected to continue rising at double-digit and possibly triple-digit rates, thereby requiring carriers to continue "lighting" vast amounts of new capacity to meet this demand. We anticipate that the U.S. telecom industry will continue its historical practice of creating new supply as close in advance of increasing demand as possible without causing severe service backlogs.

Implications

Obviously, the telecom industry is currently under tremendous pressure. Stock prices for virtually every player in the industry are at record lows. Equipment vendors have seen

FIGURE 1

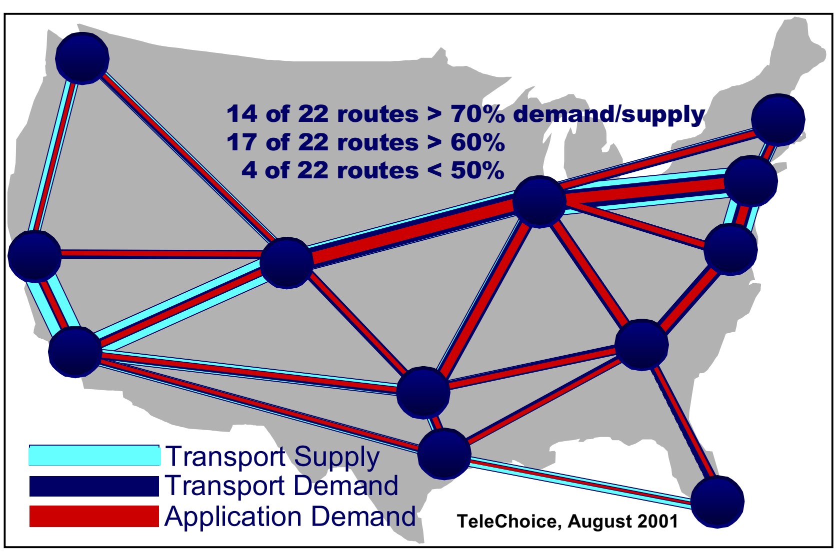

FIGURE 2

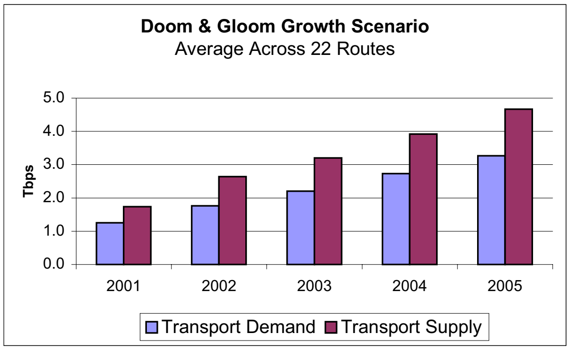

FIGURE 3

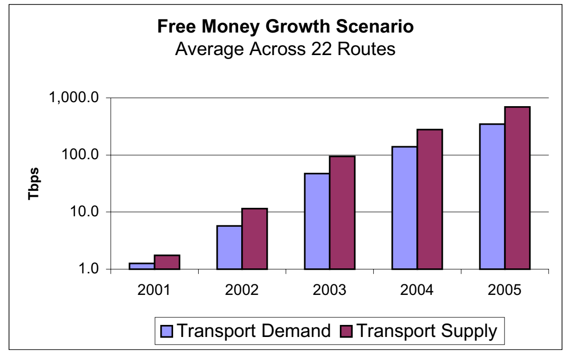

unprecedented revenue reductions. New service providers are in a race to achieve free cash-flow freedom before running out of capital while even many established service providers are struggling to work through the changing margin structures in the industry. Layoffs and bankruptcies have become a normal industry occurrence.

In the midst of this, how are we to interpret the analysis performed using the MADCAP model? The most compelling implications of this study can be summarized as follows:

- There is no widespread "bandwidth glut" in the U.S. telecom transport industry.
- The industry will continue to see healthy growth in bandwidth demand, even under the most conservative scenarios.
- Carriers must carefully consider when, where, and how to upgrade their networks to meet this demand. They must understand how their capital planning activities will play into the overall industry supply/demand picture, and they must carefully consider the implications of their technology choices on the scarce resources: primarily people and cash, but also floor space, power, and eventually dark fiber.
- Carriers must also realize that it is not an oversupply situation causing their pain. Rather, they must fix some fundamentally flawed aspects of their business model to build a business that can survive and thrive.
- Technology vendors must recognize that their falling revenues are not a result of a "bandwidth glut" and that other factors are impacting their business plans and sales forecasts.
- Technology vendors must carefully consider the technology capabilities that will fit the profile of the growing demand while addressing the pain being felt by their carrier customers. As they bring these capabilities to market, vendors must be prepared to encourage their customers to upgrade their networks while assuring them that the pain points (capital, people, space, power, fiber) will be well managed.

Industry-Wide Implications

Amidst this pain, the industry is struggling to figure out what has happened. A natural human part of that process, although not a healthy one, is to assign blame. Lately, the blame has fallen on the carriers that have spent billions of dollars to put fiber into the ground.

The implications if the carriers had failed to make this investment would be extremely painful for all of us. The network transport capacity that existed in 1994 would meet less than 2 percent of our current needs. The fiber construction projects and the technology innovations that have occurred since then have enabled us to enjoy a networking revolution that has greatly impacted our workplaces, our homes, and even the interaction between the two.

Furthermore, while pursuing those construction projects, the industry did not overbuild by putting too many fibers in the ground. The nature of network construction makes it very difficult and expensive to open the trench in the ground. Once the trench is open, carriers had better fill it in a way that they will not need to reopen it for at least the next 10 years, preferably 20. Approximately 22 percent of the fiber in the ground has been lit. Given that many of these projects have completed in the past year or two, this is a relatively high percent. Under the Doom & Gloom scenario, this will rise to 28 percent by 2005. Unless new technologies can more efficiently use the fiber, under the Rational Expansion and Free Money scenarios, all currently constructed fibers on the routes studied will have been consumed by 2004 to meet the projected growth in demand.

FIGURE 4

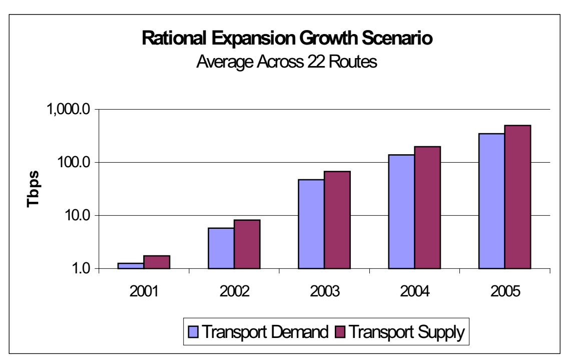

FIGURE 5

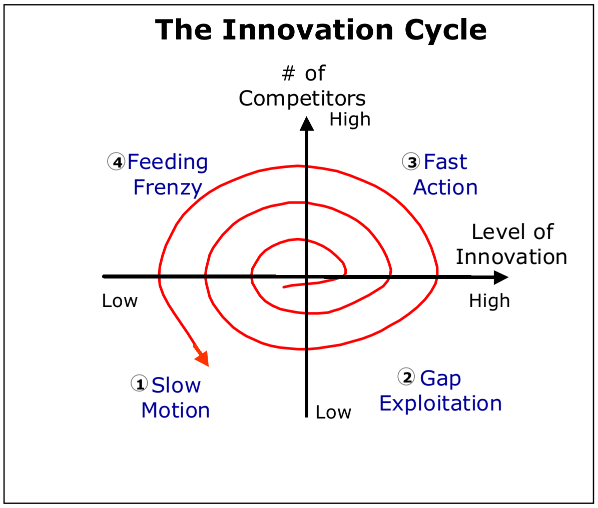


This study has also clearly shown that the industry has not lit that fiber in such a way as to create too much transport capacity, at least not on most of the major routes studied. Even on the four routes with too much lit capacity today, growing demand will eliminate that oversupply in one to four years.

However, what the industry did create were too many competitive carriers with too little innovation. Competition has become primarily price-focused, and as the industry works through the Feeding Frenzy phase of the Innovation Cycle (see *Figure 5*), the desperate players succumbing to the consolidation forces are leading the industry through irrational pricing and other irrational behaviors. TeleChoice believes that a number of clearly identifiable traits of companies are well positioned to survive and thrive in any phase of the innovation cycle. We have codified these as the "Seven Signs of Success," and we constantly work with industry players to develop these strategic traits within their businesses.

Meanwhile, on the equipment side of the story, as the industry worked through the Fast Action phase of the cycle, carriers were buying more equipment from more vendors than they knew what to do with, resulting in a tremendous inventory of undeployed equipment. At some carriers, the construction work in progress (CWIP) figure was as high as 40 percent of property plant and equipment (PP&E) even after their networks were largely completed. As companies of all sorts fail or become desperate for cash, additional equipment has become available at very low prices on the gray market. The net result is that equipment has been readily available for the needed network upgrades, without having to place a single order with an equipment vendor.

The good news for the industry is that demand growth of 20 percent to 722 percent will continue to create tremendous opportunities for all of the industry's survivors. Carriers need to work the irrationality out of their systems while they still have enough cash to carry them through. Equipment vendors need to wait as the oversupply bubble that currently exists in the market is worked out and, in the meantime, look for ways to drive sales of new technologies.

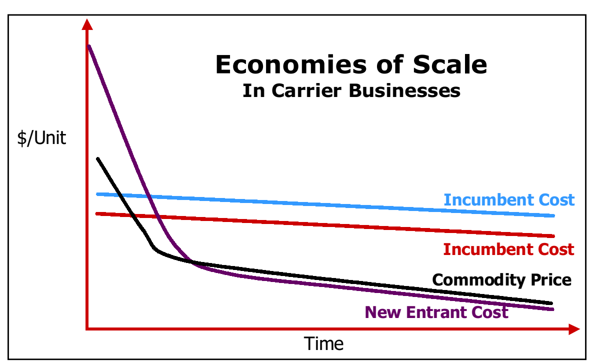
Implications for Carriers

The telecom carrier business is a scale business (see *Figure 6*). Transport services have become commodities with price as the primary basis for competition; new entrant carriers strive for the low-cost position. The technologies that they use to build their networks, combined with lean operations groups and new operations support systems (OSSs), have provided the basis for a lower-cost structure than the long-haul incumbents can offer. However, that low cost can only be achieved through high scale and high utilization. Only when the initial network cost and the corporate fixed costs can be spread across enough units will the cost per unit sold fall below that of competitors.

Most carriers have made fatal flaws in four critical strategic areas. While the industry and economy were booming, these flaws went unnoticed. Today, these strategy choices are causing incredible pain throughout the industry. The first area of challenge is in market strategy. Most carriers still model themselves after the historical model established by Ma Bell: To be "all things to all people." Most carriers lack any discipline for focusing on markets that they can uniquely serve. The result is that most carriers have an end goal of serving all telecom buyers (or at least all business telecom buyers) even though they may first focus on what is perceived to be low-hanging fruit. The second challenge is closely related: competitive strategy. Carriers generally fail to stop to identify their unique competencies upon which they can develop defensible differentiation. These two flawed strategies (or more accurately, missing strategies) have directly led to the price-focused market in which the industry operates today. The third challenge follows directly from the previous two: pricing strategy. The fourth critical strategy has been widely discussed throughout the industry by everyone with 20/20 hindsight: funding strategy.

The net result of these flawed strategies and the resulting economic realities has been a bitterly fought battle for every meaningful opportunity. Any customer representing a significant number of transport units represents a major opportunity to "push to the right" toward lower unit costs. Since pricing has become the primary competitive factor, prices have been pushed ever lower.

FIGURE 6



Compounding this problem, most of the new entrants have taken on significant debt in building their networks. Servicing that debt and meeting debt covenants has become an expensive challenge. Bringing cash in the door becomes ever more critical, even if just to push it back out to keep the creditors at bay.

So, in summary, the very real challenges facing carriers have not been caused by building too much network capacity, but rather by not building a well-tuned business:

- Focused on a winnable market opportunity defined by the company's unique strengths and assets
- Positioned and marketed to achieve compelling confidence from investors and customers
- Funded (and therefore structured/burdened) appropriately given the right business focus

Implications for Vendors

Technology vendors are similarly in a difficult position. For the past few years, vendors have been able to sell the industry more technology than the industry needed. Vendors increased their production capacities to meet this level of demand. Today, and for some period to come, sales volumes have not only fallen to a more reasonable level, but they have also shot way past "normal." Vendors' carrier customers are working through the oversupply inventory—both the additional equipment that they have purchased and the heavily discounted equipment available on the gray market.

Until this short-term oversupply gets worked out of the system, vendors will be sitting relatively idle. The greatest near-term opportunity for vendors will be to convince their customers that they need to purchase new technologies that are not in carrier inventories and cannot be found on the gray market. These new technologies must meet the carriers' current pains (capital efficiency, operational efficiency) while providing strong support for the coming growth in demand, both in terms of scale (based on raw volumes) and service attributes (based on the mix of applications and the unique demands of each service).

In short, vendors need to re-establish viable strategies around product innovation, operations scalability, and market creation. Vendors must re-establish discipline in these three key areas:

- Focus on the right product and market areas defined by the company's unique strengths and assets
- Collaboration with customers and other vendors to meet real needs with real solutions that leverage the capabilities and innovation that can be provided by the world leaders in multiple spaces
- Enabling service providers to offer profitable, non-commodity services that deliver true, measurable value to enterprise and consumer customers

Let's Improve the Market Performance of Our Joint Ventures and Alliances

Lana Phair-Sutherland
Principal
Phair-Sutherland Consulting

Internationalization, fast-developing technologies, and fast-changing markets are making alliances, joint ventures, and mergers more attractive and necessary for communications companies. There is statistical evidence that companies who do well at partnering have higher market values. At the same time, unsuccessful partnering can actually decrease market capitalization—and there is ample evidence that more than half of joint ventures and alliances fail to achieve their objectives.

This article focuses on improving the profitability of joint ventures and alliances through marketing and business strategies that are critical to success and are often underutilized. By pursuing strategies that are customer- and competitor-focused, these partnerships will enjoy positive revenue and stock performance.

Risks and Rewards for High-Growth Communications Companies

High-tech companies are at particular risk when entering into new relationships with high revenue goals, because, in the heat of pursuing a hot concept or a hot technology, the classic requirements of marketing warfare are often ignored. Yet marketing is critical to achieving those revenue goals.

A recent PriceWaterhouseCoopers "Trendsetter Barometer" finds that 30 percent of technology companies are using joint ventures to boost revenues and that more than 40 percent plan to use them in the coming year. Trendsetter chief executive officers (CEOs) achieve the following benefits:

- Acceleration of revenue growth
- Ability to increase profit margins
- Expansion to new domestic markets
- Sharing of scientists or professionals with unique skills
- Sharing of economic risk
- New product development
- Efficient commercialization of a technology or business concept
- Developing or acquiring marketing or distribution expertise
- Combining complementary R&D technologies

Five out of nine results sought are tied to effective marketing strategy, and the sixth, increasing profit margins, is closely aligned. Yet marketing issues invariably take a back seat in the formation and monitoring of joint ventures, alliances, and mergers. There are a host of synergies that may be gained by entering into new partnerships. However, neither cost savings nor rationalization will ever increase sales or profits.

The financial, governance, organization, and process issues that generally dominate the formation of various flavours of business partnerships are acknowledged as being extremely important and are very well dealt with in the literature and in practice. The focus here will be the market-related issues that drive profitability and performance.

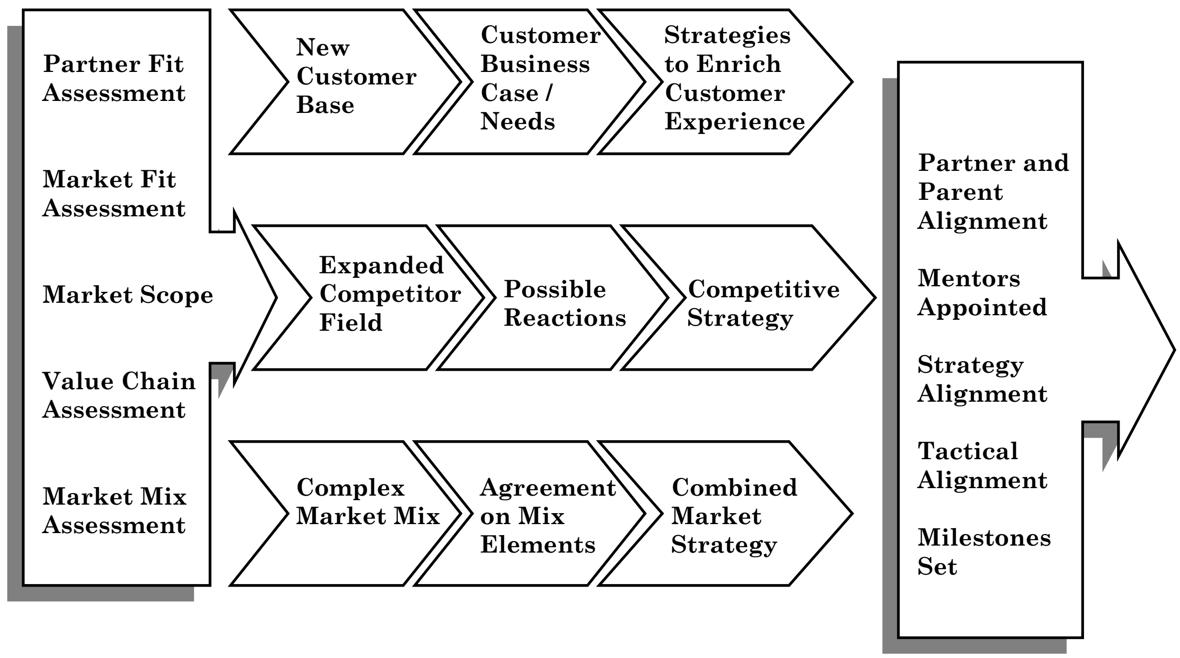
Improving Market Performance in the Planning Stages

Post mortems on alliances and joint ventures that fail to perform show that partners and parents do not always take a proactive stance in considering areas where disagreements are bound to occur. Because marketing decisions are often more subjective than finance or technology decisions, disagreements in the go-to-market phase of the execution plan can cause frustration in personnel as well as ineffective market performance. *Figure 1* shows several areas that partners can address up front, in order to form guidelines for joint venture or alliance teams, once in the field.

Deciding on a Common Market Vision

Many joint ventures and alliances fail to meet the expectations of their parents or partners because they have been ill equipped to do so. It is critical, therefore, that the teams that do the up-front analysis focus on defining a defensible market vision and a practical approach to winning in that market. The assessments will include the following:

FIGURE 1



- The scope of the markets that the new entity can address: their size, growth, market windows, and barriers to entry.
- Customer profiles and business cases
- Competitive dynamics
- The nature of the value chain that the new entity will become part of and will use to satisfy its customers
- Product/market fit in light of the joint product portfolio

Customer Assessment
After the potential partners have assessed the fit of their operations and goals, their time horizons, and the financial returns that they hope to reap, it is time for them to turn their attention firmly toward the new base of customers that the new entity will enjoy. Beyond developing briefing formats so that each part of the new venture understands the business case or needs of the other's clients, the new partners need to do a full assessment of new customer segments and sectors that the partnership may open up.

- New customer groups should be defined and described.
- New customer groups need to be analysed carefully to ensure that their needs are fully understood and that there is a good fit with the benefits offered by the partnership.
- Traditional customer groups that will now be addressed by one or both partners as part of the new entity need to be revisited in terms of the best positioning for the new relationships that are addressing them, as well as for any new needs that can be fulfilled.
- Possible areas of conflict or current customer discomfort need to be envisioned and dealt with.

Once the market has been segmented and described anew, strategies can be developed to enhance the customer's perception of the joint venture or alliance and to enrich the customer's experience.

The Competition
Unfortunately, competitors rarely stand still in the face of market change. The first task of the assessment teams is to determine the nature of the direct and indirect competition that the new entity will face:

- Has the competitive field expanded?
- What are the major characteristics of the current competition? The new competitors? Major threats?
- Has the nature of competition now changed?
- What possible competitive reactions can the competition be expected to take?

Once the review of the competition has been conducted, in light of the product/market fit determined through customer analysis, a competitive strategy can be developed by the new team.

The Market Mix
With new customer groups and competition, and with a range of new internal and external players, the development of a marketing mix that will maximize revenue can be a complicated task.

Everyone knows about the 4 Ps of classical marketing, commonly referred to with a roll of the eyes as Marketing 101. However, it is surprising how many technology companies believe that Marketing = Communications. In these companies product decisions may be driven by technology and pricing by finance. Public relations and advertising may be outsourced. Sales and distribution, the customer facing groups, are often confused and ill equipped to provide a sustained product vision and service backup to the market.

In reality, Marketing = Optimizing Profit Performance. The importance of getting the 4 Ps of classical marketing right is not only in developing the optimal Product, Price, Place, or Promotion Strategy. The importance is in how the four are combined and executed.

Savvy partners strike teams to de-integrate the value chain and processes required to service each company's customers and re-integrate them in a competitive context in the new entity and the new marketplace. Pricing, Product, and Channel decisions in particular require careful attention up front. The following are examples of issues that might arise:

- Partners will often have historic pricing methodologies and pricing relationships with customers that may be challenged by the new relationship
- Companies may have cost structures that have historically dictated product price and volume decisions as well as sales force remuneration.
- Product lines that are targeted to current markets must be rigorously assessed to see if they should be offered in their entirety to new segments
- Can/should products be adapted? To what extent?
- Channels to market that have been in competition may now be common to the new entity. What channels have the most effective combination of cost and coverage to the new market segments? What product allocation and remuneration strategies must be developed to keep channels at peak performance?
- Poorly motivated sales and distribution teams are the undoing of many partnerships. Sales forces of the two entities may have been in competition in the past. They may still compete in other product-line areas. Remuneration structures are likely to be different. These issues must be solved and communicated well before any customer contact takes place.

The completeness and cohesiveness of the combined market strategy of the partnership will be one of the most important elements in its financial success. Strategy development requires some of the best minds from each organization, while implementation will require complete parent/partner alignment.

The Importance of Mentors

Many studies and the practical experience of joint-venture and alliance veterans indicate that success is often predicated on the ability of employees in the new entity to connect easily back to the partner or parent and to get things done. This need is important in all functional areas but is often critical in the marketing and sales department, with its need for targeted product development, timely shipments, and customer service.

It is highly recommended that a mentor in each partner company be appointed for each functional area manager. These mentors could come from the original assessment teams but should be in the same function as the new entity manager with whom they are paired, should be capable of "moving things along," and should be accountable for joint-venture and alliances milestones.

The triumvirate of mentors from each partner or parent and the functional area manager should set the milestones together and should also be prepared to monitor and react to changes that demand deviation from the original plan.

Improving Market Performance in Existing Joint Ventures and Alliances

Planning for optimal market performance will improve the revenue of new joint ventures and alliances. But how can existing partnerships that are under-performing benefit from these concepts? *Figure 2* shows a monitoring and feedback plan targeted to existing companies as well as to the ongoing success of new partnerships.

Counting on Change

One of the key attributes of the head of a successful joint venture or alliance is flexibility. Reporting to two companies while trying to drive a third company to profit targets is a demanding task, without the inevitable changes that occur in any market. One way of managing change is to plan for it.

Most companies perform to specific strategic milestones and tweak the direction of the ship as they go along. This works, as the only certainty about change is that it will occur. However, market and environmental change can be more detrimental to joint ventures and alliances because of their dual reporting structures and responsibilities. Parents or partners can have radically different responses to change and may themselves be undergoing changes that will impact the new entity. Finally, as we have seen, in technology companies marketing is not a science as it is in the consumer packaged goods industry, but rather a subjective and often piecemeal function.

For this reason, we advocate a formal change monitor function that is paired to quarterly reviews of milestones and that has a set of procedures attached to it.

Market Change

Markets are never static. Like all companies, joint ventures and alliances must face changes in industry structure, the regulatory climate, and economic conditions. Competitor's strategies are also likely to change, independently or in response to other change indicators.

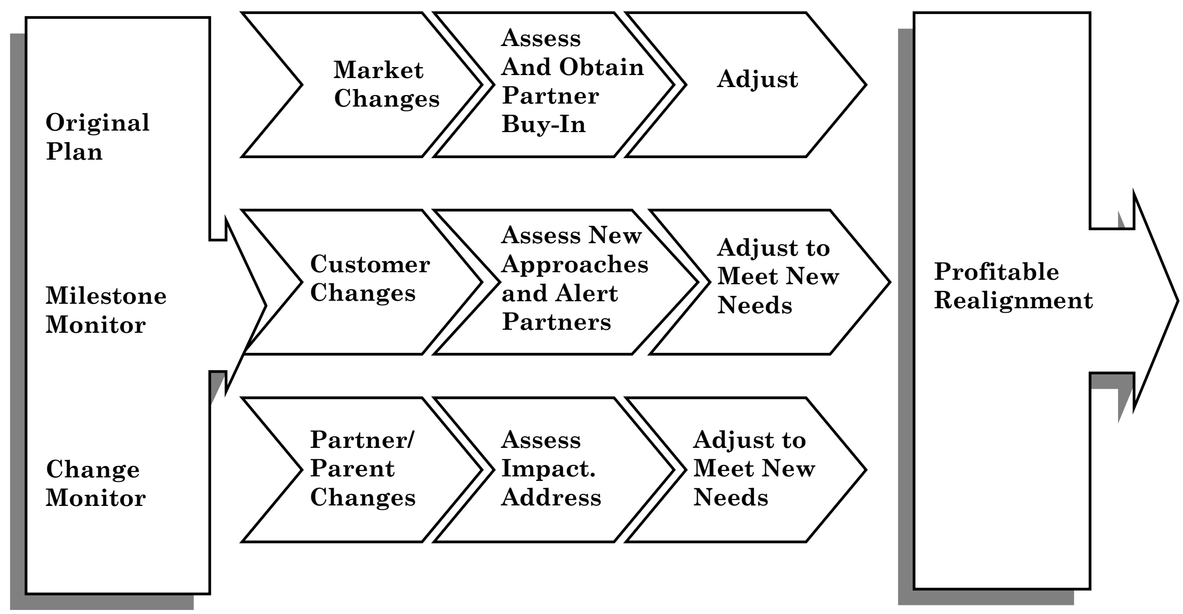
The quarterly change monitor forces early recognition and assessment of the impact of change on the joint venture or alliance. In addition to parent or partner executives, mentors from each company are alerted to begin thinking about the role that each company will play to maintain a profitable course.

Customer Change

As we have seen recently, many telecommunications companies were unprepared for the swiftness and the level of change in orders from their customers and in the planning behaviour of their customers. While some of the suddenness can be laid at the door of just-in-time processes, it is also true that many vendors and operators did not look beyond their commercial relations to the problems that their customers were encountering. Some of the change indicators are as follows:

- Change in the customer's competitive playing field
- Change in the decision structure. Is it Finance,

FIGURE 2



Technology, Marketing, or IT that is influencing buying decisions?
- Change in the economic viability of the customer's sector
- Change in market demand

When change monitoring is formally tied to quarterly milestones and is backed by the mentor structure, clarity is not obscured by fear of reporting potential problems, and adjustments can be made to manage costs and pipelines.

Partner/Parent Change
The objectives, resources, and organizational structures of partners and parents are prone to change, and these changes will impact the joint venture or alliance. Quarterly change monitor briefings and mentors for both companies should be used to assess and report on the impact that these changes will have on the ability of the joint venture/alliance to meet the needs of its customers and to operate effectively in its marketplace.

Summary

The structure and goals of joint ventures and alliances are diverse. Many are plagued with conflict potential from parents or partners that have been, or one day will be, competitors. Others are plagued with conflict potential from partners or parents that were caught up in the excitement of the initial deal but that did not put into place the processes and support mechanisms that would guarantee success. While joint ventures and alliances are becoming more numerous and more necessary in the fast-moving communications marketplace, and while more resources are allocated to them, a fairly low percentage of them meet their objectives. In addition, the employees who participate in them are often prone to extremely high levels of frustration.

Increased attention to marketing discipline in planning and operating alliances and joint ventures serves to focus participants objectively on customer needs and competitor realities. Establishing functional area mentors from each of the partner/parent firms, which advocate for the new entity and join in monitoring critical change areas as well as milestones, can improve both employee and company performance.

The Formulation and Implementation of Telecommunications Strategy

Steven R. Powell
Professor, CIS Department
California State Polytechnic University, Pomona

Abstract

Effective strategic planning requires a strategy that is both well formulated and well executed. Strategic telecommunications planning is no exception. This paper describes how the Balanced Scorecard approach to strategic management can make the formulation and implementation of telecommunications strategy more successful.

Introduction

Because of the turbulent and complex global environment in which companies nowadays must operate, current business practices emphasize speed, flexibility, adaptability, entrepreneurship, innovation, and employee empowerment (Muzyka 2000). Examples of such practices include rapidly deployable and sustainable competencies and skills, a phased experimental approach, dynamic and adaptive organization structures such as networks, and an environment where employees share in the value they create. Although the recent thinking in strategic management reflects these practices, the author has noted that relatively little of this thinking has been applied to telecommunications management (Powell 2001). In particular, issues that have gained significance in strategic management—such as vision, learning, and the role of competencies—have been neglected in telecommunications management.

Recently the author has become aware of the Balanced Scorecard approach to strategic management, which is now used by a variety of private sector, nonprofit, and government organizations, as well as the telecommunications departments within them (Kaplan and Norton 1996; Kaplan and Norton 2001). The Balanced Scorecard approach has enabled organizations that utilize it to more effectively implement their strategies, and when implemented in telecommunications departments, the approach addresses some of the strategic issues that traditionally have been overlooked. This paper examines how the Balanced Scorecard approach does this and how it can be used as part of a comprehensive methodology for formulating and implementing telecommunications strategy.

Strategic Management

Mintzberg, Ahlstrand, and Lampel (1998) have identified 10 schools of strategic management: the design school, the planning school, the positioning school, the entrepreneurial school, the cognitive school, the learning school, the power school, the cultural school, the environmental school, and the configuration school. The design, planning, and positioning schools are the older and more traditional schools of strategic-management thought. The seven younger schools better reflect current management practices. A brief description of each of the 10 schools follows:

1. The ***design school*** views strategy formulation as achieving a fit between internal strengths and weaknesses and external threats and opportunities. Direction comes from the top of the organization.
2. The ***planning school*** has the same view of strategy formulation as the design school, but formalizes the process, breaking it up into distinct steps. Strategic planners have a key role in the process.
3. In the ***positioning school***, generic strategies are followed in given industry situations. The planner becomes an analyst.
4. The ***entrepreneurial school*** views the formulation of strategy as a visionary process on the part of the chief executive, who becomes a creative leader.
5. The ***cognitive school*** looks on strategy formulation as a cognitive process, examining biases in the thought processes.
6. The ***learning school*** views strategies as being incrementally formulated and implemented by a process of experimentation. Strategists are found throughout the organization.
7. In the ***power school***, strategy making is rooted in power, either politically motivated within the organization or as power relationships among external organizations.
8. The ***cultural school*** views strategy formulation as a social process rooted in culture.
9. The ***environmental school*** looks at how organizations respond to particular environmental conditions.

10. The ***configuration school*** views organizations as clusters of characteristics and behaviors. Change comes from the transformation from one cluster or state to another.

Approaches taken in the formulation of strategy can cut across schools. Examples are dynamic capabilities (design/learning), resource-based theory (cultural/learning), chaos and evolutionary theory (learning/environment), and negotiated strategy (power/positioning.) All the schools agree on the following: Strategy concerns both the organization and its environment; strategy is complex; strategic decisions affect the overall welfare of the organization; and strategy involves issues of both content and process.

The Balanced Scorecard and the Strategy-Focused Organization

While formulating a good organizational strategy is certainly important, there is evidence that strategy implementation may be even more important, and to be implemented properly, the strategy must be measured and linked to the organization (Kaplan and Norton 2001). To accomplish this, Kaplan and Norton have developed a strategic-management framework based on the Balanced Scorecard approach, which translates an organization's mission and vision into a set of objectives and measures (Kaplan and Norton 1996). The result is a management continuum:

- ***Mission:*** Why we exist
- ***Core Values:*** What we believe in
- ***Vision:*** What we want to be
- ***Strategy:*** Our game plan
- ***Balanced Scorecard:*** Implementation and focus
- ***Strategic Initiatives:*** What we need to do
- ***Personal Objectives:*** What I need to do
- ***Strategic Outcomes:*** Satisfied shareholders, delighted customers, effective processes, motivated and prepared workforce

The Balanced Scorecard measures are balanced in several ways: external measures for shareholders and customers are balanced with internal organization measures. There is a balance between measures based on past results and measures related to future performance; and there is a balance between objective quantifiable measures and subjective judgmental measures. In particular, the Balanced Scorecard assumes that value creation comes from four different *perspectives*: (1) the financial perspective, (2) the customer perspective, (3) the internal-business-process perspective, and (4) the learning and growth perspective.

1. The ***financial perspective*** is the perspective seen by the shareholder, having as its objective increased revenues, improved cost and productivity, enhanced asset utilization, and reduced risk. The specific measures that are employed depend upon the organization, its industry, its competitive environment, and its stage in the life cycle. Many corporations use the same measures for their divisions and business units.

2. The objective of the ***customer perspective*** is to clearly identify the organization's target customers and business segments and to develop a core set of measures—such as market-share, retention, acquisition, satisfaction, and profitability—for the target customers and segments. Specific objectives and measures are drawn from three classes of attributes: product and service attributes (functionality, quality, and price), customer-relationship attributes (quality of purchasing experience and personal relationships), and image and reputation.

3. The objective of the ***internal-business-process perspective*** is the identification of the critical processes required to support the goals of the financial and customer perspectives. Three kinds of processes are incorporated in the internal-business-process perspective: innovation, operations, and post-sale service. In the innovation process, the characteristics of the market segments for future products and services are identified, and then the products and services offered to those identified segments are designed and developed. The operations process involves the identification of the cost, quality, time, and performance characteristics to deliver the required products and services. The last step in the internal-business-process perspective is the delivery of special services after the products and services are sold to the customers.

4. The ***learning and growth perspective*** recognizes that the organization must learn and grow in order to continue to fulfill the objectives of the financial, customer, and internal-business-process perspectives. There are three sources of learning and growth: employees, systems, and organizational alignment. The three core employee measurements are employee satisfaction, employee retention, and employee productivity. Because employees require accurate and timely information to be effective, there also is a need for excellent, capable information systems to support them. The last source of learning and growth, organizational alignment, deals with the organizational climate for motivation and initiative.

The Balanced Scorecard can be used as a tool for managing strategy in what Kaplan and Nolan refer to as *strategy-focused organizations*. Strategy-focused organizations are guided by five principles: (1) translate the strategy to operational terms, (2) align the organization to the strategy, (3) make strategy everyone's job, (4) make strategy a continual process, and (5) mobilize change through executive leadership.

This is accomplished in a four stage *strategic framework*: (1) clarifying and translating the vision and strategy, (2) communicating and linking, (3) planning and target setting, and (4) strategic feedback and learning.

1. In the ***clarifying and translating the vision and strategy*** stage, the senior executive team translates the organization's strategy into specific strategic objectives. Developing operational measures for the Balanced Scorecard enables vague notions of vision and strategy to be defined precisely so that consensus on the strategic objectives can be reached.

2. In the ***communicating and linking*** stage, higher-level strategic objectives and measures are disseminated throughout the organization so that employees can become aware of the factors most critical to the organization's success and can see how their role affects the entire organization. Higher-level strategic objectives

are translated into local measures at the lower levels. This process encourages a dialogue throughout the organization about long-term strategic, as well as short-term financial, objectives. Incentive compensation schemes based on the level of performance against the measures further ensure that organizational efforts are aligned with strategic objectives.

3. In the ***planning and target setting*** stage, goals for the Balanced Scorecard measures are set. Kaplan and Norton assert that the Balanced Scorecard approach is most effective when stretch targets are employed. Once the targets are set, resources are allocated by means of strategic initiatives aligned with the targets. This is accomplished in the Balanced Scorecard approach through a set of cause-and-effect relationships called *strategy maps*. In the planning and target setting stage, one-year milestones for each measure are forecast at the same time that the three-to-five year targets are set, thereby integrating the strategic and annual planning processes. In this way, the short-term targets serve as milestones along the long-term trajectory.

4. The ***strategic feedback and learning*** stage provides both a single-loop and double-loop learning process about the strategy. Single-loop learning results from feedback on how the organization is performing relative to its short-term targets along a long-term planned trajectory to fixed objectives. Double-loop learning recognizes that in a dynamic environment the objectives may change, in which case the trajectory must be modified. In the Balanced Scorecard approach, the assumptions and theory underlying the cause-and-effect relationships in the strategy maps are constantly checked with current observations and data. If after some pre-established time horizon satisfactory performance is not delivering the anticipated results, the quantitative relationship among the Balanced Scorecard measures may be changed or, if necessary, the strategy changed. Thus the strategic feedback and learning stage feeds back to the first stage, clarifying and translating the vision and strategy.

Traditional Strategic Telecommunications Management

As noted by the author previously, strategic telecommunications management has focused on the design and planning schools with very little attention paid to the other eight schools (Powell 2001). Strategic telecommunications planning supports the company's mission, is subsidiary to strategic business planning, and attempts to achieve a fit between (1) internal business requirements and organization and (2) external threats and opportunities in the technological, regulatory, vendor, and competitive environments. The process is formal, usually following the company's long-range and annual plan cycles. In addition to the required periodic reviews, ad hoc reviews may be conducted (Green 2001). The process consists of three distinct phases (Datapro 1986):

1. ***Review of Business and MIS Strategy and Their Effects on Telecommunications***
   The telecommunications strategy must not only support the company's business strategy, but also conform to its management information system (MIS) strategy, which also supports the business strategy. The key objective in this phase of the process is to analyze the company's business and organizational trends, and then to translate them into expected demand for services and products.

2. ***Projection of Environmental Trends and Effect on Service Levels and Costs***
   The objective of this phase is to analyze the key technology, regulatory, standards, and vendor trends and to forecast the impact these trends will have on the cost of telecommunications services and products and on the levels of service offered by the providers.

3. ***Evaluation of Alternative Methods of Satisfying the Communications Requirements in Terms of Cost and Service and Recommendation of a Set of Alternatives***
   The objective of the last phase is to evaluate alternative ways that the communications requirements can be satisfied and to recommend a particular set of alternatives. In addition to satisfying the given communications requirements, the chosen set of alternatives must meet established life-cycle cost, performance, and managerial (e.g., flexibility, service, support, and security) objectives (Ellis 1986).

Integration of the Balanced Scorecard Approach and the Traditional Strategic Telecommunications Planning Process

With its emphasis on balanced measures, strategic reviews, strategic initiatives, shared organizational vision, feedback and learning, and environmental analysis, the Balanced Scorecard approach incorporates a good deal of the recent strategic-management thinking described by Mintzberg et al (1998) and seems to address many of the deficiencies in the way strategic telecommunications planning has been performed traditionally. Although specific strategy maps and performance measures will vary from organization to organization, it is possible to draw some conclusions about how the Balanced Scorecard approach can be integrated with the traditional strategic telecommunications planning process based on the experiences of two current Balanced Scorecard users: the IT Department of Financial Service Company (FINCO) (Kaplan and Norton 2001) and the University of California at San Diego's Telecommunications Service unit of the Administrative Computing and Telecommunications (ACT) Department (UCSD Business Affairs 1998-2001; UCSD ACT 2000). When the Balanced Scorecard approach and the traditional strategic telecommunications planning process are consolidated, the management continuum becomes the following:

- ***Mission: Why we exist***
  The mission statement will emphasize the service nature of the organization. For example, UCSD's Telecommunications Services provides the campus with a range of telecommunications service, including telephone lines, cable installation and maintenance, short wave radios, pagers, cellular telephones, cable-television services, and data-network transmission and connection services.

- ***Core Values: What we believe in***
  The core values of most telecommunications organizations will be similar to UCSD's Telecommunications Services unit: the need for change, efficiency and cost-effectiveness, and strong customer relationships.

- ***Vision: What we want to be***
  The vision statement will express the telecommunications organization's desire for excellence so that the entire organization can be a leader in fulfilling its mission. Goals characteristic of this will be an effective and efficient use of resources, a high level of service quality, satisfied customers, reliable and innovative technology, and a high caliber of employees.

- ***Strategy: Our game plan***
  The steps in generating the strategy will be the same as in the past: (1) review the business and MIS strategy, determining their effects on telecommunications; (2) project the environmental trends and their effect on service levels and costs; and (3) evaluate alternative methods of satisfying the communications requirements in terms of cost and service and recommend a set of alternatives. For example, in their strategic plan, UCSD's Telecommunications Services unit considers infrastructure, data services, voice services, broadband services, wireless services, and emergency services separately, analyzing first the current campus situation, then campus and environmental trends, and finally future directions.

  Key to the mission, core values, vision, and strategy formulation phases in the planning process are the need to clarify the organization's overall vision and strategy, communicate and link the plan to it, and plan and set targets. This is accomplished using the Balanced Scorecard measures.

- ***Balanced Scorecard: Implementation and focus***
  The four Balanced Scorecard perspectives are the financial perspective, the customer perspective, the internal business process perspective, and the learning and growth perspective. As in the case of FINCO's information technology (IT) department, it is likely that the strategic objective from a financial perspective for the telecommunications organization will be a high return on spending, enabled by a wise amount of strategic spending and investment as well as effective cost-productivity measures. UCSD's Telecommunications Services unit measures profitability (percent excess revenue, accumulated earnings, and percent of net revenue), efficiency (total assets turnover), and leverage (total debt to total assets).

  The strategic objectives are not as clear-cut from a customer perspective as they are from a financial perspective. For example, the strategic objectives of FINCO''s IT department are to deliver (1) certain "basic," or expected, services reliably and at a reasonable cost and (2) certain "differentiated," or innovative, services that demonstrate intimacy with the customers' needs. UCSD's Telecommunications Services unit measures overall academic and administrative satisfaction in terms of its understanding of customer needs, accessibility via telephone, responsiveness, effectiveness of advice, resolution of problems, professionalism, courteousness, and movement in a positive direction.

  The strategic objectives from an internal business process perspective likely will be similar to those of FINCO's IT department: understand, anticipate, and prioritize customer needs; create and develop solutions; provide a flexible global infrastructure; manage technical and operating risk; and service the customer. UCSD's Telecommunications Services unit has used a variety of measures, including the following: minimum different log-ins and passwords needed by a staff member; monthly rate charged per user for one phone and one Internet protocol (IP) address; telecommunications cost per extension line; percentage of general assignment classes network connected as a fraction of total classrooms; and percentage of residence-hall connections as a fraction of total residence-hall beds.

  The strategic objectives from a learning and growth perspective should emphasize the development of capabilities. FINCO's IT department treats two kinds of objectives: employee and organizational alignment. The employee-related strategic objectives are to retain and train skilled people and to empower employees. Aligning and linking goals and rewards is the organizational alignment strategic objective. UCSD's Telecommunications Services unit uses a survey to assess organizational climate. Measures include the following: communication; compensation; customer service; decision-making; diversity; leadership; morale; performance management; teamwork; training and development; and vision, values, and mission. Interestingly, although both organizations deliver information, neither has a strategic objective dealing with its information system.

- ***Strategic Initiatives: What we need to do***
  The strategic initiatives are the specific programs needed to implement the strategy. For example, in its strategic plan, UCSD's Telecommunications Services unit lists a set of milestones and recent accomplishments, both for this year and for five years out, in the areas of infrastructure, data services, voice services, broadband services, wireless services, and emergency services.

- ***Personal Objectives: What I need to do***
  In the Balanced Scorecard approach, personal scorecards are based on a clear understanding of the strategic objectives for the entire organization, as well as those for the business unit, and are linked to the objectives. One way of accomplishing this is by means of variable incentive compensation arrangements tied to performance. The scorecard should be balanced, with objectives and measures distributed among all four perspectives.

- ***Strategic Outcomes: Satisfied shareholders, delighted customers, effective processes, motivated and prepared workforce***
  The strategic feedback and learning process in the Balanced Scorecard approach plays a key role in generating positive strategic outcomes. Without it, the strategic trajectory can miss its target (single-loop learning) or objectives may fail to be modified when

necessary (double-loop learning). Techniques such as correlation analysis, management gaming, and scenario analysis can be used to analyze the validity of the cause-and-effect relationships embodied in the strategy maps. A strategic-management review process, related to, but separate from, the operational-management review process, increases the effectiveness of the learning process. Strategic reviews generally are performed quarterly, while operational reviews are performed more frequently. At such strategic review meetings, strategic issues are reviewed, implications are discussed, and performance data is analyzed (Kaplan and Norton 2001).

Conclusions and Directions for Future Research

This paper has investigated the formulation and implementation of telecommunications strategy and has suggested how the Balanced Scorecard approach can complement the traditional way in which it is performed. The Balanced Scorecard approach emphasizes balanced measures, strategic reviews, strategic initiatives, shared organizational vision, and feedback and learning. These are important issues, which are addressed in strategic business management but are often ignored, or treated lightly, in strategic telecommunications management. Based on an analysis of how FINCO's IT department and UCSD's Telecommunications Services unit use the Balanced Scorecard, the paper presented a strategic telecommunications planning process synthesizing traditional methods and the Balanced Scorecard approach.

There are several directions for future research. As now constituted, the synthesized strategic telecommunications planning process is top-down in nature and quite formal. Recent strategic management thinking, as embodied in the learning school, views the strategy formulation and implementation process as an informal and experimental one. Reducing the formality of the process, and increasing the experimental nature of it, would be a welcome enhancement, especially for organizations with short time horizons. Another way that the process could be enhanced would be to increase the role that strategic capabilities, especially systems-related capabilities, play in it. Strategic capabilities were not discussed in great detail in the paper but are necessary for sustained growth. Finally, future research ought to be directed toward expanding the data base of telecommunications organizations to be studied. In addition to providing data to more fully address the roles of experimentation and strategic capabilities in the planning process, a richer data base will enable a wide variety of strategic telecommunications management issues to be investigated.

Aspects to Consider When Creating a Fully Integrated Test Environment for a Telecommunications Carrier

Normand Primeau
Associate Director, Platforms and Architecture Lab,
Service Technology, Broadband Infrastructure
Bell Canada
Senior Member
Institute of Electrical and Electronics Engineers (IEEE)

Introduction

Major telecommunication companies, as other organizations, are facing day-to-day rapid technological changes. With the advent of fast technology improvement, telecommunications network elements (NEs) evolve and need to be verified and tested. These devices must be tested in captive environments to confirm their abilities to deliver the claimed vendor functions, to interoperate with existing platforms, and to verify their maintainability. To do so, test laboratories are implemented. In some cases, as need grows, the number of these testing facilities increases to a point where rationalization and efficiency must be envisaged.

Carriers' laboratories have materialized because there were drivers to implement them. Services based on new technologies and new concepts—such as asynchronous transfer mode (ATM), Internet protocol (IP), Gigabit Ethernet, etc.—are some of the recent triggers that could have required the building of a facility to perform interoperating testing. However, with time, some duplication of a different nature (equipment, facilities, mandates, etc.), representing misuse of efforts and funding, may have materialized. This is even more true in a large organization, because different groups, having very good intentions, would create these testing environments for excellent reasons, all aiming at serving legitimate causes, but independently.

Different departments—such as operations, technology development, service, support, etc.—may have established their own testing facilities to satisfy their needs without knowing if duplications existed. Obviously, any duplication must be eventually removed to gain efficiency. Gaining efficiency may mean a streamlining of capital requirements, sharing of resources, expenditures reduction, duplication of efforts and equipment reduction, leverage of subject-matter expert skills, etc.

The amalgamation of these testing facilities then becomes a challenge. Blending existing sites that sometimes are geographically disperse is not obvious. A plan and a strategy to do so must therefore be well thought out, and steps must be clearly established to ultimately achieve a world-class testing facility. Obviously, there must be more benefits to offset any inconvenient to do so.

Key aspects required to maintain efficiency in a laboratory/testing facility must be present. Process, test-results documentation and distribution, human resources, security, environment, etc. are important aspects that should not be neglected.

Operating a Laboratory Environment

Let us look at the process aspect. In fact, a testing facility must implement a process that will ultimately satisfy the organization's needs. The internal customers being served by these testing facilities must be aware of the process to fully benefit from it. Most of the time, the facility serves network architects who develop the technology to satisfy the service and product development needs (NTI/NPI new technology/product introduction).

As an example involving a technology-development testing facility, a process was established to filter testing demands. In fact, testing demands were originating from a multitude of different groups—e.g., service development, product development, operations, manufacturers, methods, customer systems engineers (CSE), sales, etc. It was a challenge to sort out which of the demands had the highest testing priority simply because each request was considered by the owner as the number one and had to have precedence over others. It became obvious that a filtering method had to be established, confirming that the testing requests were legitimate. In this case, "legitimate" means that a testing project being performed and which may last many weeks, if not months, should not be cancelled because the original trigger was not properly substantiated. This would therefore represent a loss of manpower and inefficient use of equipment. A way to avoid such scenarios was to use the network architects associated to each of the services to evaluate testing demands associated with those services. If actual technology or upcoming services would fulfill the needs, then the request would not reach the laboratory team. Also, if a similar request would reach the architect, it would therefore stimulate a standardization of a generic solution, and associated testing would be appropriately planned. Naturally, the network architects must be part of the service- and product-planning groups.

Other testing facilities may serve operational groups to satisfy various levels of support. In some instances, methods and procedures for the deployment of new technologies, or the upgrade of software bringing new features to existing platforms, must be verified to confirm efficiency and avoid a customer's loss of services.

Therefore, testing facilities can be used for all kinds of legitimate purposes, and the proliferation of such test environments is sometimes unavoidable. The question is how to apply such a principle to other testing facilities so that a unique approach is implemented. The answer will require careful attention. Implemented correctly, this aspect would serve to reduce non-valid requests and therefore mean more efficiency.

Testing Activity List

How does one track and control a laboratory output, knowing that unplanned activities regularly materialize? One would say, "Set up a list of projects and stick to it. Any new testing requirements would be added in a queue." This approach is uncertain. The purpose of such an activity list is to obtain an excellent view of what is the known workload to come, while maintaining some flexibility for the unknown. A list of activities must be considered as a tool to manage the manpower and the priorities and, at the end, satisfy all the laboratory customers.

Individuals who have been exposed to testing facilities know that religiously following a testing schedule is almost impossible. It must be very flexible and must be built to adapt quickly to important demands. Such a list can be called a "Living Activity List." It keeps changing as time goes. Moreover, if testing work is done meticulously, it is almost certain that issues and problems will be raised. Discovering problems and resolving them with manufacturers, or proposing alternate solutions, are all normal events that take time and argue against a strict and inflexible testing schedule. It is laboratory personnel's first role to unveil issues. This approach must be therefore maintained and encouraged.

Maintaining such a list is not an obvious task, as unplanned testing demands materialize without warning. As an example, a problem of generic nature occurring in the network would dictate its importance and become the top priority for testing, as it could affect customer's traffic and impact service. We are not talking here of day-to-day isolated operational problems, but rather of problems that can be associated with the deployment of new components or software that, in this case, impair an entire telecommunications platform.

Priority changes may also be triggered by special demands for end-to-end testing, a particular telecom solution for a large customer, which amalgamates a multitude of components never before associated together. They are sometimes called "individual case basis" (ICB).

The aforementioned are examples of testing demands that cannot be planned. Most of the time, these are important matters and therefore must be inserted into the work plan. A certain flexibility of human resources and equipment must therefore become an intrinsic part of the process. Managing a test laboratory involves constantly adapting to demands, reprioritizing projects, and re-assigning resources to satisfy needs.

From one quarter to another, the list is modified and activities are shuffled. However, one ongoing aspect is the recording of progress and of the completed testing activities. The completed activities are the mirror of the performed laboratory work. At the end of a calendar year, using such a list represents the total output of a testing facility.

Again, applying this principle to a unique virtual laboratory is not a given. Some type of similar tracking system must be envisaged. If a centralized group performs such a task, it would certainly permit each of the sub-functional testing environments to perform that at which they are good—that is, performing the associated testing work. Keeping some flexibility for unplanned requests, however, will become a challenge.

Test Plans

Various types of test plans exist. Test plans are used to identify what will be tested and how. These plans must be agreed upon with the originator of the demand to insure that the work to be done will satisfy the initial needs. Some are very detailed and can be large, reaching as many as a few hundred pages. Their nature or complexity depends on the maturity of the tested technology. The secret of using test plans is balance. In fact, some test plans detail each aspect to be tested, and the tester must identify whether the test works or not (pass or no pass), sometimes in a mechanical fashion. Whenever possible, when interoperability of equipment is being tested, a certain latitude must be left to the individual. It must cover the area that will be looked at. But at the same time, it must provide the liberty to investigate aspects that may not have been considered during test-plan write-up or must drill down unexpected behaviors discovered as testing unfolds. Most of issues and problems not found by manufacturers or discovered by telecommunications laboratories personnel originate from this type of testing flexibility.

Regrouping a multitude of sites into a unique virtual laboratory means that rules would have to be established and that potentially different type of test plans would have to be recommended.

Documenting the Results

Publicizing the test results, as well as their associated documentation and distribution, is also an important aspect in the existence of a testing environment. It represents the information on which the laboratory customers (service development, product development, methods of procedures) will base their decision-making. It can also be used by the operational departments to implement corrections and avoid future major service interruptions. It is also of importance for internal training purposes. Clear content, format, detailed data, summaries, etc. are also important. To satisfy different types of demands, a formal document format and a technical note format are required. When dealing with usual testing activities, which may last many weeks, the formal document template is used. However, when a punctual testing is urgently required, and results must be made available in a quick fashion, the technical note template is more appropriate.

Implementing the aforementioned aspect into a fully integrated virtual laboratory is one of the easiest aspects foreseen.

Information Storage

Storage of this information and its accessibility, while restricted to "need to know personnel" is also an important part of the success of a testing facility/laboratory. Any time spent on performing testing and discovering issues is worthless if not properly documented, distributed, and stored where the organization personnel can access the information. Having in mind an integrated test environment, a unique storage location must be implemented. With the intranet and Web-site event, access to such information is facilitated throughout an organization in a secure fashion when well implemented. This implies that all testing facilities follow the same rules and store the resulting testing information onto one easy but secure location. Again, integrating the storage of information for all associated sites of a virtual testing facility would be a straightforward activity.

Human Resources

Human-resources selection is the basis for the success of operating such testing facilities. Personnel with a variety of knowledge and experience are critical. When interoperability testing goes on, rarely one individual possesses all the knowledge to perform end-to-end testing. It therefore requires a number of individuals who together possess the necessary skills to do so. Laboratory personnel therefore require an acute ability to work as a team. It is critical to select types of individuals that will blend with the existing team. Laboratory work is very special and needs very special personnel. They need to be self-motivated, autonomous, curious, and eager to learn and, again, must work well as a team. Although a major aspect, technology expertise is not as important as it may appear at first. It can be easily developed through training and exposure to laboratory environment. One additional necessity is to be able to document the testing results. The entire laboratory process relies on the ability of the laboratory personnel to report the findings and clearly express the results. A balanced laboratory team must be formed from a blend of people with experience within the organization, in addition to new grads that are willing to learn.

When some individuals have acquired a large scope of testing abilities and knowledge, they usually reach an advisory role. One of the laboratory advisor roles is to ensure that the acquired expertise and methodology is passed on to new resources (coaching). The advisor also performs the revision of testing results documents. Among all kinds of other responsibilities, the advisor is also involved in performing in-depth testing of critical projects.

Challenges

The aforementioned are only some aspects that need to be considered when dealing with a testing environment/laboratory. Creating a fully integrated test environment for a carrier must include these aspects and more. It is even more challenging when a multitude of geographically disperse testing sites, originally having different functions or goals, must be virtually amalgamated. Amalgamating various testing sites and groups into one virtual laboratory would mean establishing a list of resources and their knowledge. This would permit a better use and leverage of subject-matter expert skills. Means of doing so include the implementation of a database or a way to share this type of information for better use of expertise.

Developing and implementing uniform methods of procedure throughout all laboratories has to be addressed. Most of the time, each testing facility performs activities that satisfy distinct groups, which have different mandates and deliverables. This aspect becomes critical as the control and maintenance of capital investment through a common inventory-management tool is established.

Linking different geographically disperse sites will help to achieve the optimization of equipment investment. A captive core network built using each existing location will then be possible. It provides an emulation of the production environment for all products and services. Ultimately, after physically linking these different locations, one should be able to perform testing from any location or part of this virtual laboratory environment and access this shared equipment. Remote testing of new network components located in one site will be possible to a certain extent. There will be cases where proximity to the equipment will be required. The question is up to what extent remote testing will be possible. Reality suggests that there will always be some required physical proximity to tested components for all kinds of reasons. Remote testing applies particularly well to software-feature and protocol testing involving small hardware changes. However, it hardly applies to physical-layer testing. Laboratory staff and engineers will have to adapt to such an environment. Reaching the highest level of remote testing will be a challenge that should be approached in phases. Process is the key.

Creating a fully integrated test environment will take time. The initial phases will be to establish equipment inventory and identify functions for each site. Subsequently, the integration of functions will have to be addressed. This will have to be performed keeping in mind the organization's common goals. A fully integrated test environment must also effectively serve the NTI, NPI, and operational verification office as a single entity. The management of such a virtual laboratory also involves an excellent understanding of budgetary needs (capital expenses) and, at the same time, the ensuring that the organization testing needs and priorities are satisfied.

This impacts the carrier's ability to deliver new services, new products, and, in other instances, the maintenance of their telecommunications network.

Conclusion

In conclusion, creating a single fully integrated test environment will be possible. Aspects such as budgeting, documentation rules, information storage, equipment inventory, the leveraging of subject-matter expert skills (lists), implementation of a captive core networks between sites, and some of the remote testing will be the easy parts.

The challenges will be to deal with the functions and the already existing responsibilities of each of the sites. Physical presence at the tested equipment will obviously remain for a good portion of the testing, at least initially. The presence of identical equipment at various sites will also remain to a certain extent, as it will be used simultaneously for different applications and purposes. This will become critical as the delivery of results to deliver new services and products will be required.

This will only be possible and will only bring benefits if it is done through well-organized steps.

Standards Progress and Industry Efforts Status

David Shrader
President and Master Talent
Master Consultant, Inc.

The year 2000 saw many battles in the intelligent network (IN) and Internet protocol (IP) industry in the standards and forum areas. Many new forums were created, many new standards were created, and some ended in unexpected ways. Some players were lost; some combatants decided to work together, which was a new development. Among others that normally work together, a major civil war arose. This paper reviews standards progress and industry efforts status.

TINA

The Telecommunications Information Networking Architecture Consortium (TINA-C) terminated its work, but its legacy lives on; all its specifications were officially completed. The Telecommunications Information Networking Architecture (TINA) remains very controversial. The TINA-C spent significant time working on business models and service-provider models. It provided specifications to write input into various different standards organizations in an attempt to influence the way those organizations worked. A number of these concepts still can be applied, but many believe the Internet won and TINA lost.

The Battle for Internet Telephony

A battle for Internet telephony (IT) took place recently. Session initiation protocol (SIP) and H.323 represent one of the most significant battles in this space. They continue to proceed independently, one in the International Telecommunications Union (ITU) and the other in the Internet Engineering Task Force (IETF), but they have begun to look more and more like each other.

As the ITU implemented H.323, it discovered that version 1 of H.323 required a long time to set up a call. When a person picked up the phone and said, "Hello," the other person did not necessarily hear it immediately and vice versa. That has changed. H.323 continues to take on more of the flavor of SIP and session description protocol (SDP). The fast start was introduced and version 4 of H.323 now exists, implementing more of the rapid creation of sessions that SIP provides.

On the SIP side in the Internet world, as service providers have become more involved in the deployment of SIP, enhancements necessary for a carrier network have been added, and it has become apparent that hooks are needed for quality of service (QoS) and services such as caller identification (CID), 911 service, and so on. As a result, many extensions have been added to SIP that make it resemble H.323. Although SIP and H.323 use different procedures and methods, they are evolving much closer to each other. The IETF now maintains a design team to address the interworking of these two protocols, developing documents and specifications on how that might operate.

The Battle for Media Gateway Control

Another interesting battle that has emerged deals with media gateway control (MEGACO). The IETF and the ITU worked together to define interfaces for MEGACO. In an unprecedented agreement, the ITU formed an alliance with IETF to develop the MEGACO protocol, which is jointly request for comment (RFC)–3015 and H.248, to define the interface between a gateway controller and the media gateways (MG)—e.g., the interface between the circuit and the packet networks. When the standard is considered, however, the final specification supports both the text version, which is what the IETF uses for all protocols, and the binary version. Thus, these two are not truly interoperable because one is in text and one is in binary. Other elements will be needed to convert from one to the other to be interoperable.

The Battle for Network Intelligence

In the area of network intelligence the ITU and the IETF continued to partition network intelligence protocols. The ITU study group 11 (SG11) extends the IN architecture to include access gateways from the IN to the Internet to interact with Internet servers. The IETF defines some of the actual protocols, however, that fit into that IN architecture. The IETF, for example, has defined the Public Switched Telephone Network/Internet Networking (PINT) protocol that allows the server on the Internet to send the query into the telecom network, which, for many users, is the IN, and allows it to invoke services on the IN side. This was completed in June 2000.

Interactions in the other direction are in the progress of definition in the Service in the PSTN/IN Requesting Internet Service (SPIRITS) working group. With SPIRITS, an IN device or telecom device will be able to access services and systems in the Internet world and, thereby, allow some sort of user customization of services by querying the user's computer directly or another Internet server. This work is still in progress. The PINT protocol is based entirely on SIP. The SPIRITS protocol is not sufficiently advanced to determine its base.

The Battle for Service Programmability

Once all the protocols and architectures are in place the issue becomes how to program services. The two major groups, despite the appearance of competition, actually have joined forces. The Parlay group was defining application programming interfaces (API) primarily for access from an untrusted space so that networks could be opened. The Java APIs for integrated networks (JAIN) Consortium had been working on Java-based APIs for service programmability, but needed the external, untrusted access. As a result, JAIN joined forces with the Parlay group, which benefits both organizations because the Parlay group now has a Java base in addition to its other, ongoing efforts. The Parlay group now has a buy-in in the Java-based community. The JAIN group now is able to address external service-provider access in a more uniform way. While Parlay API specification is introduced into the Java technology marketplace through JAIN, the JAIN initiative is increasing its reach by addressing the external service-provider access. The goal is to define a unified call model.

Protocols versus APIs

Another battle in the industry involves protocols versus APIs. The Internet model is built on protocols. In the standards group, everything is a protocol. Standardizing APIs is not encouraged within the IETF, although it has been done in the past. In programs, however, the thinking is in terms of APIs.

The TINA-C, which, as mentioned, has completed its work, advocated a fully distributed processing environment. Its entire structure was based on an API so that remote objects could be accessed using an API. Worldwide support of this, however, has not taken hold. While readily available distributed processing environments are seen as being possible within systems, within a particular vendor system, or within some closely coupled development environments, wide-open distributor processing environments are not yet common.

Parlay has taken drastic measures to promote acceptance by joining with JAIN and opening its membership. This, perhaps, will introduce the concept of APIs more and help build momentum. Many companies, on the other hand, are promoting the use of SIP to access applications without a distributed processing environment (DPE) or use of standardized APIs. Services can be bundled on a processor, perhaps using the extensible markup language (XML) method of coding those services. The thinking here is that routing the call using SIP and letting that processor handle it all on its own is inexpensive and easy; therefore, there is no need for letting distributed objects communicate with each other.

Instant Messaging and IN

Another new service that has exploded on the telephony scene and is trying to influence the IN community is instant messaging (IM). The issue is determining how the telco industry can take advantage of IM. A Presence and Availability Management (PAM) Forum has been created and focuses on this as a technology—how to provide it and how to make services that are based on it. As a result of this interest and effort, a civil war started in the IETF over how to provide IM and presence protocols. The IM and Presence working group in the IETF could not agree on one protocol. A set of requirements was agreed upon, but three protocols were proposed that satisfied the requirements for IM and presence. A stalemate resulted and no further progress could be made on one protocol. A group of experts was formed to identify the common elements and the differences in all the proposed protocols. This group defined a single model for transporting data. Then, because the differing elements were in the transport area, they defined three transport protocols, but all three transport protocols are for a common presence format designed to be interoperable via gateways.

ITU Telecommunication Standardization

The ITU started a new four-year study period. SG11, the lead group for IN standards, is developing standards for the SPIRITS capabilities and for how the IN invokes services on the Internet and takes advantage of what is available on the Internet to provide more advanced services or interaction with a customer. Study group 16 (SG16) in the ITU is developing multimedia communications standards. Formerly the home of H.323 and the other 320 family of standards, it is now the lead group for a new initiative called Mediacom 2004, which will hopefully define how multimedia services are done over the next few years.

IETF

In contrast, the IETF solves problems related to interoperability over the Internet. The one key group is the SIP working group, which currently is applying SIP to all aspects of interpersonal communications, from voice telecommunications, to voice calling to voice, to setup of multiplayer games, to videoconferences. It is also trying to do IM and presence transport for it. SIP provides a mechanism that will allow all that to occur over a transparent link. The goal is integrating all interpersonal communications.

The PINT working group has completed the definition of a protocol for Internet servers to access the IN. The management information base (MIB) is in final review. The SPIRITS working group is defining services for an IN element to query the Internet for information. The architecture is defined and protocol requirements are under development.

The IM and Presence working group of IETF has completed protocol requirements, and three subgroups are forming to define the IN transport protocols and the presence transport protocols. The MEGACO working group has completed H.248 base protocol. For every different type of device, however—the black phone, the computer, an integrated services digital network (ISDN) phone, and so on—a package is needed to support that device. The definition of supplemental packages is underway.

Mergers and Acquisitions: Making Them Work

Geoffrey Thomson
Business-Development Manager
Compaq Computer Corporation

Introduction

Mergers and acquisitions involve a host of complex interactions, and anyone involved with them will constantly face an ever-shifting set of challenges and questions. The more one is prepared for these challenges and armed with solutions to these questions, the smoother the transitions will go.

This paper discusses some of the challenges and issues involved with mergers and acquisitions, in an attempt to provide some possible solutions. Its purpose is not to define the one-and-only path to success, but rather to present some ideas, perspectives, and approaches that have worked in the past.

The Role of Change

Change is the one constant element in mergers and acquisitions. Change is inevitable in this arena, and although it can be stressful, it must be accepted. The many various groups who have an interest in any merger or acquisition are often referred to as “kingdom keepers,” because they tend to seek ways of locking their interests away in safety. This kind of resistance to change, however, can threaten the success of the endeavor.

Consolidation of the interests involved requires a rapid, concentrated effort to make sense of the elements in the merger or acquisition. A variety of company types, including vendors, carriers, and Internet service providers (ISP), will play roles in this kind of consolidation, and all these sectors must be addressed with tact and attention.

Unfortunately, the people responsible for making these transformations work are faced with limitations in both funding and time, and these limits can often cause them to make choices too quickly or without enough forethought. In the rush, seemingly obvious and important issues are often overlooked. And in an increasingly competitive environment, such oversight can lead to major problems. Companies who wish to survive in the current environment need to make sure they are examining their reasons for doing the things they do as closely and diligently as possible.

Convergence and Differentiation

It has been said recently that service providers today are all seemingly striving to become similar to one another. However, most service providers are, in fact, striving to differentiate their offerings in order to stand out from the competition. To do this, these companies must bring a number of different systems into alignment.

Such an alignment process can often be more complex than it first appears. Those companies that find themselves faced with only one or two vendors providing different applications and productsævoice mail systems, billing, and so onæare very fortunate; most companies have no such luck. And when multiple vendors come into play, the only way to sort through the maze of details and often-conflicting vendor requirements is to take the time to examine the situation in its entirety.

A converged solution may or may not be the best choice. In some circumstances, divergence presents a better option. The vendor community as a whole usually favors a converged solution, but it is not necessarily the right choice. No one can afford to throw away the parts of a system they are using on a daily basis, and those legacy items must be considered when selecting a solution. Choosing a single vendor in any area brings with it its own set of problems. In the rush to conclude a changeover, companies often forget to consider what is best for them in their particular operating environment.

A number of critical questions plague the evaluation process:

- When, if ever, does convergence present the most viable solution?
- How many of the individual solutions being considered are too expensive or too disruptive?
- Will these solutions, by their cost or their function, possibly injure the competitive posture of the company?

A Formula for Success

The first step toward success in the evaluation process is for the company to define itself and what it wants to do in both the short and long terms. Certain processes, procedures, and applications will show themselves to be critical to the company's business environment; and these cannot be eliminated. Once those critical elements are identified, the path forward becomes much clearer. Thus, this process of self-definition requires serious attention.

The second step, if the company plans to stay together as a unit, is to decide on one future application and use that as a guideline for choosing all the other solutions. Again, a clearly defined business plan is essential before taking any action.

Furthermore, it is highly advisable to bring in outside professional services to help plan, design, and manage this whole process. Too often, providers make the costly mistake of trying to do everything "in house." More often than not, though, the in-house approach fails miserably, as the aforementioned kingdom keepers bring all progress to a halt in their attempts to guard their territories. If they truly want to make the process work, companies need an independent, neutral party managing the change. The expense of bringing in these outside services will be easily forgotten when the process is successful, while any attempt to effect changes without such outside help is very likely to end in failure.

With regard to the solution itself, central to any viable option will be a sort of "traffic cop"æan element at the heart of the system that can pull everything together and manipulate and move the parts of the system around. The traffic-cop element enables a company to have a fairly complete view of the workings of the network and helps direct functionality and data movement. It provides the ability to move the critical data application solutions and to manage the network efficiently and effectively.

The Whole Picture

Sales, order entry, provisioning, and customer satisfaction are the critical components of a successful OSS solution. And if a company is looking after its network's health, it should be able to detect potential problem areas and see certain things almost before they happen. This kind of foresight and quick action make it much easier for the company to retain customers.

The key to success is to offer demonstrable, embedded value. If all the elements are managed correctly, the carrier or provider will survive. If not, the company will inevitably start losing customers and may find itself on the receiving end of a merger.

The choices made in mergers and acquisitions affect a company's agility, credibility, and profitability. Managed adeptly, these choices can move a company in the right direction and give it a strong competitive edge. A well thought-out and comprehensive OSS solution is usually the result of this kind of smart and savvy decision-making.

In going through these processes, the company should remember that asking for outside, professional help is not a sign of weakness, and that if they do not seek it out, their competitors probably already haveæand that puts the competitive edge on the other side.

MPLS and SONET Comparative Economics

Wael Yared
Principal
Cambridge Strategic Management Group

Synopsis

Multiprotocol label switching (MPLS) over a mesh network offers significant economic advantages, both in capital expenditure (CAPEX) and operating expenditure (OPEX), when compared with a traditional Internet protocol (IP)/asynchronous transfer mode (ATM)/synchronous optical network (SONET) network architecture. We model the comparative economics of these two approaches to estimate the potential cost advantage of MPLS, which derives both from less expensive equipment and from its more efficient use of network capacity. We also look at the basic economics of Gigabit Ethernet (GigE), which offers cost savings but generates lower revenues. Our analysis shows that a greenfield MPLS carrier leasing bandwidth and collocation space can anticipate investment payback in less than half the time required for a carrier using either an IP/ATM/SONET network or a Gigabit Ethernet network.

MPLS and SONET Economics

Cambridge Strategic Management Group (CSMG) is actively engaged in evaluating technology advances in communications, with a particular emphasis on the economic and financial implications of those advances. The following discussion focuses on MPLS and its ability to apply the economics of packet-switched networks to voice and other circuit-switched traffic.

Despite the recent downturn in many Internet-related businesses, Internet traffic growth continues to be extremely strong, running according to some estimates at up to 400% annual growth rate in the first quarter of 2000.[1] Data traffic in general is believed to have passed voice traffic in August 2000, yet data-generated revenue is estimated at only about 20% of total telecom revenue, with the rest derived from voice traffic. Cost-effective ways of carrying the rapidly growing share of data traffic are therefore of great importance to today's service providers, and they regularly assess new technology options that may yield lower costs. Conversely, on the revenue side, the ability to leverage the installed bandwidth base more effectively by carrying additional traffic with some flexibility is equally needed.

MPLS offers an attractive economic solution, while also providing critical technical advantages. It can work with any of the commonly used data-communications protocols (frame relay, ATM, IP) and provides a clear route to truly converged networking—networking that would require only one management level and one set of management tools. As a hybrid, sharing characteristics of both connectionless and connection-oriented networking, MPLS allows a traffic-engineering solution for IP, improving bandwidth utilization and delivering differentiated quality of service (QoS).

In the following analysis, we take the viewpoint of a new carrier, deploying its network without sunk costs. Our carrier will avoid having to acquire ducts and lay its own fiber—instead we assume that it will lease unprotected wavelengths as well as co-location space. Its only capital investments will thus relate to its MPLS network deployment. Our study examines MPLS's potential for applying the economics of packet data networks to the delivery of traffic, which today generates far higher margins—namely voice and video traffic. These applications require the traffic engineering currently lacking in IP alone. Using MPLS, however, a service provider can deliver the QoS assurances essential to competitive voice and video offerings, and can also offer virtual private network (VPN) and other managed data services.

For purposes of comparison, we also look at the economics of GigE, a simple protocol with very low costs, but without the traffic-engineering capabilities of MPLS.

We compare the current multilayered IP/ATM/SONET approach with that of MPLS and GigE, both from a limited technology perspective and from the perspective of revenues and costs. SONET offers a premium service with hard bandwidth guarantees, and typical prices for a digital signal (DS)–3 between major U.S. cities currently range from $500 to $750 per Mbps per month. For example, our research indicates that an interexchange carrier (IXC) can offer a DS–3 from New York to Los Angeles for about $650/Mbps/month. Such a private line can carry both voice and data traffic because of its dedicated bandwidth and built-in redundancy.

GigE, in contrast, offers service on a best-effort basis, with no guarantees. Today, GigE is confined to the metro area, and a very large metro connection (say 100 megabits per second [Mbps]) retails for about $300/Mbps/month. Because there are no quality guarantees, customers typically use such a connection for large database file transfers—a major pharmaceutical company, for example, might link its intra-city sites with a GigE connection.

MPLS, in contrast to both alternatives just described, can deliver a range of service levels:

- SONET–like guarantees at reasonably comparable (or slightly lower) prices
- An intermediate level of service aimed at less critical applications but still providing 100% packet delivery at significantly lower prices
- A best-effort service level like that of the open Internet, with no guarantees, at prices comparable to GigE. Traffic at this level is essentially pre-emptible, and no separate investment is allocated to it in our modeling

For example, a typical user of MPLS might deploy a number of 512 kilobits per second (Kbps) connections across different sites for videoconferencing at the highest service/price level, with e-mail and Internet traffic connections at the best-effort level.

MPLS thus offers considerable flexibility in service quality and a commensurate flexibility in pricing. The pricing flexibility derives from the lower capital and operating costs of basic MPLS equipment, and from the characteristics of the mesh network approach as compared with a typical SONET ring structure.

For illustrative purposes, CSMG has considered a carrier entering the inter-city market using MPLS and compares this carrier's situation with one using traditional SONET architecture. CSMG has built financial models of MPLS and SONET networks linking the top 15 U.S. markets. The SONET network is constructed of five interconnected rings, while the MPLS network is partially meshed so that each node is on at least three separate links (see *Figure 1*).

The MPLS carrier can enter the business with a very small upfront investment, because it can acquire unprotected wavelengths, co-location and last-mile connectivity using short-term contracts, and take advantage of quarterly to annual price declines in both connectivity and equipment. (It is essential, however, that the new carrier be able to lease at least three links out of each of the cities it serves.) Services of the three types listed can be offered on both the wholesale and retail levels. Wholesale customers include carriers such as competitive local-exchange carriers (CLECs), incumbent local-exchange carriers (ILECs), IXCs, and wireless providers, as well as Internet service providers (ISPs) and intra-city entrants such as metropolitan-are network (MAN) providers. Specialty applications providers are also a potential target: content delivery, storage services, and other application service providers (ASPs) can use the new carrier's network to connect to their customers as well as to connect their internal operations. Finally, large enterprises are an important target market for inter-city transport.

While many of these customer groups will focus exclusively on data, others (such as large enterprises) will also want voice capability. In nearly every case, whether or not voice or video is offered, service-level agreements (SLAs) will be essential to meet the demands of ultimate end users. MPLS can address this requirement while still offering price advantages and the option of best-effort delivery where appropriate.

Our financial model incorporates the costs for each of the required network components as well as the variation in revenue-generation between the networks, since SONET revenues will be higher due to its inherent QoS. We describe these elements in sequence below.

Capital Costs

Figure 2 compares the required equipment for the three implementations. The SONET network requires add/drop multiplexers (ADMs), digital access cross-connect systems (DACS), and ATM switches. The MPLS network requires transceivers, MPLS–enabled edge and core IP routers, and an optical cross-connect (OXC). For comparison, we also

FIGURE 1

SONET Ring and Partially Meshed MPLS Networks

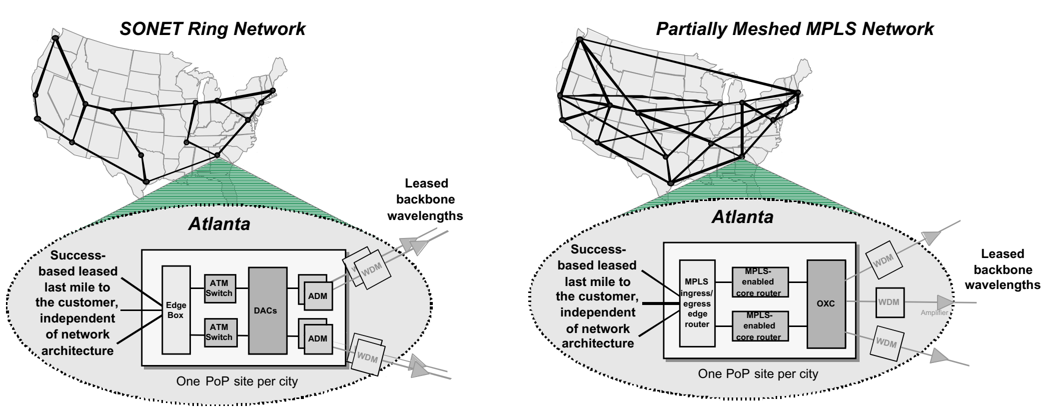

FIGURE 2

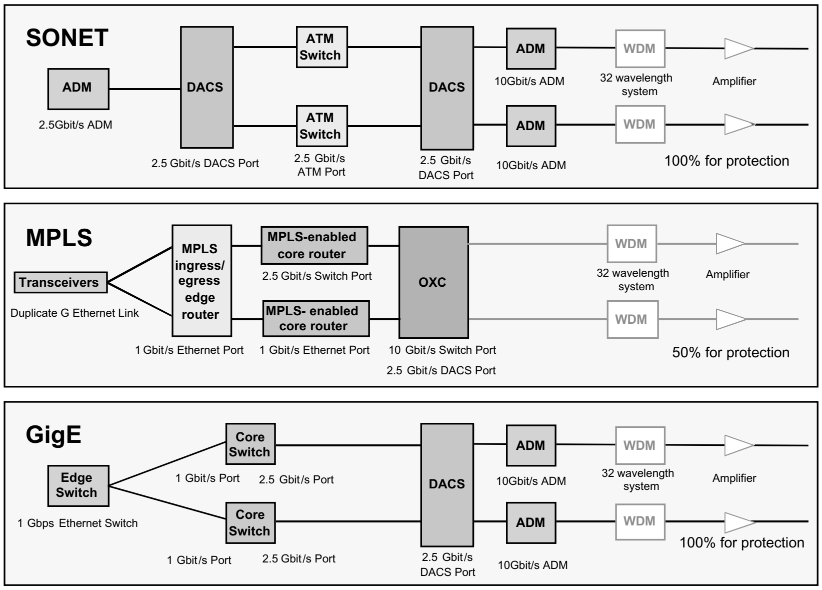
Network Components



look at the GigE implementation. This requires an edge switch, core switches, DACS, and ADM (since our version is built on SONET).

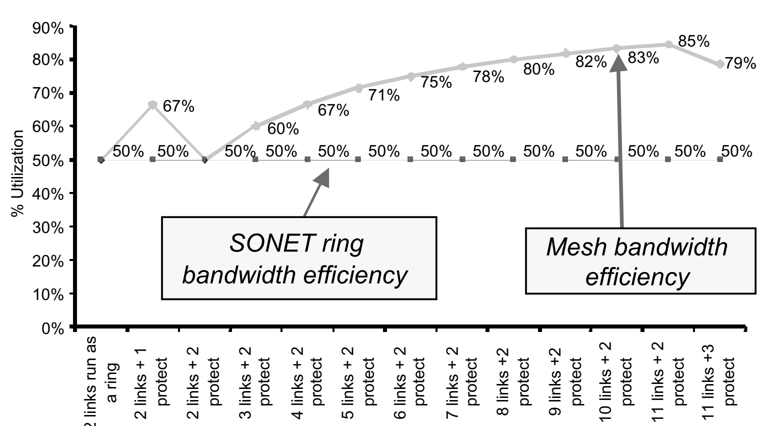
We assume 50% protection for the MPLS mesh network, while SONET and GigE over SONET require 100% protection (1+1), as will be explained. The normalized effective cost per gigabit per second (Gbps), assuming 100% for the MPLS network, is 177% for SONET and 86% for GigE. Clearly MPLS offers a very attractive option based on investment costs alone.

We then look at the network-protection requirements for meshed versus ring topologies to quantify the bandwidth utilization rates in each deployment. Since ring networks have two links per node, and provide an extra full ring for protection, bandwidth utilization is static at 50%, regardless of network scale. In contrast, mesh networks have at least three links per node, yielding bandwidth utilization higher than 50%, and varying depending on the level of protection sought and the number of links at the node (more links means higher utilization levels for the same protection level). *Figure 3* makes the comparison, showing that the mesh network is always at least as efficient as SONET, and far more efficient under most topologies.

Another key factor in the cost of the network is how much transit traffic must be handled at each node. Traffic just passing through a node still requires bandwidth and equipment. In a ring, traffic typically passes through many nodes, since

FIGURE 3

Ring versus Mesh Bandwidth Utilization



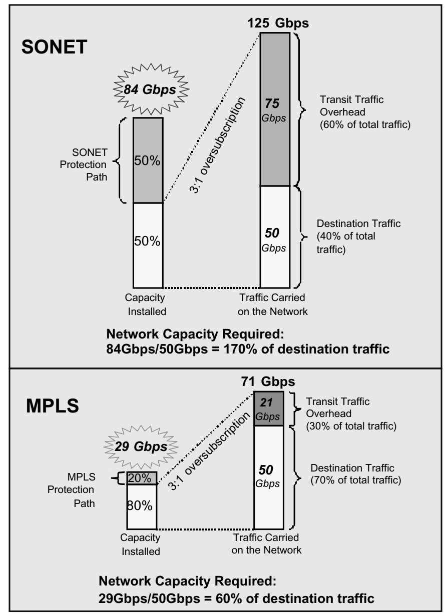
only adjacent nodes exchange traffic directly. In a mesh network, more cities are directly connected, and in a fully connected mesh, there is no overhead transit traffic. In a partially connected mesh, there is some transit overhead, but less than in a ring. For example, our sample analysis shows that our 15-city ring network would have to allocate an additional 279% capacity at each node for transit traffic. (We assume that all of the cities in our model generate similar levels of traffic.)

Combining these last two analytic approaches, we consider a representative connection that has 50 Gbps of destination traffic, using both SONET and an equivalent MPLS network. In addition to the destination traffic, the SONET network will have to handle a transit traffic overhead, which in our example we estimate at 75 Gbps. At similar levels of oversubscription for both networks in our comparison, this adds up to a total payload of 125 Gpbs and will require installed capacity of roughly 42 Gbps. In addition, however, a further 42 Gbps will be required for protection, equal to the capacity required for the actual payload. To carry the 50 Gbps of destination traffic with full protection, then, the SONET network needs capacity of about 84 Gbps or nearly 170% of destination traffic.

For a typical partially meshed network using MPLS, the same calculation looks quite different. Again, we start with the destination traffic of 50 Gbps, but the transit traffic overhead is far lower: in this case about 21 Gbps. To handle this total of 71 Gbps using similar oversubscription, nearly 24 Gbps of capacity is needed. To provide protection in a meshed network, only an additional 20% of capacity is required, bringing the required capacity to about 29 Gpbs or about 60% of destination traffic. (This analysis is summarized in *Figure 4*.)

FIGURE 4

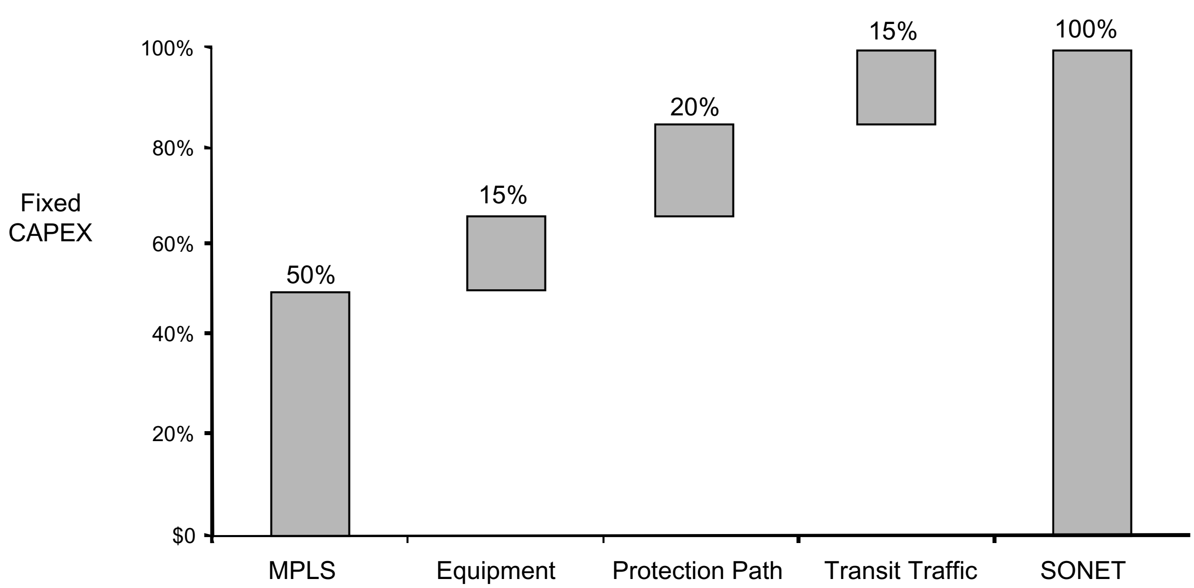
SONET versus MPLS Comparison



In summary, our analysis of capital costs shows three advantages for the MPLS mesh network when compared with a SONET ring, aggregating to a 50% savings in CAPEX when compared with SONET (see *Figure 5*):

FIGURE 5

Normalized CAPEX for Comparable Networks with the Same Traffic (Excluding Last Mile)



- Equipment costs are about 15% lower
  - A multilayer IP/ATM/SONET legacy network requires more expensive hardware
- Less protection bandwidth is necessary, saving another 20%
  - 50% of bandwidth is allocated for protection in a SONET ring, compared with a lower fraction for a mesh topology, resulting in the need for more inter-city bandwidth and higher equipment costs for the SONET implementation
- Transit traffic is handled more efficiently, yielding a further 15% savings
  - A SONET ring network requires increased capacity at each node to handle transit traffic

Operating Expense

Each of the three CAPEX advantages is mirrored in operating savings, and these account for a 43% advantage for MPLS. The savings, as indicated in *Figure 6*, come from three major sources:

- Network maintenance and upgrade costs are 18% of the savings
  - The greater complexity of the SONET leads to higher maintenance costs
  - Because the SONET is made up of rings, there is more inter-city capacity, resulting in more equipment that requires maintenance
- Equipment installation costs account for another 18% cost differential (We estimate that installation represents about 15% of the cost of equipment.)
  - MPLS requires less equipment and offers better network scalability
- Backbone leasing costs contribute 7% to the cost differential
  - MPLS uses backbone more efficiently, and therefore needs less backbone capacity

Financial Comparisons

If we consider the costs in conjunction with the revenue potential for the two networks, it is clear that MPLS will pay back its CAPEX far faster than SONET (assuming new builds in each case).

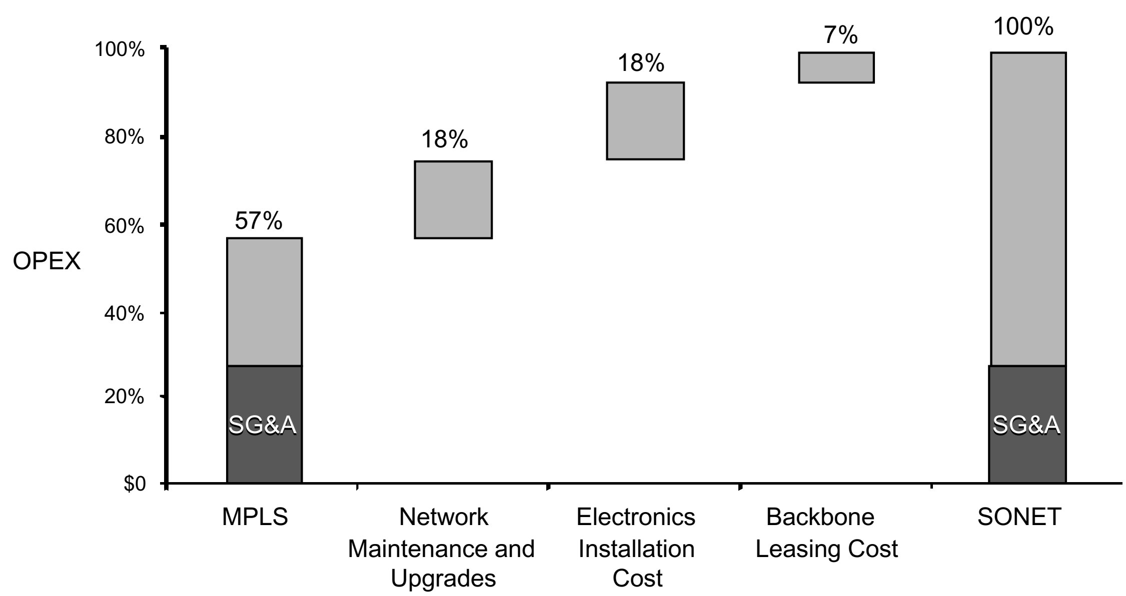
We assume revenue for MPLS of about 80% of SONET revenue, since the service does not offer the same level of quality. The lower cost of operating and upgrading a meshed MPLS network makes up for its lower revenue potential, so that MPLS and SONET have very comparable earning potential. The big difference is in the CAPEX, where MPLS has a significant advantage, leading to a more rapid payback.

Our financial model shows an EBITDA (earnings before interest, tax, depreciation, and amortization) margin of 42% for SONET and 52% for MPLS. MPLS's fixed CAPEX, as already noted, is about 50% of SONET's CAPEX, yielding a payback period for MPLS of just eight months, as compared with 20 months for SONET.

We can make a similar comparison with GigE. Revenues from a GigE deployment will be only about 38% of potential SONET revenues, due to its lack of service quality. Operating costs for GigE are similar to those of MPLS, meaning that GigE has only half the earning potential of MPLS. The capital savings for GigE over MPLS are modest: While MPLS

FIGURE 6

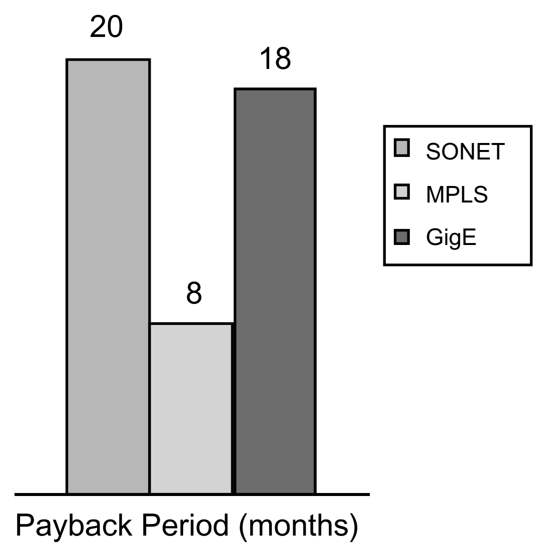
OPEX on a Fully Utilized Network



saves 50% over SONET, GigE saves 58%. As a result, an MPLS network pays for itself in less than half the time of a GigE network (18 months). *Figure 7* summarizes the payback periods.

FIGURE 7

Payback Period Comparison



MPLS Trends

We believe MPLS will soon play a more important role in voice/data convergence, due to its theoretical capital and operating benefits. Like any new protocol, there continue to be technology and execution risks, which will slow initial acceptance. In particular, the QoS capabilities of MPLS have not yet been fully tested, and scale issues are not fully resolved, as there has been no full-scale deployment thus far. Interoperability, as with any protocol in an early stage, is also a concern. Also a risk is the tendency of proponents to oversell a new approach, leading to disappointment when it fails to solve every possible problem immediately and at low cost.

Nonetheless, some significant deployments occurred in 2001, including service offerings by Global One/Equant, Level 3, WorldCom/UUNet, Bell Canada/Teleglobe, Global Crossing, and AT&T. Trials were announced by Verizon, Qwest, Cable & Wireless, and BT, among others.

Looking ahead, we see three broad approaches to traffic engineering among today's major service providers. The first, which we term the "Brute Force Method," solves redundancy and quality issues by over-provisioning the network. If bandwidth is cheap enough, traffic engineering becomes an unnecessary expense. Carriers with this option, typically GigE MANs and ISPs, are unlikely to implement MPLS in the near future. The second approach treats different traffic flows separately, depending on the time requirements of specific types of traffic. Carriers using this approach—such as ILECs and public telecommunications operators (PTOs)—are usually technically conservative and will not migrate to a new network technology without well-documented performance data. The third approach is a hybrid one in which service providers experiment with MPLS to assess its operational benefits. They will allocate network capacity within a single network to different traffic classes and will use traffic engineering to reduce costs. IXCs are likely to be in this group, as are very large enterprises that manage their own communications networks and that must compete for internal resources (both dollars and technical personnel). It is from the organizations using a hybrid approach that most significant near-term MPLS deployment can be expected to come.

Section III:

Network Technology and Applications

Solving the Remote–DSL Challenge

Mark Abrams

Director, Product-Line Management

Advanced Fibre Communications

This paper considers solving the remote digital subscriber line (DSL) challenge in three different ways: converging edge applications driving the new network, providing universal broadband in the context of actual demographics and geographical issues, and integrated multiservice access platform (IMAP) solutions to meet the full sweep of demand in a profitable manner.

Converging Edge Applications

In the beginning there were voice services at the edge: 64 kilobits (k) plain old telephone service (POTS) and data services up to T1 speeds. Eventually an optical network was put in the core over a circuit-based network. In reality, quality of service (QoS) was the element providing revenue. The phone always worked, and the T1 had variable data hit rates. Customers could count on reliable services they purchased as consumers, and the service providers focused on building networks that accommodated these kinds of requirements.

Over the past 20 years there has been an explosion of data services. The network has accelerated all kinds of services being offered at the edge. This is being done primarily in packets. It is fundamentally a data service that is being offered, with new services added through the delivery of data alone. To accommodate this growth, the optical core continues to grow with optical carrier (OC)–12 types of services. The key is now revenue through bandwidth. With DSL, consumers will pay more for higher speeds of rates—T1s, T3s, and so on.

Further progress, however, will require the integration of these services. In the long run, the integration of voice and data services at the edge of the network is what the industry is striving to accomplish. At the same time, the optical core is growing. OC–48s and OC–192s are beginning to be deployed, and the issue is revenue from integrating variable bandwidth with QoS. What is needed is the ability to put both voice and data services on the same network and to use quality service mechanisms to generate revenue appropriate to the services being offered in the most cost-effective way. IMAP products will be a way for these solutions to be found throughout the network. The end result of this convergence is illustrated in *Figure 1*.

There are more and more digital carriers in the network. In 1999 11.9 million lines were added, and digital loop carriers (DLC) accounted for 88 percent of these lines (see *Figure 2*). An increasing number of services are being deployed over DLC. As a result, the challenge is to find ways to meet the needs for deploying these advanced services over digital carriers. The industry must solve this DLC challenge in the most effective way to maximize revenues at the edge of the network.

Today's Urban Broadband Technology

Digital subscriber line access multiplexers (DSLAM) have made an impressive start. They can serve 12,000 to 15,000 feet, and an extensive telecommunications infrastructure already exists to enable this service to be deployed quickly and easily. In addition, the demographics are highly predictable. For a town of a given size, it is relatively easy to determine who is there, what the chances are to sell specific services, and how to market to that specific group.

Furthermore, high-density populations mean cost-effectiveness for service delivery. A large building, or central office (CO), usually exists with all the necessary space, power, and environmental control to drive virtually any type of telecom or datacom equipment. This is a very low-risk proposition for carriers thanks to the law of economies of scale. In putting a 500-line DSLAM in a CO in a town that serves 100,000 people, the demographics and the population to a large extent ensure that the DSLAM can be filled up and, as a result, the optimal price point can be achieved. Thus, DSLAMs have worked well as DSL has been rolled out throughout the network COs.

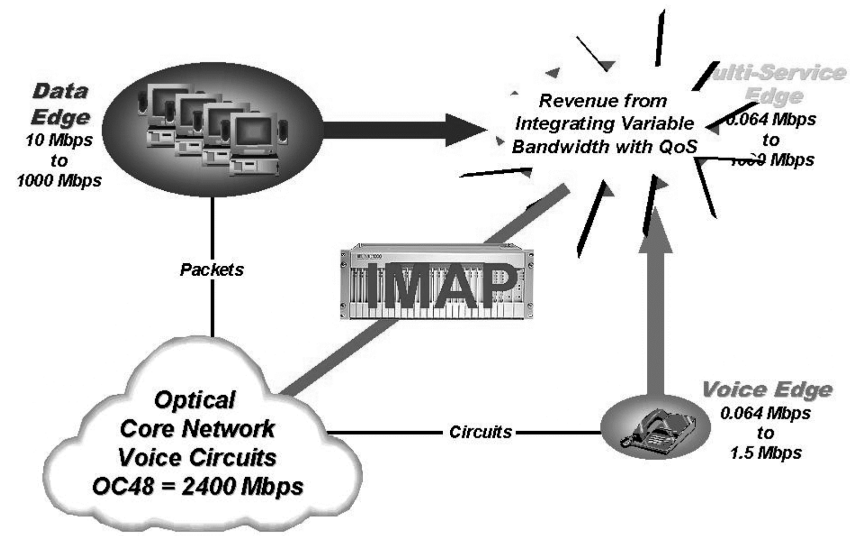
The Remote Challenge

However, CO DSLAM solutions address only about 10 percent of the total geographical area that they actually cover. The area beyond 12,000 feet represents an area that can be 800 percent to 1,500 percent greater than the CO radius. A great deal of territory has lower population densities, and new construction and new customers are difficult to predict. The end result is that network planning and service delivery are significantly more difficult. The outcome, then, is what might be called broadband-deprived areas. When customers call to order DSL service, they find that they are served by a DLC and therefore unable to receive these kinds of services. Solving this challenge will be critical for continued growth in the industry.

There are three alternatives for deploying broadband using telephony techniques, though CO–based technology cannot

FIGURE 1

Converging Edge Applications



deliver beyond the CO. This leaves only two choices stand out in terms of extending the broadband reach beyond the CO. One, discrete box-on-box systems, puts a remote DSLAM next to the remote terminal. The other, broadband multiservice access platforms, integrates DLC functions along with the DSL types of solutions.

Box-on-box solutions are one way for the networks to build out in many places. Products can be mixed and matched to meet the service needs as they arise in a given area. This works well in COs where a multiplexer might carry the services out and low-speed shelves could add POTS, specials, and integrated services digital networks (ISDN). A digital system cross-connect (DSX) with some T1s in the area, or a T1 repeater bay, might be added to provide high-capacity T1 services at that site. Or these services might be provided over high-bit rate digital subscriber line (HDSL), which can be added to leverage the capabilities of that service. The newer synchronous HDSL could perhaps be used to take advantage of symmetrical DSL and asymmetric digital subscriber line (ADSL) for business and residential services. The result is a series of platforms that may or may not be well integrated, but that can meet all service needs as growth occurs (see *Figure 3*).

FIGURE 2

Overarching Deployment Trends

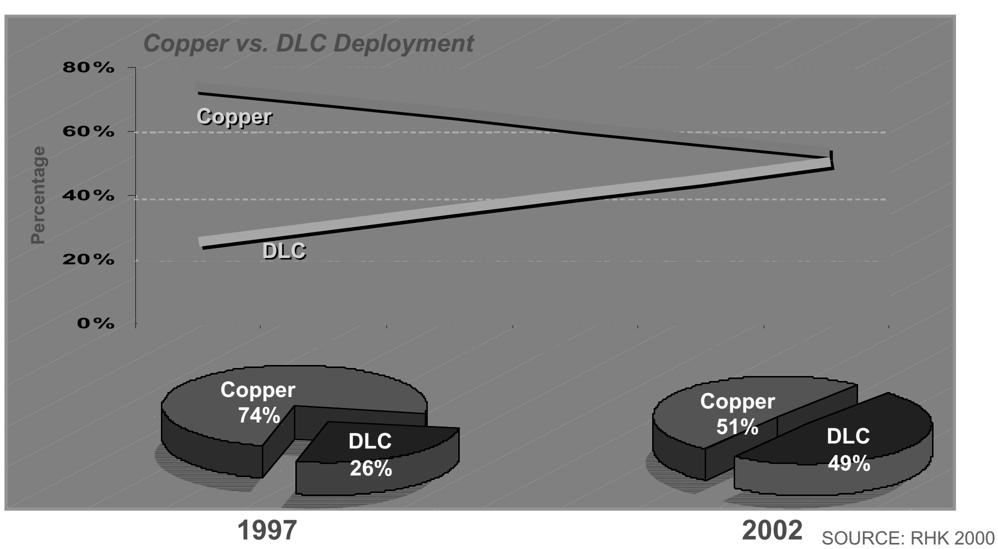


FIGURE 3

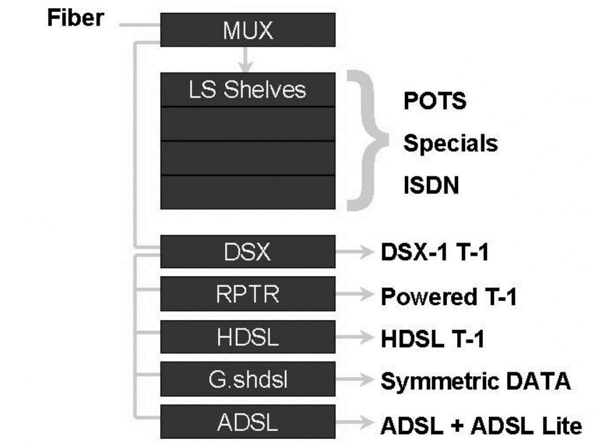
Box-on-Box Solutions



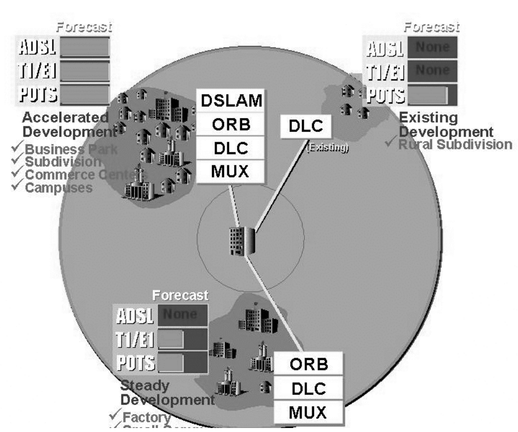
The forecasted development in the current network must be considered in building out the network. A network planner in suburban or rural areas must predict or forecast what will happen in the outlying areas. Typically there is not much time to react. Telephony and datacom demands must be forecast, solutions that meet the forecast must be deployed, and then the next problem must be addressed. This process is expensive, time consuming, and difficult to manage (see *Figure 4*).

For example, in a town there might be three areas. One would have accelerated development, perhaps a business park, subdivisions, and campuses with great opportunities to sell a great deal of ADSL, T1s, and, of course, POTS. Another area would have an existing development with services outside the carrier serving area along a DLC to provide POTS at that site. The third area would be a commercial area with speedy development. Consequently, only T1-type services and POTS sites and services would be needed.

The question then becomes how to serve these different areas. In the traditional model the various products that are needed would be deployed in those areas and the services marketed. For example, a DSLAM, T1s, and DLC would be carried out to the accelerated-development area. In the accelerated-development area with commercial development, a repeater bay with a DLC would be placed to handle all the needed services. The rural subdivision area of existing development would remain unchanged and would be served as is.

FIGURE 4

Forecasted Development for the Box-on-Box Solution



In actuality, many unpredicted developments can occur between the planning, deployment, and marketing cycles. In the accelerated-development area, for instance, cable modems might arrive and undercut the market for the planned services or they may take up some of the demand for the T1 services in that area. In this case, while the POTS is able to serve the basic needs, the DSLAM would remain empty and the repeater bay would be underutilized, resulting in a stranded investment. In the commercial area it may turn out that those businesses prefer ADSL to meet their business needs as opposed to T1s. As a result, despite the T1 equipment placed there, the actual need is for DSL–type services. In the rural subdivision area with the DLC, it might turn out that a business park moves in and demand vast increases for ADSL in the neighborhood, with T1s for local business and POTS. The original planning has left this area under-built and as a result demand goes unmet. Once it is netted out by deploying overlay solutions, it becomes more likely that it will either be over-built or under-built rather than hitting the exact build target. There are real cost and revenue penalties for these misbuilds.

IMAP Advantage

One view is that an IMAP brings a key advantage—integration. The integration lowers the cost of deployment and the risk over the long term. The next-generation DLCs with DSLAM and multiplexer functionality together represent the industry definition of IMAPs. The result is a full-service platform for remote deployments. Whether the transport company has fiber, copper, or radio, the services can be any in and any out, including POTS, specials, T1, ISDN, DS–T1, powered T1, G.shdsl, and ADSL. Plug-in cards enable the addition of whatever services are needed at a given site.

Benefits to the carriers from deploying these kinds of platforms include the following:

- A smaller footprint, because it is all contained in a single product as opposed to multiple different boxes
- Lower power as a result of the ability to integrate all of these solutions
- A single management system to run a full suite of services from a single point, which provides cost savings in the long run
- Loop testing and test access, which will increase the success rate of deployment of DSL types of services
- Integrated voice and data transport that allows the transport part of the network costs to be kept to an absolute minimum

Using broadband integrated multiservice access, the entire serving area can be turned broadband-ready cost-effectively with an IMAP. This can solve the problems for the entire geographical area. By providing plug-and-play, on-demand broadband at any location, IMAP eliminates the digital divide.

In the situational model described above with three development areas, the forecasted deployment now, rather than box-on-box solutions, would use IMAPs to serve the entire area. As a result the actual growth that differs from the forecasted growth is not a problem. It is merely a matter of plugging the appropriate cards into the system to allow it to deliver the necessary services at the necessary time because the carrier deployed a fully integrated broadband multiservice access solution. No over- or under-building takes place. In addition, the system can be managed fully from a single element-management system. All the problems are solved by having a platform that only needs a plug-in module to provide any of the needed services.

The box-on-box solution appears attractive when there are many ports optimized for the maximum price per port. In reality, however, the network often becomes very over-built and underutilized, and there is a high, erratic cost of ownership. In fact it may be nearly impossible to obtain recovery costs at the low line sizes found in remote terminals. This is the step function wherein every addition of a service requires deployment of the additional box to support those services (see *Figure 5*).

Profitability becomes nearly impossible. In areas of accelerated development, there will be demand for increased services with respect to time. If the carrier under-built the network, it will have to add hardware, software, management, logistics, and training incrementally to meet the demand and deliver the services. The carrier, having waited until demand appears, is not in a favorably competitive position against competitive local-exchange carriers (CLEC) and cable companies. It cannot respond quickly, and it loses revenue and market share. With an IMAP, though, there is low scalable cost of ownership. Adding new services only requires the appropriate line cards, and the costs incurred are the services deployed. This allows the continued profitable growth of a full suite of services no matter what the take rates are and what the mix is at any given site (see *Figure 6*).

Box-on-box solutions work with large numbers where future demand is certain to ensure the anticipated return on investment. IMAP is optimal for remote and/or small sites with uncertain future demand where the mixes may vary dramatically. Consequently, deploying IMAP solutions for service and cost-optimized network over the long term is preferable.

High Cost of Box-on-Box Solution

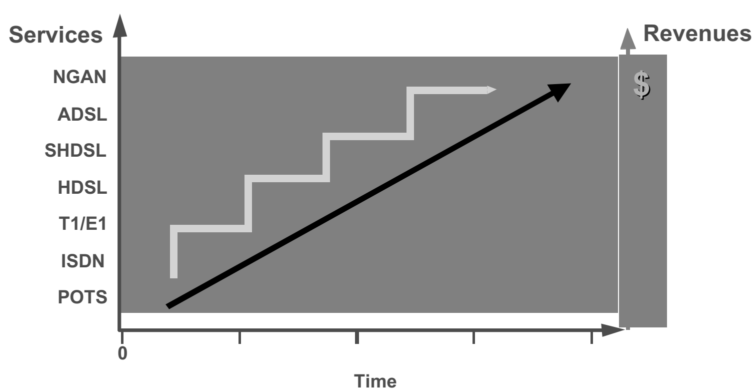

FIGURE 6

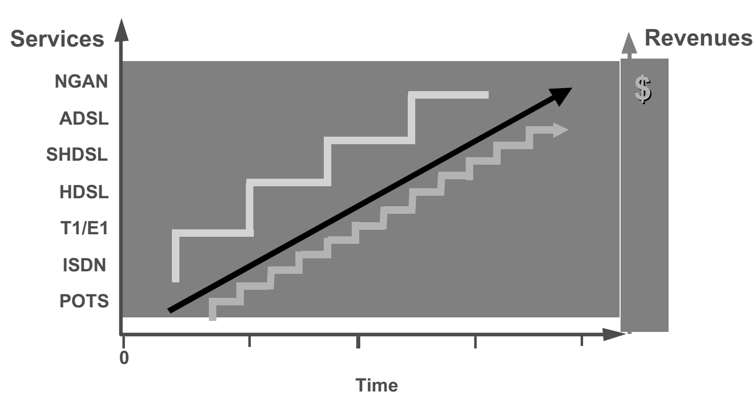
The IMAP Solution and Profitable Growth



Scaling DSL Profitably

Eric Andrews
Vice President, Marketing
Turnstone Systems

The loop-management business helps service providers more efficiently deploy and maintain digital subscriber line (DSL) services. The focus is on profitability and reducing the costs, particularly in the upfront processes. This paper discusses issues and challenges for DSL service providers.

DSL Service-Provider Challenges

Several issues frequently arise for DSL service providers. One is profitability and the actual cost to get a customer up and running, as high as $900. At a rate of $40 per month in revenue, it will be difficult to make a profit on that customer. There is a concern for profitability and how quickly profitability can be reached with a service offering.

The second issue is coverage. Many service providers are interested in trying to have a pervasive service. It is very frustrating for them to deny service to a customer because they cannot reach that customer because DSL is not available through the digital loop carrier next to that customer's home. It is even more frustrating when customers are told service is possible, and then service in fact cannot be provided, or vice versa. In this respect accuracy of information up front and coverage are serious issues.

A third issue is volume. DSL is an emerging market, still in the early stages. But many people are interested in DSL becoming a mass-market phenomenon; making that migration from a specialty service to a mass market will require significant maturing on many of the back-end operations support systems (OSS) and automated-provisioning systems. Provisioning problems currently hamper moving volume up.

Operational Issues for DSL

Many operational challenges exist for DSL service providers. It is not as simple as turning on a voice switch port and then, suddenly, there are plain old telephone service (POTS) on that line. Many different technologies are involved. Multiple providers' infrastructure, data, Internet, and POTS as well as substantial network activity—loop, splitters, and customer-premises equipment (CPE); digital subscriber line access multiplexer (DSLAM) and asynchronous transfer mode (ATM) backbone; and routers and concentrators—impact operations processes in terms of service negotiation, activation, and assurance. ATM switches, DSLAMs, Internet protocol (IP) configurations, and routers must all be configured. There are outside-plant, copper technology, and cabling issues. Many different things are rolled into a DSL service, and this complexity leads to operational challenges.

Most of the regional Bell operating companies (RBOC) in the United States are currently deploying DSL as a special. Everything that is not POTS tends to be specials, which is typically a high-touch, high-volume, or high-revenue type of application (such as T1 lines).

The challenge is that DSL is, in fact, not high revenue. Marketing DSL to the residential community as a commodity service means revenues of perhaps $40 per month, as opposed to hundreds of dollars per month on that line with another special. As a result there is a need to migrate DSL from the specials mentality to more of the turnkey, flow-through provisioning systems such as a POTS–type service that is easy to deploy, troubleshoot, and so on. This is a significant migration.

Applying Loop Management to DSL

Loop management helps streamline provisioning in the deployment of DSL, and thus should be applied as early in the process as possible. Viewing DSL testing as a troubleshooting tool is not optimal. By the time a customer reports a problem in the network, loss has already occurred because money is wasted trying to find the problem and troubleshoot it. The key is to apply many of these techniques early in the process—during the ordering and provisioning processes—to eliminate troubleshooting calls. By the time a customer receives the service, he or she should not be calling with other questions that need to be resolved.

Loop management can fit into each phase of deploying DSL and help reduce mean time to service, increase customer satisfaction, increase revenue, and decrease costs. At the ordering phase, prequalification can be used; at provisioning, automated-service verification can be used; and at the operations phase, troubleshooting and maintenance can be used. In the ordering phase, a customer calls to order DSL from a service provider. The first question is whether service can or cannot reach that customer. That answer is not always accurate. There are many challenges in trying to get accurate information up front regarding whether or not that customer can actually get service. A technique called prequalification can assist in that process.

One of the problems is that although there are many inventory records on what is available in terms of the copper plant, these records were designed around telephony service and POTS, and they do not translate well to DSL. Those old records and databases are often not useful when used as a source of information for DSL customers—the line may turn out to have a loading coil on it, or it may turn out to be too long, or some other problem may occur. The current loop records are not very accurate, and techniques such as mapping software are being used. Legacy test systems, however, are not effective. Mapping software is limited and does not reflect actual loop path, while handhelds require significant manual labor. Traditional POTS testers are not designed for DSL testing. The result is false positives and false negatives—approximately 30 percent of negatives are false and 20 percent of positives are false. False positives cause wasted effort trying to deploy service to a customer who cannot get it, and false negatives lead to missed revenue opportunities. Thus prequalification becomes a significant way to recapture money being left on the table. Accurate prequalification improves operational efficiency through target marketing to a prospective customer base and avoidance of cost and frustration related to false positives and negatives.

In the prequalification solution, a DSL loop-management system is connected to existing voice switches to test all phone lines and identify those that are eligible for DSL in terms of loop length, load coils, alternating current (AC)/direct current (DC) characteristics, and narrowband noise. Creating this software database provides an accurate picture of the copper plant from a DSL perspective—how many of these lines can actually support DSL and at what rates. Eligible candidates for DSL can be predetermined. This avoids the uncertainty of labor-intensive handhelds and works with back-office components to maintain accurate loop records. When a customer calls, the database can be accessed with a Web interface, for instance, from the order-management system to determine exactly whether or not service is possible (see *Figure 1*).

After prequalification on the ordering phase, the next step is provisioning. The loop-management component fits into that process through automated service verification. The self-install model can help in this area, but other steps are needed to help streamline the entire provisioning process. Potential problems include modem trains without provisioning for the end-to-end ATM virtual circuit; misconnection at the main distribution frame (MDF), perhaps with tip and ring crossed on a pair; CPE configured for virtual path identifier (VPI)/virtual channel identifier (VCI) zero and 35, but a DSLAM configured for eight and 35; cabling errors in the central office (CO), perhaps with the POTS line connected to the wrong splitter port; loop records showing a customer's loop should support asymmetric digital subscriber line (ADSL), but in reality the loop is too long; and router transmission control protocol (TCP)/IP configurations that do not match the modem's configuration, making IP connectivity impossible. As a consequence, the end-user is forced to help with the troubleshooting. Human processes lead to human errors. Automated tools are needed to verify service and streamline provisioning.

Proactive management is required to eliminate problems through service verification before a customer receives a modem. Customer experience can be simulated before shipping a modem by verifying that cabling in the CO is correct, qualifying copper loop, and verifying upper-layer network configuration. If a problem is found at this early stage it can be handled cost-effectively. Results are reduced delays, reduced costs, and more satisfied customers.

Typically the problem is coordination because many different groups are involved in provisioning DSL. Some are setting up the ATM circuits, some the DSLAMs, and some the outside plant. All these organizations must time everything correctly to synchronize on the day the modem is delivered to the customer. In the provisioning and service verification, the final step before shipping a modem to the customer, then, should be to confirm not just the physical outside plant but also all the different protocol configurations (IP, ATM, protocol encapsulations, and so on). Cabling should be verified by checking the DSLAM signature to ensure proper cabling, checking for improper termination at MDF, and verifying that the phone number

FIGURE 1

Prequalification Solution

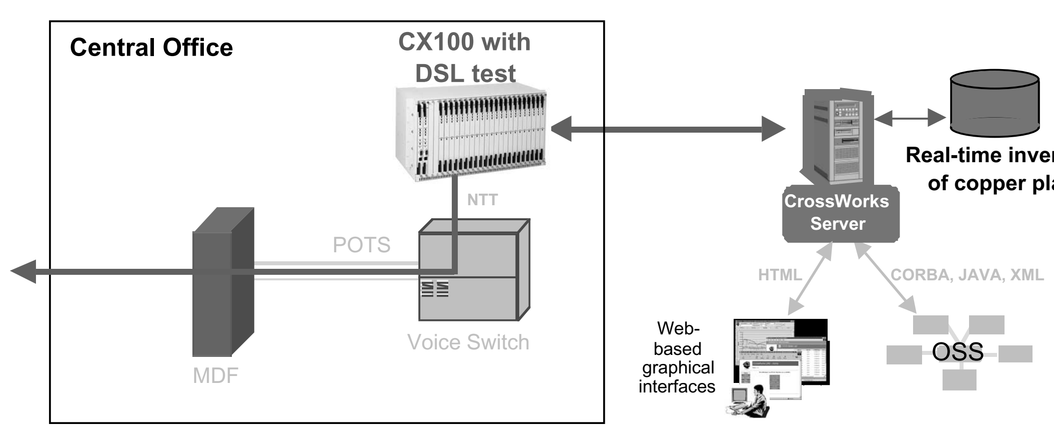


FIGURE 2

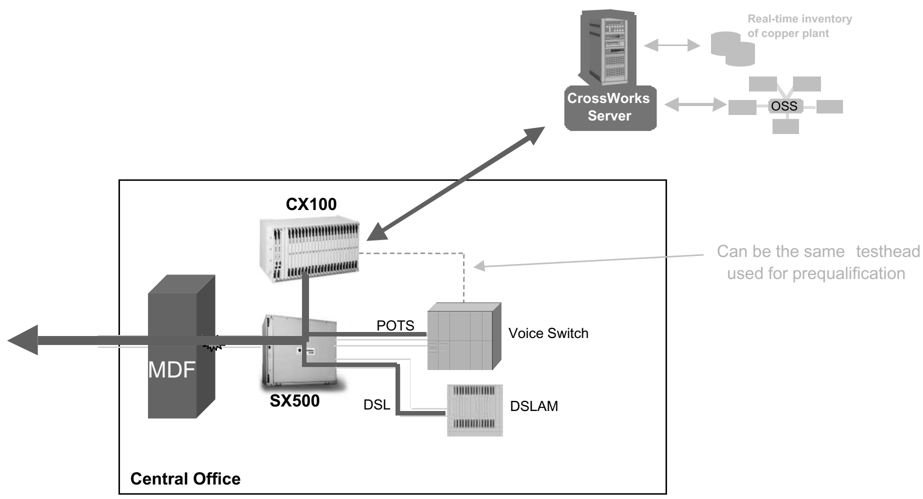
Cable Verification and Loop Qualification



matches the DSLAM port—automatic number identification (ANI). Loop qualification should include testing the loop (bridge taps, load coils, loop length, and so on) and comparing the test results to benchmarked information. The end result will be more satisfied customers and faster troubleshooting (see *Figure 2*).

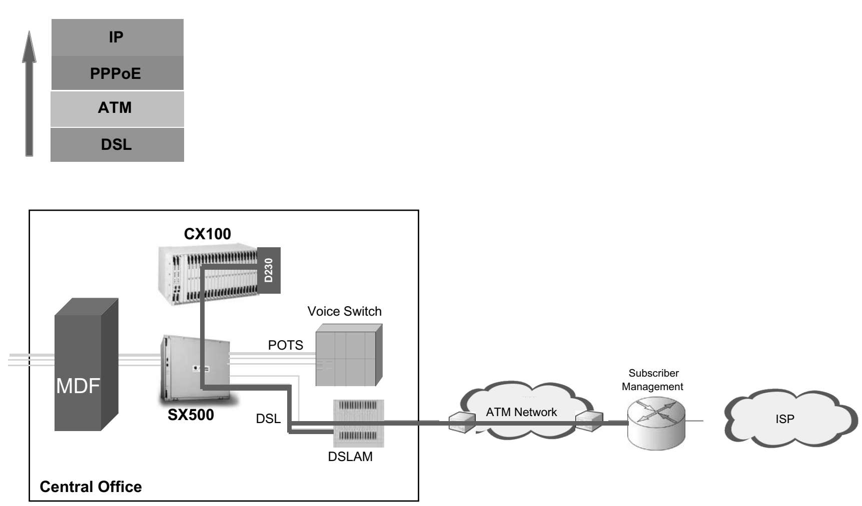
Beyond just the physical plant, service verification can confirm the upper-layer protocols. Self-install can be simulated prior to shipping CPE to a customer through verification of the IP layer (IP ping, trace route, and address resolution); verification of encapsulation (for example, point-to-point protocol over Ethernet [PPPoE], point-to-point protocol over asynchronous transfer mode [PPPoA], and so on); verification of ATM signaling channel F4/F5 operations, administration, and maintenance (OAM), and ATM ping; and verification that the DSLAM line card trains (see *Figure 3*).

If a problem is found, it can be addressed instantly. This eliminates frustration for the customer and also saves money for the service provider that can effectively deal with these issues up front and ensure that self-installs are accurate. Those two steps are very significant in terms of reducing the cost and complexity for DSL deployment and installation.

The final step is ongoing operations and maintenance. Historically, any service ever deployed to a mass market has included remote-testing capability; indeed, it is more expensive in the long view not to include testing. For instance, the POTS network, the ultimate commodity network, has testing capability and automated systems.

FIGURE 3

Service Verification



Dispatching a technician every time there is a trouble call is extremely expensive. That is the case with DSL currently, and that needs to change. The migration to a mass-market type of service requires automated testing capability built into the infrastructure.

One of the issues is single-ended testing. This helps avoid truck rolls unless absolutely necessary. Another issue is accurate fault isolation to identify where the problem is—an outside-plant issue, an ATM issue, or an IP–layer issue—as opposed to exactly what the problem is. The appropriate groups then can be involved in solving the problem. Finally, testing also must work with splitters. As testing infrastructure begins to be deployed into DSL networks, problems are emerging with testing through the splitter. There is limited testing from the equipment side of the splitter. The DSL side cannot perform such basic loop-qualification tests as loop length. The POTS side cannot perform wideband tests; POTS test systems, for instance, are not designed to handle DSL–specific issues such as load coils. The same is true with testing through DSLAM (see *Figure 4*).

One key issue is test access at the right places in the network. The ability to identify network and loop issues requires visibility. A concept called a smart splitter provides metallic access on all sides of the splitter. This eliminates the problem of the splitter impeding ability to view what is occurring on the circuits. Clear visibility is necessary, both out toward the loop and back toward the network, to do an effective job of loop management in DSL networks. A smart splitter offers cost-effective integration of metallic access and splitters, simplified cabling, and full loop-management capabilities (see *Figure 5*).

DSL and the Remote Terminal

The remote-terminal (RT) space is a challenge for DSL service providers. Many people behind digital loop carriers currently cannot get DSL, even if there is a DSLAM in the CO. Those digital loop carriers are fiber-fed from the CO, and thus there is no copper going back to that CO. Service providers are very interested in reaching 100 percent of the potential customer base, and to do that they must find ways to get DSL into the RT space. DSL deployments, in fact, are emerging in the RT space. The same loop-management issues apply—prequalification, automated service verification, and troubleshooting and maintenance. In the RT space, however, everything is magnified because of the higher number of locations. There might be 10,000 RTs, rather than 1,000 COs. In addition, truck rolls are extremely expensive, and visiting the RT to do something is costly. As much automation as possible is necessary.

In the DSLAM approach to DSL in the RT space, service providers place a DSLAM–type device, basically a separate cabinet, side by side with the existing cabinets. That device is DSL focused, and at the same time it is focused on all the data services. The splitters, the testing, and the DSLAM all are put in that cabinet, and it is cabled across to the existing digital loop carriers for POTS. This is seen in certain RBOCs and incumbent local-exchange carriers (ILEC).

A different approach is to use an integrated, next-generation digital loop carrier. Some digital loop carriers have DSL line cards that can be plugged in, and some new products are emerging that integrate POTS and DSL on their report. Many developments are underway. In either scenario the same concerns remain—visibility to test those loops, both

FIGURE 4

Limitations of "Dumb" Splitters

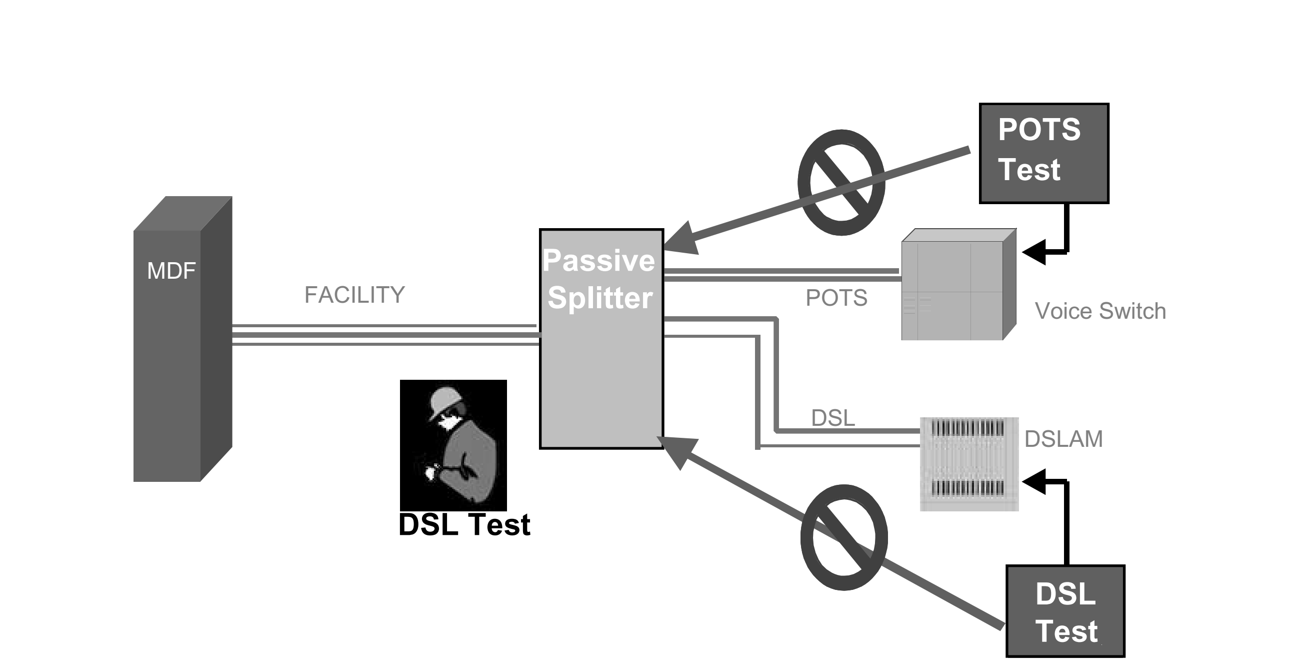


FIGURE 5

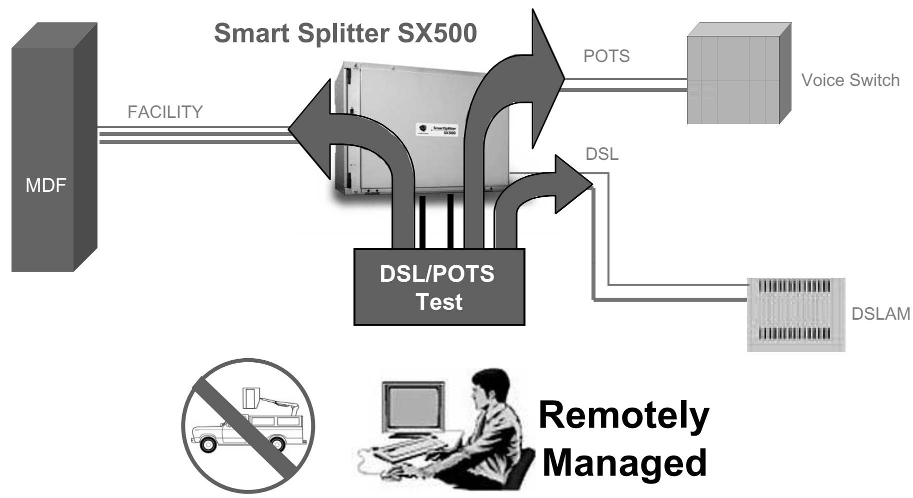
Smart Splitter



out toward the outside plant as well as back toward the network, and the correct infrastructure to perform the necessary testing and automate it.

Conclusion

Loop management is critical for profitable DSL. DSL can be deployed without loop management, but it will cost more in terms of truck rolls and other expenses. With loop management the service providers can accelerate revenue growth through fewer delays and errors in deploying DSL, lower operation expenses by reduced requirements for troubleshooting and on-site labor, and improve customer satisfaction by increased first-pass success and shorter time to deploy and repair.

The Architectural and Economic Advantages of 1D MEMS–Based Wavelength Cross-Connects

Douglas J. Arent
Director, Strategy and Business Development
Network Photonics

Bevan Staple
MEMS Development Engineer
Network Photonics

Multiplexed domain switches enable low-cost, simple, reliable, and scalable architectures for a wide variety of wavelength selective cross-connects, dynamically reconfigurable add/drop multiplexers (ADMs), and hybrid optical core switches (OCSs).

As dense wavelength division multiplexing (DWDM) becomes ubiquitous in long-haul and metro core networks, carriers are looking to optical switching to manage the ever-growing number of wavelengths and to automate wavelength routing, restoration, and grooming. To meet these requirements, OCSs need to scale to accommodate high wavelength counts, high tine division multiplexing (TDM) bit rates and various types of transport protocols, such as synchronous optical network (SONET) and Gigabit Ethernet (GbE).

O–E–O versus O–O–O Architectures

OCSs, also known as optical cross-connects (OXCs), can generally be classified into three categories: 1) opaque, electronic core switch, 2) opaque photonic core switch, and 3) transparent photonic core switch. Opaque, optical-to-electrical-to-optical (O–E–O) OCSs offer the ability to groom services down to subwavelength bit rates such as synchronous transport signal (STS)–1. This grooming capability results in scalability challenges due to bit-rate limitations and high power consumption of the electronic switching fabric. Furthermore, O–E–O OCSs are bit-rate and protocol dependent (opaque), which limits flexibility and requires forklift upgrades.

Opaque photonic switches combine O–E–O conversions and optical switch fabrics, addressing the power and scalability issues of O–E–O OCSs while remaining bit-rate and protocol dependent. In contrast, transparent or optical-to-optical-to-optical (O–O–O) OCSs, where no O–E–O conversion takes place, are bit-rate and protocol transparent. O–O–O switches thus offer more flexibility to carry diverse protocols and bit rates and are particularly useful in topologies where TDM rates may be upgraded without requiring O–O–O OCS upgrades. Furthermore, since OOO switches route signals using passive optics (without O–E–O conversions), their power consumption can be significantly less than that of equivalent scale O–E–O switches.

O–E–O and O–O–O OCSs do not necessarily compete with each other. When viewed from a network-wide perspective, O–E–O and O–O–O switches offer complementary benefits. O–E–O switches are best used at the transport edge, where the grooming of services is needed, and O–O–O switches are best used in the core of the network, where management at the wavelength level is needed.

OOO Switch Technologies

While multiple technologies are being developed for the core of O–O–O switches (e.g., including bubbles, MEMS, nonlinear optical materials such as Lithium Niobate, holograms, and liquid crystals), the micro-electromechanical system (MEMS) has emerged as the leading technology of choice. Generally, these MEMS switches are classified as two-dimensional (2D) or three-dimensional (3D). The 2D planar arrays, also known as N^2 architectures (since N^2 mirrors are required to switch N wavelengths) are now available in low port counts (e.g., 2x2, 4x4, and 8x8), but the 2D architecture has limited scalability (e.g., 32x32) due to diffraction challenges and limitations on the size of the MEMS die. 3D MEMS architectures are currently under development in an attempt to achieve high port counts without sacrificing optical performance. However, 3D architectures, also known as 2N architectures (since 2N mirrors are required to switch N wavelengths) pose complex and expensive control and packaging challenges.

In 3D architectures, since each micromirror must have multiple stable positions, a sophisticated closed-loop servo system with feedback must be implemented for each mirror to ensure that the mirrors move to and remain in the desired position once commanded. Using a closed-loop control scheme implies that one must monitor the beam positions over time, space, and environments and actively feed this information back to the system in a timely fashion. The required 2N servo systems force solutions that are large in size and power consumption, and have high costs.

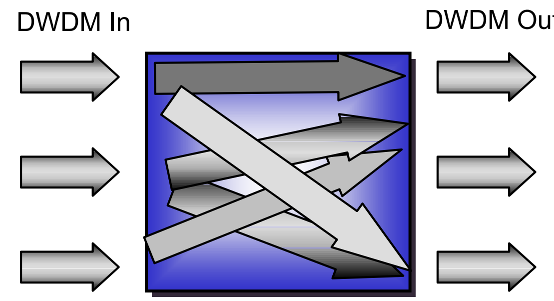
WXC Architectural Advantages

In contrast to OCSs, wavelength selective cross-connects (WXCs) are transparent, optical multiplex-domain core switches that offer significant advantages over OCS–based architectures.

WXCs offer multiple advantages over OCSs. As shown in *Figure 1*, a WXC natively switches wavelengths in the multiplexed domain. The multiplexed DWDM wavelengths enter the WXC and are switched among input and output fiber ports, and then exit the WXC as multiplexed signals on the desired fiber. Switching in the multiplexed domain eliminates the need for external demultiplexing and multiplexing, as well as multiple O–E–O conversions. The WXC offers significant fiber management and cost savings by requiring only a *single port per DWDM fiber*, as opposed to a single port per wavelength in OCS–based systems. For example, each fiber in the 3x3 WXC shown in *Figure 1* may carry 80 wavelengths, thus the 3x3x80 architecture offers effectively 240x240 wavelength switching capacity, but only requires six fiber ports.

FIGURE 1

An All-Optical WXC



As a purely photonic cross-connect switching in the multiplexed domain, a WXC has extremely small power requirements (< 10 watts), in contrast to many kilowatts for traditional O–E–O OCSs. By eliminating the external demultiplexing/multiplexing and O–E–O conversions and reducing fiber-management complexity, the WXC has an extremely small footprint. Because it photonically switches optical signals, the WXC is both bit-rate and protocol transparent. Wavelength bit rates may be upgraded at the transport edge (i.e., from 155 Mbps to 40 Gbps), while the WXC does not require any additional operational input or change.

As summarized in *Table 1* for comparable OCS and WXC configurations, significant cost savings complement all of the noted advantages. Capital expenses are reduced through the elimination of O–E–O conversions, closed-loop servo controls and the required demultiplexing/multiplexing equipment. Operational expenses are reduced through lower space, power, and management costs. The dynamic nature of the WXC allows for remote software control and advanced protection features, offering significant advantages from an operational level and in the ability to rapidly provision services. The CrossWave™ technology enables all of these advantages.

CrossWave™ 1D MEMS Technology

CrossWave integrates demultiplexing/multiplexing and switching into a single operation, in contrast to other all-optical switch-based systems that require external demultiplexing/multiplexing. This powerful functionality is achieved through a hybrid integration of one-dimensional (1D) MEMS and a wavelength dispersive element. Within CrossWave, wavelengths from input fibers are spatially separated by the dispersive element. Each separated wavelength is focused onto the surface of a micromirror in the 1D MEMS array where the switching occurs. The independently switched wavelengths are then recombined into DWDM signals and exit into the output fibers.

TABLE 1

Comparison of Key Features of a 512x512 OCS and a 8x8x64 1D MEMS–Based WXC

	OCS	**WXC**
# of DWDM fibers switched	8x8	8x8
# of λ's per fiber	64	64
Switch configuration	512x512	8x8x64 (512x512)
# of physical ports	1024	16
# of DWDM mux/demux channels, transponders, and receivers	1024	0
Equipment footprint		
Power required		
Total cost	**$$$$$$$**	**$**

The CrossWave 1D MEMS technology consists of a single, linear array of micromirrors. The 1D architecture is highly scalable in that only one mirror is required to switch each wavelength (e.g., an N-type switch versus N^2 for 2D or 2N for 3D architectures). Furthermore, each mirror is positioned accurately in one of several highly stable positions within switching times of less than a millisecond. The 1D linear array of micromirrors is powered with simple digital electronics in an open-loop configuration. With digital positioning, there are no complex servo systems necessary to ensure stable and repeatable positioning of the micromirrors. Furthermore, digital control eliminates the need for complex sensing and low-noise electronics. This results in a dramatic reduction in size, cost, and power consumption compared to 2D and 3D systems, while increasing system reliability. An example of the 1D MEMS architecture is shown in *Figure 2a*, in which N mirrors address N optical signals.

Another key difference between the 2D or 3D and 1D MEMS switches is the mirror packing density of the die. While 2D or 3D MEMS typically occupy much of the real estate on large silicon die, 1D MEMS utilize much smaller mirrors arranged in a linear configuration, occupying only a small fraction of the die. This results in higher manufacturing yields due to lower susceptibility to contamination and handling damage. In fact, the die dimension and layout for 1D MEMS are driven by packaging needs instead of the mirrors, thereby increasing the yield and reliability of the overall packaged device.

Summarized in *Table 2*, the key features of MEMS–based optical components indicate the relative advantages and disadvantages among 1D, 2D, and 3D devices. 3D MEMS devices, while holding strong promise for scalability, offer a number of challenging issues such as mirror control, packaging complexity, and overall reliability. 2D MEMS devices have been deployed in small cross-connects but do not scale well and also offer packaging challenges. The combination of Network Photonics' CrossWave 1D MEMS architecture, ease of manufacturing, ease of control, simple packaging, operating robustness, and scalability offers an elegant, reliable, and low-cost solution.

Physically, CrossWave is fully athermal, eliminating any requirement for active temperature control and extremely low power (e.g., < 1 watt per device). Network Photonics leverages Crosswave technology to produce highly reliable, low-cost optical switching and transport equipment to meet the stringent requirements of the telecommunications industry.

Network Applications

CrossWave-based WXCs can address a number of applications in a variety of network topologies, ranging from linear to ring to mesh topologies. In ring topologies, distributed or centralized WXCs or ring interconnects enable wavelength routing, protection, and restoration while eliminating many O–E–O conversions. Similarly, in mesh networks, WXCs can be applied to all-optical wavelength routing. In linear net-

Cost	Low	Medium	High

works, WXCs effectively address two pressing applications and are subsequently described in more detail: flexible add/drop capability in long-haul (LH) and ultra-long-haul (ULH) DWDM networks and hybrid OCS switching.

Backbone Network Applications

One critical challenge in deploying LH and ULH DWDM networks is cost-effectively serving the numerous add/drop sites to the backbone. Since current generation LH and ULH DWDM network equipment allows all-optical transport up to many thousands of kilometers without regeneration, carriers must address the need to add, drop, or groom wavelengths at network nodes in between the end terminals.

Figure 3 depicts a long-reach DWDM network link including intermediate add/drop sites. At the intermediate sites where wavelengths need to be flexibly added, dropped, or groomed for appropriate services, the key challenge is to effectively minimize any perturbation to desired express traffic and cost-effectively add, drop, or groom the required wavelengths. While the required wavelength-level functionality can be addressed with a variety of solutions—including fixed filters, power splitting combined with full demultiplexing and selective extinction, or banded filter architectures—these solutions are neither cost-effective nor sufficiently flexible to address traffic patterns that are neither static nor reliably predictable. Furthermore, cascading multiple elements in a single link requires excellent optical performance, such as flat-top passband and dispersion free design. Ideally, service providers prefer to deploy a flexible add/drop network element to effectively address low initial cost requirements, low operating expenses, required flexibility, and scalability to handle changing and unpredictable traffic demands.

Dynamic Wavelength Selective Add/Drop Cross-Connects

At the intermediate nodes, the wavelength selective add/drop cross-connect allows one to individually address any wavelength or set of wavelengths within the multiplexed cross section, thus allowing dynamic, flexible reconfiguration of express and add/drop traffic. In these configurations, wavelengths can be reassigned from the express path to the add/drop paths with no effect on the wavelengths remaining in the express path.

Functionally, multiplexed DWDM signals enter, are switched among fiber ports, and then exit the add/drop WXC as multiplexed signals on the desired fiber. For express traffic, switching in the multiplexed domain eliminates the need for external demultiplexing and multiplexing, and multiple O–E–O conversions. This capability directly eliminates 50 to 70 percent of the costs of intermediate add/drop nodes compared to alternative solutions.

For drop traffic, small wavelength count demultiplexers may be used to isolate individual wavelengths from the multiplexed signal. In addition to the advantages previously outlined, including bit-rate and protocol transparency, extremely low power, and a remarkably small footprint, the add/drop WXC offers significant fiber management and cost savings by requiring only a *single port per fiber*, where each fiber can carry a large number of wavelengths.

Hybrid OCS

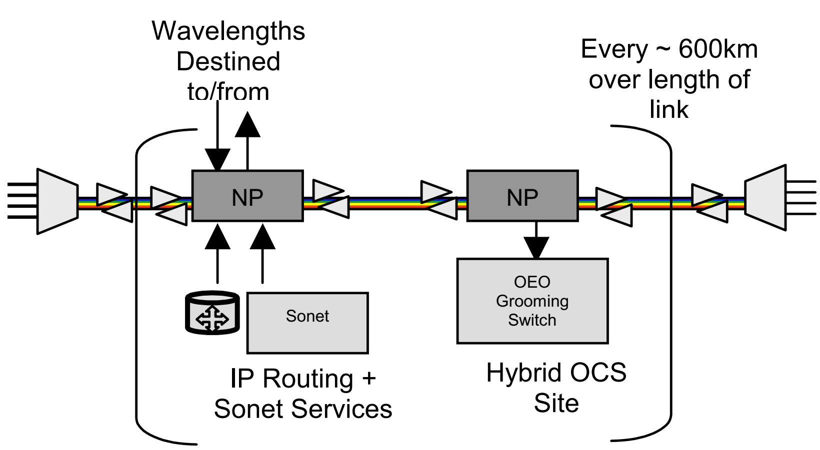
Similar to the wavelength selective add/drop cross-connect, hybrid OCS architectures allow dynamic, flexible reconfiguration of express or grooming traffic. In these configurations, wavelengths can be reassigned from the express path to the grooming switch fabric with no effect on the wavelengths remaining in the express path. By selectively grooming only the required services, the hybrid OCS offers effective wavelength management as well as cost-effective and appropriately sized grooming capabilities, resulting in lower overall costs, space utilization, and power consumption.

CrossWave Technology

CrossWave multiplexed switching enables a new paradigm in all-optical networking, making fully functional, highly

FIGURE 3

Extended-Reach LH or ULH DWDM Network with Dynamically Configurable Intermediate Add/Drop and Grooming Nodes



The left-hand node offers dynamic wavelength routing to/from other service nodes as well as SONET and data services. The right-hand node offers dynamically configurable hybrid OCS wavelength grooming services. The intermediate nodes are typically spaced ~600 km to serve lower-tier cities and mid-span connection points.

reliable multiplexed switching possible while enabling new economic efficiencies required by service providers. Utilizing a highly integrated architecture of 1D MEMS and passive optics, CrossWave leverages advances in high-reliability volume manufacturing, 1D MEMS scalability and reliability, fast switching times, and packaging simplicity to bring new features to all-optical DWDM networks. CrossWave multiplexed domain switches enable low-cost, simple, reliable, and scalable architectures for a wide variety of scalable WCXs, dynamically reconfigurable ADMs, and hybrid OCSs. In long-reach DWDM networks, flexible add/drop network elements and hybrid OCSs may be deployed to effectively address low initial cost requirements and low operating expenses as well as to provide the required flexibility and scalability to handle changing and unpredictable traffic demands.

Intelligent Agents on the Web: An Overview of Design and Applications

Sunil Babu
Graduate Student, Computer Science, College of Engineering and Sciences
Louisiana Tech University

Vir V. Phoha
Associate Professor, Computer Science, College of Engineering and Sciences
Louisiana Tech University

Abstract

Since its inception, the Web has become more popular with each passing day. New concepts are being researched and implemented for efficient usage of the Web. Web intelligence is one new, emerging area, which promises to bring together artificial intelligence (AI) technology and advanced information technology (IT) for the next generation of Web-empowered products, systems, and activities. Intelligent agents that use Web intelligence are software tools with AI techniques whose application brings intelligent features to the Web and Internet. This paper introduces intelligent agents (IAs), their design, and some of the applications in which they are being used.

1. Introduction

IAs are autonomous and adaptive software programs that accomplish their goals by proactively executing predetermined commands. Agents are software tools that act to help users to perform certain task efficiently. In a broad sense, an IA can be thought to be a back-seat driver that gives suggestions at every turn or as a taxi-driver who transports a passenger to his destination. There are advantages in preferring the usage of agents [8]. To name a few, agents adapt dynamically to their environment, execute autonomously, are robust and fault-tolerant, and encapsulate protocols. Agents are used in e-commerce where they can act on behalf of customers; they are used as personal assistants to assist users; they are used in secure banking, in distributed information retrieval, in telecommunication networks services, and in parallel processing; they are used for information dissemination, such as automatic news and software updates for vendors; they are used to monitor a particular information source, and they are used in workflow management, in air-traffic control, in network management, and in smart databases-to name a few applications.

Etzioni and others [13] have reasoned that since the development of analyzing tools have not kept pace with the information growth, the information superhighway has not been forgotten by people and still seems to be prominent in human lives. The growth of agents pave the way for this information superhighway disappearance, as they have the property of abstraction (the technology and resource agents use are abstracted from the user) and distraction (the agents' inherent abilities distract a person from performing complex and tedious tasks).

2. Intelligent Agents

Wooldridge and Jennings [1] define an agent as any software system, possibly including a hardware system, with the following properties:

- *Autonomy:* Agents operate on their own without the intervention of any humans. They have control over their actions and their internal states.
- *Social Ability:* Agents interact with each other exchanging useful information in a pre-defined language (agent communication language) of their own.
- *Reactivity:* Agents gather information from their environment and respond appropriately to the changes that occur in the agent environment.
- *Proactive:* They are proactive, performing their desired goal with their own initiative.
- *Mobility:* Depending on their application, agents are mobile, moving around the electronic world and exchanging information with their peers.
- *Veracity:* Agents do not communicate any false information that is not supposed to be communicated by them.
- *Benevolence:* Agents do not have conflicting goals, and all agents collectively co-operate with each other to achieve the desired goals.
- *Rational:* Agents will act toward achieving their goals and do not act in a manner that prevents them from achieving their goals.

Every agent has the first four properties along with a subset of the remaining properties. A simple agent can be thought of as a program (e.g., a UNIX process) that has a determined goal and exhibits the properties of an agent that were listed.

3. Building an Agent

Wooldridge and Jennings [1] have given steps to design and realize agents. Agent building can be categorized into three main phases.

1. *Agent Theories:* Deals with the specification and conceptualization of agents. It identifies what properties an agent must have and how these properties are formally represented. Agent theories define formal methods for representing the properties of an agent, including methods to represent dynamic aspects of agents. Agent theories must include representational methods for representing the relation between the attributes of an agent as well as defining the cognitive state change in an agent, the effect of the environment on the agent, and the way in which agent information leads to its action.
2. *Agent Architecture:* Deals with the design and implementation of an agent in a computer system. It specifies the decomposition of the agent design into component modules and has a provision for interaction between these modules.
3. *Agent Language:* Deals with the communicational aspects within peer agents. The agent communicating language (ACL) must be capable of communicating the state, properties, goal, information, and behavioral aspects of agents. A few examples of agent languages include concurrent object language, agent-oriented programming language (AOP), telescript, planning communicating language (PLACA), concurrent MetateM, APRIL, the Foundation for Intelligent Physical Agents' agent communication language called (FIPA), FIPA ACL, and MAIL.

3.1 Layered Architecture of Agents

In designing agent architecture, Kendall and others [2] give a layered architecture design for agents. This design has seven layers (see *Figure 1*). The higher-level layers are dependent on lower layers for functionality, and there exists a two-way flow of information between layers. This framework design is reusable, robust, and is based on object-oriented patterns. This framework demonstrates that agents can be designed and implemented using objects. This framework is employed in network-management applications, network-intrusion detection, and enterprise-integration applications.

The seven layers, from the bottom up, are explained in the following:

1. *Sensory:* This layer proactively senses the agent environment and updates the agent information. This layer co-operates with domain-specific interface classes.
2. *Beliefs:* This layer stores the belief of an agent. The input from the sensory layer is used to update the belief of an agent, which will be used for reasoning.
3. *Reasoning:* This layer determines the next step/action of an agent. This layer interprets the beliefs, and, based on the interpretation, an action is initiated or the state of the agent is changed.
4. *Action:* This layer is responsible for executing an action responsible for the goal of an agent. Each action is an intended goal of an agent, which takes the agent toward its final goal.
5. *Collaboration:* This layer is responsible for carrying out interactions and exchanging services and negotiations between agents. It addresses the issue of collaboration and co-ordination of different protocols between agents.
6. *Translation:* This layer is responsible for any translation of different protocols that is being exchanged between the agents.
7. *Mobility:* It supports for the virtual or actual migration of agents between environments. It provides for the cloning of an agent for actual migration into another environment.

4. Taxonomy of Agents

Franklin and Graesser [10] suggest various ways in which an agent can be classified. An agent can be classified based on the subset of the properties listed in Section 2. Every agent has the first four properties. Agents having additional properties are classified differently according to the properties. For example, agents having the property of "mobility" are classified as mobile agents. A hierarchical classification is thus possible based on the property subset. Thus mobile learning agents are of a sub-class of mobile agents.

Other possible schemes of classification are suggested. Based on the task that agents perform, they are classified as information-gathering agents or e-mail-filtering agents. Based on their control mechanism, agents can be classified as rule-based, algorithmic, fuzzy, neural net, or machine learning. Agents can also be classified based on the environment in which they operate, such as software agents and artificial life agents. Agents can even be classified based on the language in which they are written and on the application for which they are written.

Brustoloni and C. Jose [11] provide a three-way classification of agents:

1. *Regulatory Agents:* These agents do not perform any planning. They have knowledge built in them to cope with the stimuli of an environment. They have a set of prescribed actions that satisfies the overall objectives of the agent. An example of this kind of an agent is a thermostat that controls the temperature. These kinds of agents know what to do based on the inputs they receive from their environments. Such agents can be "tunable" according to their environment and "configurable," that is, a pre-determined behavior can be selected.
2. *Planning Agents:* These agents, along with the functionality of regulatory agents, have the capability to plan. Some of the methods used as planning strategies are as follows:
   - Control systems and automata
   - Problem-solving paradigm of AI
   - Case-based paradigm of AI
   - Methods described in operations research
   - Randomizing algorithms

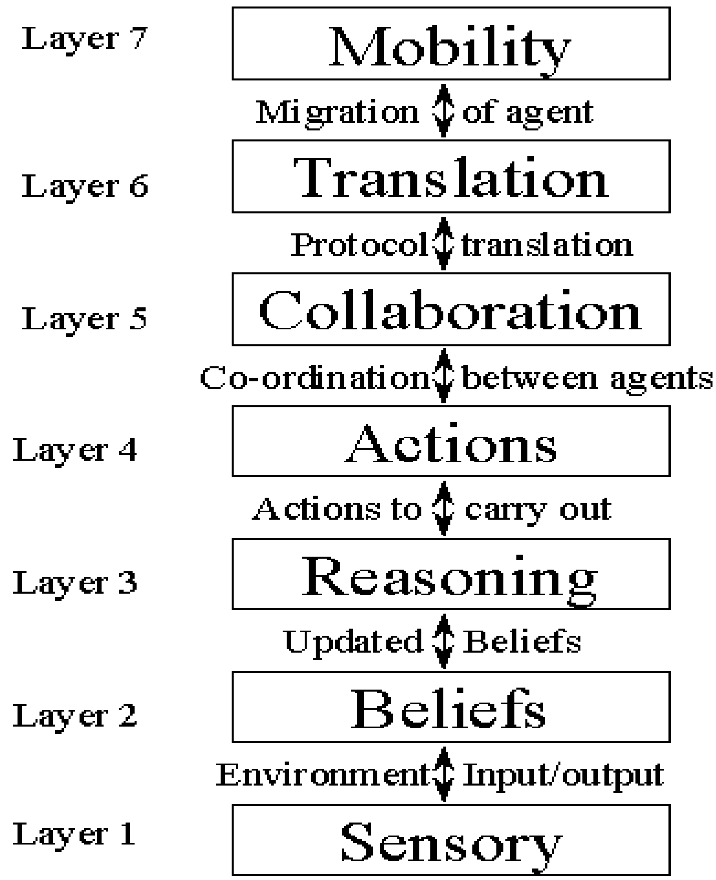
     A common problem in using these approaches is that they are very expensive.
3. *Adaptive Agents:* These agents have the capability of planning along with the ability to acquire knowledge for planning. They are capable of acquiring domain knowledge, which gives the agents the ability to perform new actions. An advantage of this method is the improvement of performance through new techniques. These agents are particularly suitable for an environment that is dynamically changing.

5. Agent Security

In the world of the Internet, agents are used mainly for information gathering or in e-commerce. These agents have

FIGURE 1

Seven-Layered Framework of an Agent



to move about from host to host performing their intended goals. The hosts that they visit may not be trusted and have the malicious intention of attacking the agents. Grimley and others [14] have given ways in which a malicious host may attack an agent and possible solutions for these attacks. The types of security attacks a malicious host may perform on an agent are as follows:

1. *Invasion of Privacy:* The malicious host has access to the agent's memory space and hence can read the potential information present in the agent that was not intended to be shared by the hosts. The data read could be a secret key, electronic money, or the lowest price bid of an item.
2. *Data or State Manipulation:* The malicious host can alter the data or information present in the agent. For example, it could change the cost of an item or, even worse, it could change the agent's belief or commitment so that the agent favors the host.
3. *Code or Control-Flow Manipulation:* The malicious host can alter the code of the agent to suit its needs or desire. Even worse, the host can implant a virus into the code of the agent.
4. *Purposeful Misinterpretation of Agent Code:* Agents are normally coded using an interpretive language such as Java or TCL. The malicious host can change the interpreter itself such that the execution of the code favors the needs of the host.
5. *Cloning:* The malicious host can clone a copy of the agent and analyze its code and behavior. In the next visit of the agent, the host can then perform any of the attacks previously listed.
6. *Denial/Delay of Service or Misdirection:* The malicious host can redirect the agent to a host not in the itinerary of the agent, or the host may not release the agent.

Possible solutions exist to prevent/detect the attacks and involve varying levels of overhead, which determine the compromise balance between the security level and runtime efficiency of the agent. The possible solutions for these attacks are as follows:

1. *Data Encryption:* An obvious solution is to encrypt the agent's data. The agent that does not require its data until it has reached its home encrypts the data and delivers it in the encrypted form to the home base. The home server possesses the decryption key to decrypt the data.
2. *Code Encryption:* In this method, the code itself is encrypted. An encrypted code has to be decrypted on the host before it executes. This poses the same threat as an unencrypted code. An approach to counter this is

called blackbox security, where the execution layer accompanies the encrypted code, and this execution layer executes the agent code on the host machine.

3. *Time-Sensitive Agents:* In this approach, the amount of time an agent executes on a host is determined. If the time is exceeded, then the agent shuts itself or transfers itself to another host. This approach is suitable given the fact that it takes time for a host to examine and evaluate an executing agent for possible attack.
4. *Code Obfuscation:* This technique obfuscates the code so as to make it less readable and comprehendible. This technique removes modularity, splits the meaningful variables, and inserts code that does not alter the goal of the agent. An agent visiting the host again has a different form of code.
5. *Phoning Home:* A method to minimize the damage after tampering is to have the agent phone home and send the data collected. This prevents the loss of data and its disclosure to future hosts. This technique allows the host to determine if the agent is functioning properly, and if not, at which node it has failed.

6. Applications of Agents

Much research is being carried out in applying agents in new areas. Agents are useful tools and are predicted to be ubiquitous in the near future. A common application example of an agent is a personal digital assistant (PDA) [1]. The PDA filters e-mails and sorts them in order of importance. It draws attention to any important message that has been received, like a paper being accepted in a conference. It proactively searches travel agencies and provides a list of economic travel schedules to attend, for example, a conference. All of this is done even before the e-mail is read.

Existing agent applications include finding citations on the Web [3], improving network operation [4], use in electronic commerce [5], Web-browser intelligence [6], and the intelligent profiling of users [7]. In the following sections, we will explore the details of agent implementation for a few important applications.

6.1 Improving Network Operations

A network has to be constantly supervised and managed for any errors or high traffic. Simple network management protocol (SNMP) provides means to poll the network devices to know their performance. This constant polling can lead to more network traffic. To reduce this, intelligent agents are used locally that constantly pool the network device and send a network signal to the manager only if the device is not functioning properly [4]. Agents can even have corrective-action capabilities to rectify any error. Intelligent agents can be used in similar applications, such as managing many branches of a bank. Localized branches have agents present. Agent sends a message to the manager in a higher hierarchy only if any problems, such as a storage error, occur in the localized branch. The manager, which is also an agent, can then dispatch a specialist, in this instance a storage specialist, to rectify the error.

The agents are used in the following network-management areas [4], where the data collected by them is useful in determining the type of the error. The type of data being collected is based on the application of the agent.

- *Performance Management:* Performance monitoring can help managers to understand network behavior. Agents can gather information regarding application usage, client/server performance, and data correlation to determine which of the nodes has peak usage and at what times.
- *Fault Management:* It is important for fault to be identified immediately to reduce the negative impact on the services. The agents can be used to identify the faults, immediately notify a manager, execute automated resolution procedures, and isolate the faulty node for the manager to get at the heart of the problem.
- *Capacity Planning and Reporting:* This service is crucial to deliver service levels to the user. Agents can be used in load balancing, identifying loaded nodes and diverting traffic to lesser-loaded nodes.
- *Security Management:* Intelligent agents help to discover security holes in the system. They monitor the firewall configuration and determine if it is functioning well. They monitor access to secure subnets for security breaches.

6.2 IAs for Electronic Commerce

IA models have been developed to assist in electronic commerce. The multi-agent negotiation testbed (MAGNET) [5] is an e-commerce architecture developed to assist in a business-to-business (B2B) situation where companies outsource production to contractors. Agents have been developed to automatically negotiate and monitor the execution of contracts. There exist two main agents: the "customer" agent that needs resources from outside and bids for contracts and the "supplier" agent that provides services. The supplier agent offers its services to the customer agent. The customer agent in turn bids for the contract based on the cost, risk, and time constraints. A list of best bids is generated, the best bid is selected, and the execution manager (part of customer agent) is notified, which in turn oversees the contract to its completion.

6.3 Reconnaissance Agents

Reconnaissance agents (RAs) are programs that look ahead of user's browsing activity and act as a recommendation tool for the user to select the most appropriate links and ignore the needless paths [9]. They look ahead of the user's link for the "404 Not Found" error or for the relevance of the user's search. The RA can warn the user of the irrelevance of the link or draw attention to a more relevant link. Libermann and others [9] have suggested two RAs: "Letizia" for local reconnaissance and "Powerscout" for global reconnaissance.

6.4 IAs for Citation Finding on the World Wide Web

For the scientific community searching for relevant papers, research is an important task. On-line citations having links to a research paper are valuable sources of information. Searching for citations through search engines on the Web does not yield satisfactory results. Loke and others [12] have suggested a method to develop an intelligent agent for finding citations on the World Wide Web (WWW). They search the Web for citations based on the author's name and the title of the paper. They provide many search strategies, such as searching the Web for a hypertext markup language (HTML) version of the paper, searching the author's home page, searching the university home page, or searching the technical-report archive. They query search engines to obtain starting points for their searches. They also provide navigational rules to follow further links (searches) in a page.

6.5 Web-Browser Intelligence

The WWW consists of two tightly coupled systems: Web browsers and Web servers. The user requests information on the WWW from browsers in the form of universal resource locators (URLs), links, and forms, and servers respond with a page appropriate to the user's request. This tight coupling has undesirable consequences-namely that the displays that Web servers generate are impersonal presentations that many Web users find unattractive and difficult to use. Barrett and others [6] have introduced a model, Web-browser intelligence (WBI), where a programmable intermediary is introduced between the browser and the server. WBI interprets browser commands and dynamically reconstructs the document returned by the server for viewing. The advantage of WBI is it can modify the appearance of the Web pages returned by the servers for more elegance. It adds colors around links to indicate and warn the user about the speed and traffic at the server. WBI can also maintain a "user requests" history and provide methods to query this history, generate popular pages, and recommend shortcuts to links.

WBI has a set of four main modules: monitors, editors, generators, and rules. Monitors record the list of URL links requested, which is useful for maintaining a request history. Editors change the content and appearance of Web pages by adding links or extra buttons. Generators handle Web requests, such as performing searches on a person's history based on a keyword. Rules define a list of specific monitors, editors, and generators to be used for a given request, such as using HTML-modifying editors only.

7. Conclusion

Significant research is being conducted in the area of IAs. They show promise in their usefulness and do not have significant disadvantages or performance hindrance. IAs have found their presence in many applications on the Web. Many models and tools are being developed at a fast pace, and new ideas are being researched. Not long from now, the IA's presence is going to be felt in many areas and applications.

Abstract

This work provides an overview and a comparison of various techniques used to restore lightpaths in a layered architecture. The comparison takes into consideration figures of merit such as speed of restoration and redundant capacity. The objective is to optimize the performance of the network (including fast end-to-end service survivability, minimizing the spare resources required) under all circumstances, using available resources and implemented mechanisms.

1. Introduction

It is widely accepted that optical cross-connects (OXCs) will be used to implement the next-generation mesh optical networks [1]. Optical network equipment vendors are currently implementing the next generation of optical switching systems capable of switching hundreds of lightpaths, each carrying millions of voice calls or thousands of video streams. Optical network architectures not only provide transmission capacities to higher transport levels, but also the intelligence required for fast lightpath provisioning and fast and efficient failure restoration [2,3,4]. The emergence of intelligent optical network elements is instrumental in making such optical architectures a reality today.

Optical network architectures can suffer failures and breakdowns, either due to accidental fiber cuts and operation mistakes or equipment malfunctions, such as switch, card, or component failures. Two competing approaches are being proposed for providing the appropriate recovery mechanisms in these circumstances. In the *peer-to-peer* approach [5,6,7], interweaved optical and higher-layer equipment act in symbiosis under the same control plane. In the *overlay* approach [5,6], optical and higher-layer domains are two separate entities with individual control planes, exchanging management services through a standard interface. The peer-to-peer approach relies on a unified bandwidth-management protocol to reassign bandwidth away from defective areas in the network and re-establish the interrupted data services. In the overlay approach, each layer independently relies on its own restoration mechanism in a manner that is independent and transparent to one another.

A single network layer or a combination of multiple layers can be used for failure restoration in a layered architecture. The aim is to provide service protection against a variety of failure conditions while restoring all failures quickly and with the minimum amount of protection capacity. Failure restoration involving multiple layers can enhance end-to-end survivability of the service by having each layer's protection scheme supplement each other. It is important to note, however, that multilayer protection may not be required or may be difficult to implement because of race conditions and complex escalation strategies and inter-layer protocols.

Section 2 presents the layered network architecture and describes each layer. Section 3 examines how restoration can be addressed in such anarchitecture, and Section 4 addresses restoration specifically in the optical layer. Section

5 discusses whether multilayer restoration is necessary and addresses possible escalation approaches in a network architecture where multiple layers can be used to restore a service. Concluding remarks follow in Section 6.

2. Overview of a Layered Network Architecture

In this section, we review the fundamental parts that constitute a network and its functionality. It goes without saying that many architectures exist or have been suggested, and it is not the intention of this paper to enumerate them exhaustively (see [5,8,9,10] for further information and useful references on this topic). However, we observe that all of the proposed architectures repose on a common denominator. It is this generic model that we present here. The model consists of three superimposed layers. Each layer provides well-defined services to its superjacent layer while concealing implementation details to it. As shown in *Figure 1*, from top to bottom, the layers are the service layer, the logical (electrical) layer, and the optical layer.

2.1. Service Layer

In the service layer, clients such as edge or service routers or MSPPs located in a provider point-of-presence (POP) represent users and the data communications among them. Using a graph representation, a node corresponds to a client that emits and receives data, and a link represents a service or a two-way data stream between clients. Link attributes in this layer correspond to minimum quality of service (QoS) requirements, which transpose into bit rates, jitter, and bit-propagation or round-trip delay constraints. Service-level agreements (SLAs), for instance, are negotiated and crafted in this layer.

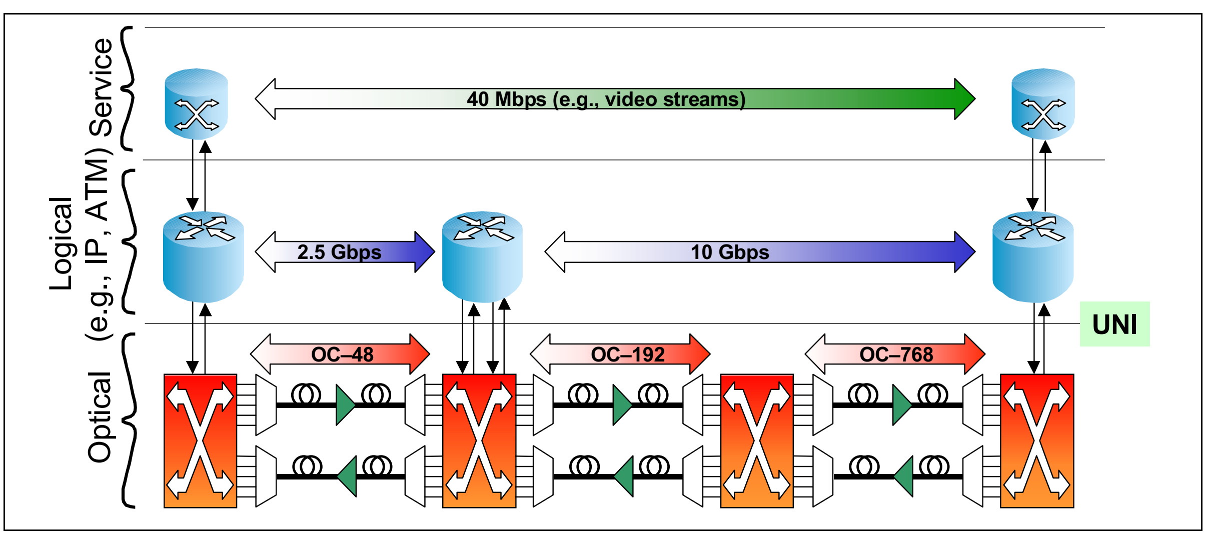
2.2. Logical Layer

Also known as the electrical or digital layer, the logical layer aggregates services into large transmission "pipes" and assures their proper routing from POP to POP with prescribed QoS. Using a graph representation, a logical node corresponds, for example, to an Internet protocol (IP) core router, an asynchronous transfer mode (ATM) backbone switch, or a digital cross-connect, and a logical link connects the ports of two adjacent nodes. Capacity of a link and data processed by the nodes are expressed in units of bits per second (bps) in increments of digital signal (DS)–3 (45 Mbps) to optical carrier (OC)–192 (10 Gbps). The logical layer may consist of several interconnected sub-networks, either for scalability reasons, as it is easier to manage several smaller networks than a large network (hierarchical decomposition), or because the sub-networks belong to several independent carriers (multivendors, two-tier networking) or employ different technologies (e.g., IP versus ATM). In either case, boundaries and proper network interfaces within the logical layer delimit the sub-networks and their respective domains of operation.

The logical layer fulfils several roles: it maintains a consistent topological view of the layer; it manages the address space; it routes streams on request; and it polices the traffic to ensure a fair share of capacity among data streams and to guarantee each individual's QoS. The first part, also called topology discovery, is achieved by way of a neighbor discovery protocol (NDP) in conjunction with the open shortest path first (OSPF) protocol[1]. NDP operates in a distributed manner through in-band signaling to construct local port-to-port connectivity databases at each node. OSPF completes the topology discovery by assembling and globally disseminating pieces of information collected by NDP, plus additional information such as link states, to the logical plane. Logical nodes have only a few tens of ports, and with the exception of very small networks, a full connectivity featuring one link between every pair of node is not probable. Instead, services may have to be routed in the logical layer through one or more transit nodes to the desired destination using the constraint-based routing–label distribution protocol (CR–LDP)/resource reservation protocol (RSVP) explicit routing and bandwidth reservation protocols. The computa-

FIGURE 1

Layered Architecture



tion of a logical path must satisfy a set of constraints, such as round-trip delays and spare bandwidth, defined in the service layer in accordance to prescribed QoS. Note that the failure of a logical link or logical node is detected by NDP, and advertised by OSPF. That is, the layer has the primitives to detect a failure and resume interrupted services.

2.3. Optical Layer

The optical layer offers and manages the capacity required to transport traffic between clients in the logical layer. *Figure 2* depicts an example of a logical network (two IP routers) linked to an optical network (four optical switches). Optical switch ports are either add/drop ports interfacing the optical layer to the client's logical layer or network ports interconnecting optical switches. Using our graph representation, nodes are optical switches, and links are bundles of bidirectional optical channels between pairs of optical switches. An optical channel is a wavelength that connects the network ports of adjacent optical switches. A link in the logical layer is realized by way of optical channels in tandem forming a lightpath (circuit) between the end nodes of that link.

The optical layer faces the same challenges, and conceptually even borrows solutions from the logical layer. For instance, it relies on generalized MPLS (GMPLS) [11–13], also formerly known as MPLambdaS (an extension of MPLS) to encompass all types of architectures, including wavelength-oriented traffic engineering and management. It also relies on the NDP/link-management protocol (LMP) [6,7,14] and OSPF protocol [15] to create and publicize the network's topological views. Differences that set apart the optical layer from its logical counterpart are, among others, as follows: routing in the optical layer is exclusively circuit-oriented; circuit set-up and tear-down is done at a much slower time scale; and the bandwidth granularity of the logical layer is much lower than the granularity of the optical layer.

In the overlay approach, the layers work individually, with the client logical layer leasing resources from the optical layer. The user network interface (UNI) harmonizes communication of control messages between the two domains. The Optical Interworking Forum (OIF) is currently specifying UNI requirements and is working on their standardization [16]. In addition, an optical carrier will normally acquire network components from several vendors. A suite of protocols is being developed in the Internet Engineering Task Force (IETF) to allow for the seamless interaction between the various network components. As part of the suite, the LMP, for example, is used to maintain control channel connectivity, verify component link connectivity, and isolate link, fiber, or channel failures within the network [17].

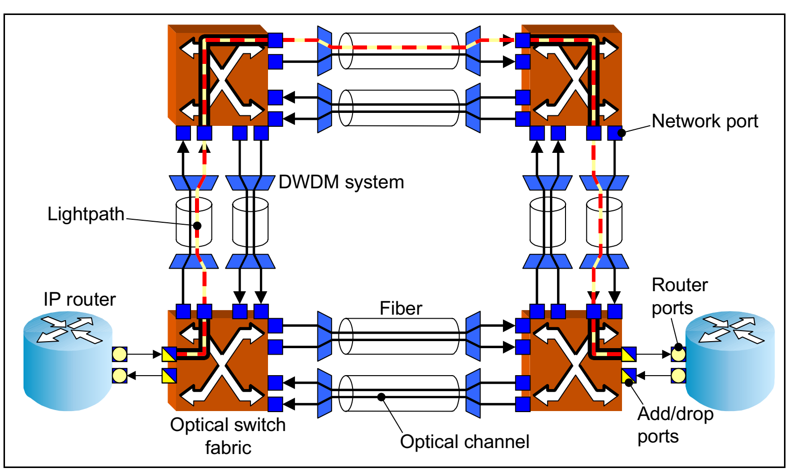
3. Failure Restoration in a Layered Architecture

Restoration is invoked upon failure of one or more elements along paths carrying end-to-end services. Both logical and optical layers may implement an autonomous recovery scheme, and both may react to the same defect. Failures are either one of two types: logical (such as a malfunctioning IP router) or optical (for instance, a fiber cut). There are thus four possible scenarios, depending on the origin of the failure and the layer that provides the restoration [18]:

1. Failure and restoration in the optical layer as shown in *Figure 3(b)* based on the original routing shown *in Figure 3(a)*. *Figure 3(a)* illustrates the connectivity in the optical layer and the resulting connectivity in the logical layer during normal mode of operation. *Figure 3(b)* is an example of optical failure restored in the optical layer. The affected lightpath is restored away from the failure using optical capacity that was reserved for this purpose. The operation is transparent from the logical layer, which remains unchanged.
2. Failure and restoration in the logical layer as shown in *Figure 3(c)*. This figure illustrates a logical failure (ATM switch or IP router failure) restored in the logical layer. After failure, the service is rerouted using the remaining capacity of the logical layer. The operation is transparent to the optical layer.

FIGURE 2

Optical Layer



3. Optical failure repaired in the logical layer as shown in *Figure 3(d)*. This figure illustrates an optical failure restored in the logical layer. If the optical layer fails to restore the optical failure after a certain time lapse, the logical layer can restore the service on a different logical path, using for instance implicit LSP protection in MPLS.
4. Logical failure repaired in the optical layer as shown in *Figure 3(e)*. Unlike any of the previous protection schemes, restoring a logical failure with leverage from the optical layer involves reconfiguration with creation of new connections in the logical layer and the optical layer. This type of restoration may be necessary if, after logical failure, the remaining capacity in the logical layer is insufficient to reroute all of the affected services. Additional logical capacity can be created with the provisioning of new lightpaths.

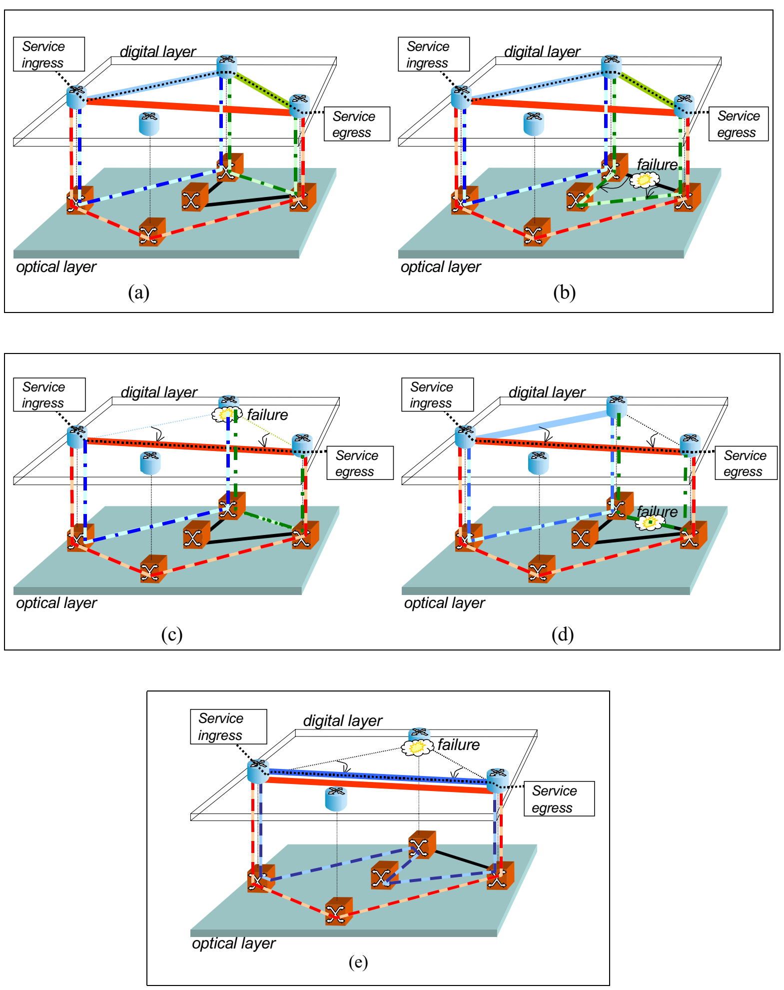
A fifth and most realistic situation consists of optical failures repaired simultaneously and independently in both layers. Since this is a combination of the aforementioned scenarios, it is not considered here.

Restoration in an IP–centric logical layer is accomplished by MPLS [19]. MPLS enables a hierarchy of label-switched paths (LSPs) to be defined by pre-pending a stack of labels or tags to packet headers. Upon an optical or electrical failure occurrence, packets along a given disrupted LSP can be routed to a predefined restoration LSP by modifying the label maps of the routers at the end-points of the original LSP [20]. In a similar manner, restoration of optical failures in the optical layer is also achieved by way of redundancy. Studies indicate that restoration in the optical layer requires substantially more spare capacity, depending on the diligence and the quality of the protection, yet overall the solution is more economical due to a lower cost per units of capacity [20].

MPLS offers undeniable potentials for fast restoration. The principal advantage of MPLS is its ability to recover indiscriminately from failures in the logical layer or the optical layer, as suggested in *Figure 3(c)* and *Figure 3(d)*. However, a single failure may affect thousands of LSPs and trigger an avalanche of alarms and corrective actions. The resulting

FIGURE 3

(a) Routing before a Failure Occurs; (b) Failure and Restoration in the Optical Layer; (c) Failure and Restoration in the Logical Layer; (d) Optical Failure Restoration in the Logical Layer; (e) Logical Failure Restoration in the Optical Layer



amount of signaling can be orders of magnitude higher than in the optical layer, which is able to switch hundreds of LSPs multiplexed into a single wavelength at once. Also in MPLS restoration, primary and back-up LSPs must not succumb together to a malfunction in the logical or in the optical layer. Tto satisfy the second condition, the logical layer must explicitly inquire about the risk relationship between the lightpaths that compose its logical connectivity and compute the LSPs, primaries, and respective back-ups accordingly. Proposed specifications for the UNI interface allow the logical layer to request lightpaths that are disjoint from selected subsets of pre-established lightpaths. However, this approach yields lower availability than other approaches that allow the optical layer to decide on the restoration mechanisms. Such requests may thus sometime be impossible to realize, even if the capacity is available in the optical layer. Another strategy is to rely on NDP, OSPF, and IP self-routing properties to advertise and correct failures in the logical configuration, but then the restoration time is not as attractive in terms of restoration speed as it would be with predefined restoration LSPs.

The fourth scenario implies a minimum of synergy between the restoration architectures deployed in each layer; the optical layer does not know a priori the logical connectivity of the client, and hence cannot take the initiative to restore a logical failure. Both layers, however, could coordinate their effort to resume interrupted services, with the optical layer getting directives from the logical layer. In particular, the logical layer could provision spare capacity in the optical domain and reclaim some of it upon failure of one of the routers to create new logical connections and balance the load on the surviving routers. The feasibility of this scheme is subject to UNI specifications.

To summarize, although the aforementioned scenarios one and three address the same problem of recovering from failure in the optical layer, the first, which recovers the failure in the layer where it occurs, is preferable in terms of cost and speed [21,22]. The same is also true with the second over the fourth scenario. In addition, because the preferred mechanisms are confined within their own layers, that helps to simplify the restoration approach and to avoid architectural complexities and the interdependence of mixed-layer approaches.

4. Restoration in the Optical Layer

In end-to-end OXC–based path protection, the ingress and egress nodes of the failed optical connection attempt to restore the signal on a predefined back-up path, which is link-disjoint from the primary path. Path diversity guarantees that primary and back-up lightpaths will not simultaneously succumb to a single failure. There are two sub-types of path protection: 1+1 dedicated protection and mesh restoration.

4.1. Dedicated Protection

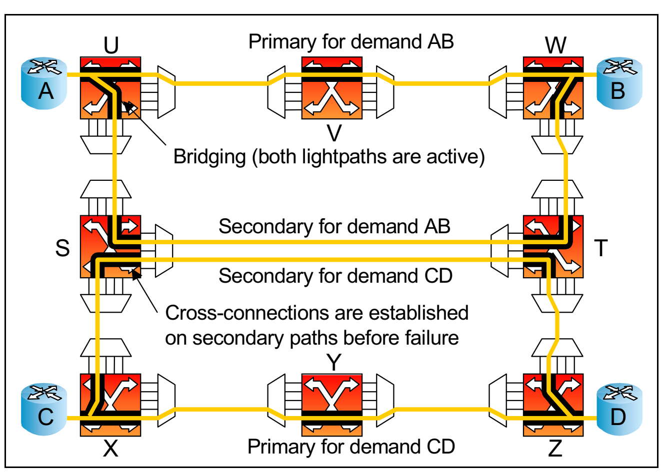
Dedicated 1+1 protection is illustrated in *Figure 4*. The network consists of four logical nodes (A to D) and two demands (AB and CD) accommodated across an eight node optical network (S to Z.) The provisioning algorithm of this architecture computes and establishes simultaneously the primaries and their link-disjoint protection paths. During normal operation mode, both paths carry the optical signal, and the egress node selects one of the two copies. In the example of *Figure 4*, all of the optical channels on primary and secondary paths are active. In particular, the configuration reserves two optical channels between nodes S and T for protection. This is the fastest restoration scheme, since, for every lightpath, one device at the termination of the lightpath is responsible for all of the necessary failure detection and restoration functions. But it is also the most exigent in terms of resource consumption.

4.2. Mesh Restored Lightpaths

As in dedicated protection, in mesh restoration back-up paths are predefined, but the cross-connections along these paths are not created until a failure occurs. During normal operation modes, the spare optical channels reserved for protection are not used. Because the capacity is only "soft reserved," the same optical channel can be

FIGURE 4

Dedicated 1+1 Protection



shared to protect multiple lightpaths. There is a condition, though, that two back-up lightpaths may share a reserved channel only if their respective primaries are link-disjoint, so that a failure does not interrupt both primary paths. If that happened, there would be contention for the reserved channel, and only one of the two lightpaths would be successfully restored. *Figure 5(a)* (for normal mode) and *Figure 5(b)* (for restoration mode) picture an example of mesh restoration. The dashed lines represent reserved channels. In this case, the protection paths for demands AB and CD share a single optical channel in link S-T, one less than in dedicated protection. However, the restoration involves a bit more processing to signal and to establish the cross-connections along the restoration path. There is thus an evident trade-off between capacity utilization and recovery time.

Simulation experiments were run on a 100-node (N100), 137-edge network that has a degree distribution of (50, 28, 20, 2) nodes with respective degrees (2, 3, 4, 5). It was assumed that this architecture has infinite link capacity. Three network robustness scenarios were considered: no protection, dedicated protection with provisioning to recover from single link failures, and mesh restoration to recover from link failure. In N100, 3,278 node pairs out of 4,950 possible node pairs are connected by one bidirectional lightpath. Requests for lightpaths arrive one at the time (on-line routing) in a finite sequence and in an order that is arbitrary but common to each scenario to ensure a fair comparison. Figures of merit are capacity requirements separated into their primary and restoration parts and expressed in units of bidirectional OC–48 channels. Results are presented in *Figure 6*. The quantities shown in the chart are averages over a series of 10 experiments using various demand arrival orders. These results clearly demonstrate the advantages of shared mesh restoration over dedicated protection in terms of redundant capacity required to protect against all single link failures [23].

5. Multilayer Protection

Notwithstanding the architectural complexities and interdependence of mixed-layer restoration approaches, this section investigates how more than one layer can offer protection in a multilayer network. The goal of such an approach would be to use the protection capabilities of each layer to provide additional survivability capabilities in the network.

A number of different multilayer protection strategies can be implemented in a layered architecture. As pointed out in the previous section, restoring the network at the layer where the failure occurred is a fast approach better suited for the recovery of failures in that layer. In addition, protection and restoration in different layers may be mixed together for the best overall result. For instance, fast optical protection architecture for fiber and OXC failures can be supplemented by service-based restoration at the logical layer. In this case, the optical layer can offer bulk recovery of the services while the logical layer can offer finer restoration granularity.

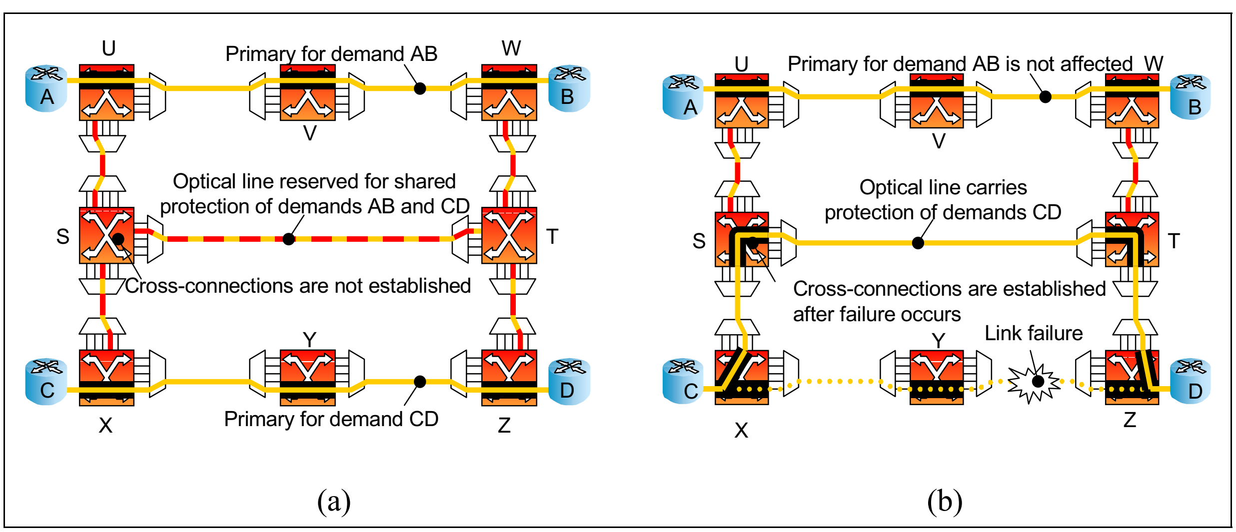
5.1. Escalation Strategies

If a multilayer protection approach is adopted, an escalation strategy has to be provided to coordinate the protection processes of the different layers. The absence of an escalation strategy can create race conditions between the protection mechanisms with unpredictable (and potentially catastrophic) results. This section identifies the issues associated with the escalation strategies and presents a comparison of the different escalation options.

The escalation strategies can include either a parallel or a sequential activation of restoration mechanisms. In the parallel approach, restoration mechanisms from different layers are trying to restore the same failure simultaneously, which will result in a very fast restoration time. However, the different restoration mechanisms must be coordinated so as not to obstruct each other or compete for the same restora-

FIGURE 5

Mesh Restoration (a) Network Connections before a Failure Occurs; (b) Network Connections after a Failure Occurs



tion resources. In the sequential case, restoration mechanisms from different layers attempt to restore the failure one layer at a time. One sequential approach could be to wait until one layer has failed to restore the services or a fixed time interval has passed before the restoration process is taken over by another layer [24,25].

Typically, the sequential approach will be slower in terms of overall restoration times, but it is more easily implemented. Such a strategy only needs to predetermine the order in which the layers will attempt restoration and when the transition from one layer to another takes place. The type of failure will usually determine the layer where the sequential restoration process will start. For example, if a fiber is cut, restoration can start at the optical layer, where it can achieve fast restoration of bulk traffic. On the other hand, if an IP router fails, restoration can start at the logical layer. This will allow for finer granularity of the restoration process, but it will be much slower.

A hold-off timer function can be used in the sequential approach to mark the transition from the protection mechanism of one layer to the protection mechanism of another layer. Although this is a simple approach, it can result in a cascade effect and potentially introduce considerable delay to the restoration process. Another sequential escalation strategy can use a diagnostics method to ascertain that a protection mechanism will not be successful before the hold-off timer expires and subsequently hand over the restoration control to the next layer. Even though this scheme will result in much faster restoration times, this is a much more complex approach to implement. Other escalation strategies include signaling approaches (e.g., through the UNI or through the management system) to coordinate the passing of the protection responsibilities to another layer.

Take for example a multilayer network consisting of IP, Gigabit Ethernet (GbE), and wavelength division multiplexing (WDM) layers. Restoration in such a network can take place at the WDM and/or IP layers, as GbE does not support restoration capabilities. If the WDM layer only is used for restoration, fast restoration can be utilized to quickly restore services during a network-failure condition at the optical layer. If the IP layer only is used for restoration, router-based rerouting will result in longer restoration times, but it will require less redundant capacity because of the finer restoration granularity in this layer. In general, using the IP layer only for restoration may not meet the service's QoS requirements. However, for some data services, such as e-mail and file transfer protocol (FTP), restoration at the IP layer only may be sufficient.

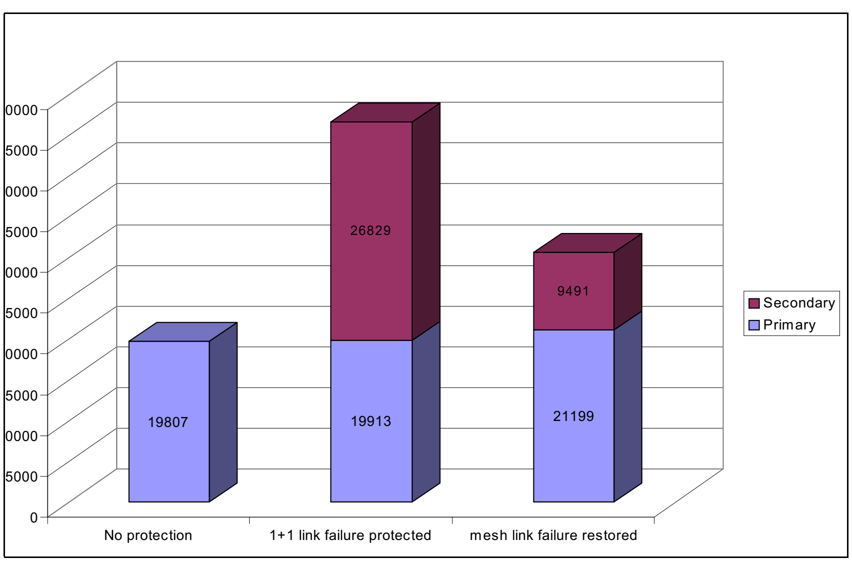
If a two-layer strategy is employed, a parallel escalation strategy may suffice. Because of the different time scales between the restoration mechanisms in the WDM and IP layers, the WDM layer will restore the traffic before the IP layer even detects the error. A sequential approach on the other hand would require coordination between the optical layer and the routing protocols used in the IP router-based rerouting. The best approach for such a network would be to use the optical layer for the restoration of time-sensitive services and use IP router-based rerouting for the restoration of less critical and time-insensitive services.

6. Conclusion

This paper describes multilayer networks and how a single layer utilizes its protection capabilities to restore services after a failure occurs. Specifically, restoration in the optical layer is described, and dedicated and mesh lightpath-based restorations are presented. A number of escalation strategies are also presented for the case in which a combination of different restoration methods from different layers is to be used. From the discussion, it is evident that the simplest solution is to allow the layer where the failure occurred to restore for that failure. This will help in avoiding functional

FIGURE 6

Comparison of Capacity Usage for Different Protection Architectures (100 Nodes)



duplication, race conditions, as well as complex interaction and inter-layer coordination problems. Even though allowing for a multilayer restoration mechanism can enhance the overall survivability of the network, complex escalation techniques will violate the layering principle by violating inter-layer independence. Because the optical layer is the lowest layer in the transport hierarchy, using the restoration mechanism in that layer is ideal for fast recovery of critical services during failure conditions such as fiber cuts and optical switch failures. In contrast, IP router-based rerouting is a best-effort approach more suitable to the restoration of less critical and time-insensitive data.

Notes

1. In this paper, the assumption is of a single network running IP–centric multiprotocol label switching (MPLS) protocols.

Metronomics

Scott Berry

Director

Metromedia Fiber Network

This paper discusses metronomics, or the economics of bandwidth delivery in the metro, particularly via fiber. Consideration will be given to the market, architectures, fiber, and the new networks and infrastructure in the metro going forward.

Bandwidth Distribution

Bandwidth is not merely growing—there is a fundamental shift occurring in the distribution of bandwidth demand. In recent years a substantial amount of bandwidth demand has been driven by corporate data needs. The Internet is still relatively small, but it is growing rapidly; voice is fairly large, but it is shrinking. The projections for 2005 indicate significant Internet growth, although as is currently the case a large portion of this growth will be corporate driven.

From another perspective, newer applications require more and more bandwidth—and by extension higher-speed connections—in much the same way that software applications have driven the development of higher-speed processors. The result is an exponential growth in bandwidth demand per application, something likely to continue as video and other high-speed applications take hold.

The primary enterprise application driving this exponential growth right now is data storage. As companies are becoming more Internet- and data-centric, a larger and larger part of what they produce is going to be data—and this must be stored. But as the amount of inexpensive bandwidth available to the corporation increases, a number of other applications become possible that weren't before, and some of these applications will be revenue generating. Thus the drop in bandwidth pricing not only improves an enterprises' bottom line; it can grow the top line as well. While storage is the current "killer app" for metro bandwidth, video (supporting such applications at telemedicine and distance learning) may well be next in line.

The most popular approach to network architecture has been to build "big pipes" in the long-haul backbone. However, in reality all data starts and ends with the end user, and so any network that does not connect directly with the data sources and sinks will not capture the bulk of the bandwidth demand. You can't have a nervous system built on a spinal cord alone. Because of the large amounts of bandwidth being required by enterprises, this connectivity will, by necessity, be fiber based. Customers are connecting with fiber to regional offices, to hosting centers, and from there to the Internet. Just as voice drove infrastructure in the past, data will drive it in the future. Today's Internet hosting centers will become the central offices of tomorrow.

Contrary to the perception in some quarters of a fiber and bandwidth glut, such a situation cannot arise until each part of the network has a glut, and that's nowhere near the case today.

The key advantage of fiber, of course, is that its capacity is virtually unlimited; it is determined only by the equipment placed on its ends—and technological advance in optical end-gear is happening at exponential rates. Fiber thus provides future-proof infrastructure. Although better fiber is being manufactured all the time, what is going in the ground today can hold many orders of magnitude more bandwidth than is currently demanded by the typical enterprise. In addition, extra conduits can be placed when fiber is installed to permit more fiber to be pulled as needed in the future.

Although bandwidth is generally priced by the bit, so that greater usage leads to higher costs for users, fiber is priced at a flat rate. This provides a very attractive financial model for enterprises and other high-bandwidth users because it not only cuts costs but also facilitates new, revenue-generating applications. Savings actually grow as bandwidth usage increases. Indeed, we have seen that as the price for bandwidth drops, more is consumed, indicating true elasticity of demand.

For example, in a typical metro area, procuring digital signal (DS)–3 service from a local provider might cost roughly $12,000 a month for some 200 megabits of capacity. Alternatively, several buildings could be connected with private fiber, and if synchronous optical network (SONET) gear were installed, and the cost amortized over three to five years, over 10 times the capacity might be realized at the same monthly cost as for traditional telco service. Moreover, adding the next DS–3 would be as simple as installing relatively inexpensive line cards and thus paid for only once, while additional capacity from a carrier would be paid for each and every month.

Several different options exist for customers to obtain bandwidth. As in the past, they can obtain carrier service. They can also lease dark fiber and then purchase optical equipment—dense wavelength division multiplexing (DWDM) equipment, a router with optical interfaces, or SONET gear, for example—and manage it independently. Customers can run their own networks much the way that companies run their internal networks. The last option is for customers to lease dark fiber and then go to a third party who offers a value-added service to equip and operate the fiber network for them.

Typically, the current architecture in the metro involves a service provider aggregating multiple customers' traffic out of a building into one or two central offices using public switches and public facilities. Private, fiber-based solutions, however, are different because they are unshared. Nobody else's traffic is on that fiber; the end equipment is utilized 100 percent by the customer and nobody else. Nor does the traffic on that fiber need to transit central offices or other shared aggregation points. It is, therefore, a truly private network. By using a third-party outsourcing method for managing that network, customers avoid a capital outlay for the equipment. They would have a monthly lease for fiber and a monthly charge for equipment, maintenance, and monitoring, all bundled as a single service. While this resembles the pricing model for telecom service, the cost can be orders of magnitude lower for the same capacity.

Take the case of a customer with six buildings connected in a metro area with two optical carrier (OC)–48 rings from a carrier (a total of about 5 gigabits). This service could easily cost $200,000 a month. With a fiber solution using DWDM equipment, for example, that customer would be able to do 24 gigabit-Ethernet channels (many times the capacity) between those same six buildings for less money.

Or, take a customer with a rapidly growing need for infrastructure. They have an interoffice local-area network (LAN), do a substantial amount of transaction processing with the financial services industry, and have six sites. The connectivity required is meshed gigabit Ethernet. With a fiber-based solution, they would be able to put one ring together with DWDM gear and provision six wavelengths to mesh those six gigabit Ethernet channels, fully protected with 50-millisecond switching. Plus they would have the flexibility to change the gigabit Ethernet to fiber channel or some other protocol at any time. This would be some 50 percent less expensive than what it paid for an equivalent telecom service, and the marginal cost to add another managed, wavelength-carrying gigabit-Ethernet channel would be about the price of a DS–3 on a monthly basis. The end result overall would be a twenty-fold improvement in its cost structure—plus the advantage of a truly private network.

These sample business cases also help demonstrate the price elasticity of bandwidth. In some instances, customers installing DWDM networks are actually ordering additional wavelengths before their networks are even up and running. Realizing how inexpensive it is, they are identifying a host of applications that had been thought infeasible because bandwidth was too expensive. In effect, the cheaper bandwidth becomes, the more of it they use.

Trends and the Future

Customers want flexibility in terms of where the traffic goes, as well as in terms of protocol and applications supported. Security and reliability are also critical. Enterprises do not want their data going through public switches if they can avoid it. Finally, they want the ability to use multiple (and non-standard) protocols—they are tired of being limited by the voice-driven SONET architectures of the past. Because of this, a private optical network is an appealing idea for many end-users.

Outsourcing is also a strong trend. Many customers may find the economics of fiber attractive, but they do not know how to run optical networks. And hiring engineers with the right talent is difficult, as is retaining them. In addition, once customers have fiber leaving the building, even if they are managing the optical gear themselves, they still have an outside vendor to deal with (namely the fiber provider) if there is a problem. In other words, you can't insource outside plant.

Finally, avoiding capital expense is an important benefit to such outsourcing. Rather than facing a significant investment up front to obtain less expensive bandwidth, customers can simply continue paying the same type of monthly bill they are used to, yet receive 10 to 20 times the bandwidth as before.

Demystifying eLearning Portals: The Convergence of Enterprise Intelligence and Learning

Bray J. Brockbank
Senior Vice President, Business, Technology, and Marketing
IBC, Inc.

Challenging Times

In recent years, the focus of organizational learning and training has shifted from traditional, new employee orientation and personal development seminars to continuous learning and development programs designed and implemented to provide employees with the knowledge resources necessary to successfully fulfill their roles and responsibilities. The goal of the new knowledge economy is to channel knowledge into ideas and use those ideas to create business solutions and competitive advantage. These ideas can then be channeled and used by the organization to thrive in an environment of intense competition, relentless change, and highly educated customers.

Organizations are burdened with channeling knowledge and ideas in the form of training and learning to employees more rapidly, more effectively, and in an even more efficient manner than ever. In an effort to meet these objectives, organizations are seeking to consolidate disparate knowledge and learning technologies into a centralized point of access and management, while leveraging existing investments (legacy systems, resources, etc.) in enterprise infrastructure in order to provide employees with simple, seamless access to knowledge, training, and learning.

Solid and intense competition is forcing organizations to implement collaborative solutions that integrate internal systems and leverage existing (legacy) technology to harness the knowledge and intellectual capital that exists in the public domain, while utilizing knowledge and intellectual capital that resides across the organization and among suppliers, partners, and customers.

Current Realities

The new economy is fueled by knowledge. Organizations possess incredible intellectual capital. The challenge has been, and continues to be, providing access to that capital and assembling it for the development of best practices and collective learning. Once defined marketplaces are melding into one global marketplace. Human capital is now an asset to be scrupulously managed. Learning is a strategic advantage and weapon. Workforce supply is in flux—everyone's a free agent. The world is in a state of rapid-growth and hyper-efficiency—and its all beginning to blur at Internet speed.

The critical and differentiating force of countries, organizations, and individuals lies in their knowledge and intelligence and how they use it in the new knowledge economy. eLearning is critical to the success of individuals, organizations, communities, and economies in the commencement of the knowledge economy. eLearning portals offer customization, 24/7 accessibility, convenience and flexibility, cost-effectiveness, just-in-time user-centric learning, and centralized management of knowledge.

In a recent IDC and eWorld survey (www.idc.com, IDC #24788, June 2001), training and education was rated in the top three applications integrated with U.S. organization Web sites. Nearly one-third of U.S. organizations have their training and education integrated with their Web sites. Training and education ranks third in priority (behind customer service and support and customer-relationship management [CRM]). More than 60 percent of large organizations are leading the way in integrating education and training with their Web sites—roughly the same as those who planned to integrate knowledge management and materials management into their Web sites.

Learning and training processes are becoming increasingly integrated into strategic organizational processes. Industries rapidly moving to integrate their training and education include health-care, government, education, banking, transportation, media, telecommunications, and utilities.

eLearning Industry

The eLearning industry is comprised of three vendor segments: technology, content, and services.

- *Technology:* This segment includes learning management systems (LMSs), learning content management systems (LCMSs), authoring tools, training delivery systems, enterprise resource planning (ERP), application service providers (ASPs), live eLearning tools, streaming video, EPSS, and testing and assessment tools.
- *Content:* This segment includes third-party content providers, books and magazine publishers, enterprises, subject-matter experts, government agencies, colleges, universities, schools, training organizations, eLearning portals, information technology (IT) firms, and system integrators.
- *Services:* This segment includes enterprise information portals (EIP), corporate universities, learning service providers (LSPs), content aggregators, learning consultants, consulting, professional services, certification service providers, collaboration services, and on-line mentoring services.

Even though many vendors are "pure-players," some vendors cross over or offer "hybrid" solutions. Several vendors market themselves as eLearning portals, end-to-end solutions, blended eLearning solutions, best-of-breed technology, global learning management solutions, integrated learning and management systems, and eLearning infrastructure technology.

Components of eLearning

eLearning components include LMS or LCMS, content, collaboration, testing and assessment, skills and competency, e-commerce, and Internet video-based learning (see *Figure 1*). A complete eLearning portal represents the total integration of multimedia, instructor-led, and real-time training—in a human, collaborative environment.

When implemented correctly, eLearning portals can help organizations to develop and maintain a competitive advantage in the following areas:

- *Recruitment and Selection:* The attraction, evaluation, and hiring of new employees
- *Retention:* The retention of intellectual capital (human capital)
- *Learning and Career Development:* Classroom training, on-line learning, and other forms of learning activities
- *Rewards, Recognition, and Response:* The recognition of individuals according to their ability to meet/exceed performance expectations as defined by the organization (according to appropriate business goals)
- *Succession Planning:* The identification and development of peak performers with the appropriate competencies and skills needed to advance within the organization

Types of eLearning Portals

eLearning portals can be categorized into five key categories: learning management, content aggregation, community collaboration, content creation, and internal.

- *LMS or LCMS Portal:* Tracks courses or learning content that the user is taking and his or her progress
- *Content Aggregation Portal:* Users can access knowledge on many topics from various sources
- *Community Collaboration Portal:* Users can interact with and learn from colleagues and peers
- *Content Creation Portal:* Where the user can create content directly on the site
- *Internal Portal:* Users can access all of the services of the organization's training and development department

Learning Management System

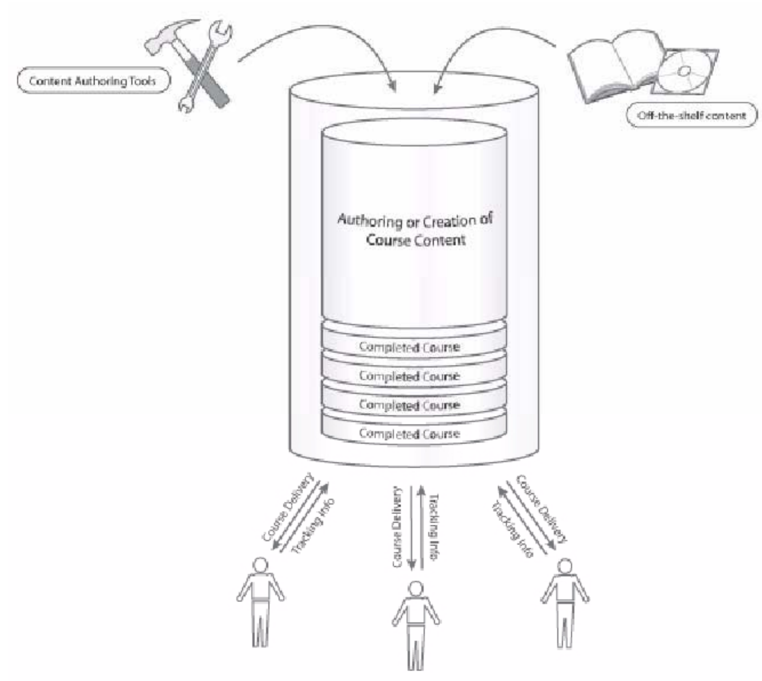
An LMS ties all other eLearning components together (see *Figure 2*). The LMS is the infrastructure or framework used to track, support, manage, and measure eLearning activities. An LMS helps to manage and measure the entire learning process, whether the organizations' needs are managing computer-based training (CBT), Web-based training (WBT), document-based training (DBT), instructor-led training (ILT), or blended training methods (BTM).

Learning Content Management System

An LCMS is a system used to create, accumulate, assemble, and distribute personalized eLearning (see *Figure 3*).

FIGURE 1

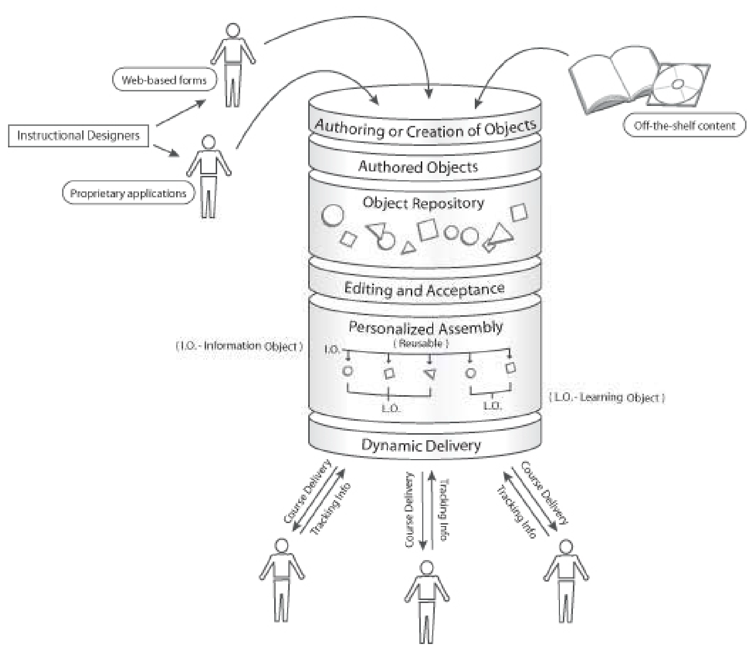
FIGURE 2



The LCMS was developed to more effectively deliver "small-chunks" of learning tailored to the users learning style and needs.

Content is delivered to the user in the form of learning objects. A learning object is an independent piece of education containing content and assessment based on specific

FIGURE 3



learning objectives. A learning object has descriptive metadata enclosed around it describing what is contained within the object. The object is assembled in an effort to help users to achieve specific learning goals and objectives.

Course Content

Organizations may assemble course content through various processes: buying off-the-shelf content, developing courses internally (in-house, home-grown), and outsourcing for custom courseware development. A complete eLearning portal should offer interoperability with all learning content.

- *Off-the-Shelf (or Third-Party):* Content developed to meet general organizational needs. Off-the-shelf content vendors include NETg, SmartForce, SkillSoft, etc.
- *Authoring Tools:* Authoring tool products include Authorware, Dreamweaver, etc.
- *Custom Developed:* Content developed to meet the unique needs of an organization and capture knowledge proprietary to a specific organization

Future-Built from the Ground Up

eLearning portals that offer scalability, flexibility, interoperability, and extendibility offer a "future-built" solution approach to eLearning.

- *Scalability:* How well the solution will work when the size of that need increases or decreases over time
- *Flexibility:* Allows the processing to be customized to meet business processes without writing additional code
- *Interoperability:* The ease with which the solution works and integrates with third-party content, collaboration, and software packages
- *Extendibility:* The capability of extending or adding new functionality to current or existing product features

Defining the eLearning Portal

There are basically two types of eLearning portals: external and internal. The first focuses on providing access to external learning services. The second focuses on providing access to all learning within the organization. Of course the internal portal may also include the use and management of external learning and providers.

Essentially, an eLearning portal is a virtual environment set up by an organization to give users access to knowledge. These portals have also been called eLearning centers, on-line education centers, internal portals, corporate universities, and virtual universities.

A portal is merely a vessel, framework, or infrastructure for training, learning, and the assessment of knowledge and competency. With the advent of eLearning portals, organizations now have tools to help knowledge workers aggregate, access, and navigate through full or bite-sized "learning chunks" or "learning objects" from internal databases, repositories, courses, and Web sites. The complete eLearning portal supports the learning cycle with various components of eLearning.

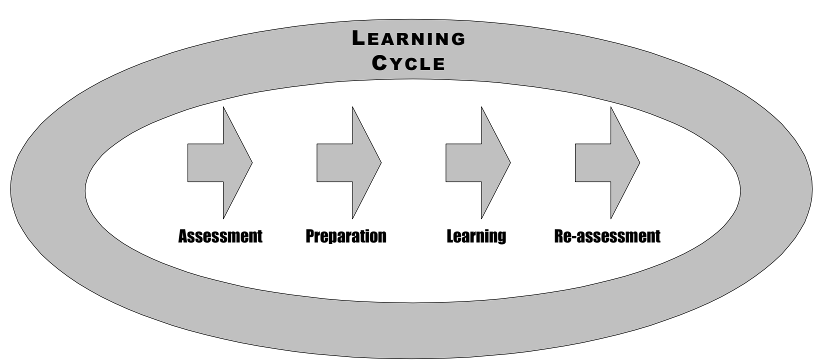
Market Categories

eLearning portals service three primary market categories: corporate, academic, and consumer. An eLearning portal is an access point to various applications, services, courses, and learning directed at one or more of three user groups: employees, partners/suppliers, and customers. The eLearning portal is a personalized, single point of access for the internal and external user where the organization's Web channels come together—the Internet, intranet, extranet, and marketplace exchanges—to exploit the cumulative information, knowledge, and data that will enable greater business efficiencies.

Intelligent Portals

The eLearning portal is an intelligent portal. The portal advises users on what skills and experience they need to advance to other levels in the organization, provide competency maps and assessment, and discussion forums related to essential learning themes—on-line learning communities. It recognizes what the user knows, certifications earned, experiences, and his or her ideal learning style. As eLearning portal technology has evolved, navigation has become more sophisticated, content more relevant, and interfaces more user-friendly and intuitive. Until most recently, eLearning was offered only in the form of full, off-the-shelf, or customized courseware. However, users also need a way to efficiently turn their proprietary knowledge into effective eLearning content through content-authoring

FIGURE 4



tools. While general knowledge provides a necessary foundation, proprietary knowledge provides organizations with competitive advantage.

Learning Cycle

As work, life, and learning continue to converge, portals will be the primary tool used to facilitate access to knowledge and learning. The ideal eLearning portal model supports the learning cycle from assessing needs through the learning process to learning evaluation. The learning cycle consists of four elements: assessment, preparation, learning, and re-assessment.

Full-Service eLearning Portal

The complete or full-service eLearning portal supports the learning cycle with different components of eLearning. Many of these components are foundational to the learning process and are critical in creating a full-service eLearning portal. All components of a full-service eLearning portal are fully integrated with seamless transition from one component to the next.

The full-service eLearning portal is comprised of three stages: assessment, competency, and learning evaluation. The assessment phase is composed of components for knowledge assessment, competency assessment, and learning evaluation. The preparation stage contains learning catalog, e-commerce, and enrollment components. The learning phase is comprised of learning activity, expert forum, and community components.

- *Assessment:* Assessing the learning needs of a user begins with an evaluation of his knowledge or competencies. This knowledge assessment is then compared with the competencies required for the job.
- *Preparation:* The user makes preparations for fulfilling his learning need through creating a plan from the list of learning activities that would best meet his need.
- *Learning:* The user engages in learning activities to build knowledge and develop competency (from expert forum to community collaboration.)

The learning-cycle revolution is accomplished when increased competency is verified through user evaluation. Underpinning a successful, full-service learning portal is the inclusion of an LMS.

ReLearning

eLearning combines traditional classroom instruction with technology-based delivery, offering blended learning solutions to the masses. eLearning offers the following:

- *Real-Time Learning:* Immediate and up-to-date application of critical knowledge and information.
- *Learner-Centric Training:* Training focus changes from traditional instructor-centric to learner-centric training. Instruction is tailored to the users professional responsibilities and capabilities.
- *Attract, Train, and Retain:* Addresses the need for the user to develop new knowledge and skills by providing the user with learning on demand.
- *Personalized Individual Training:* System is adaptive; it learns about its users and tailors its offerings to their learning style, job requirements, career goals, current knowledge, and personal preferences.
- *Ownership and Empowerment:* Users are responsible for their own learning—empowering them to manage and implement their own learning and development plans.
- *Simulation:* Introduces to the user the required, "interactive" part of learning—interaction and participation with a local or global audience.
- *Collaboration:* Accomplished through either joint problem solving or discussion among study groups through forums, discussion groups, and chat rooms—opening the path to broader thought and innovative processes through the sharing of ideas and experience.
- *Anytime, Anywhere:* The reality of training in a virtual information classroom across continents is now possible—anytime, anywhere. eLearning is less intrusive to the user, saving time and money through less interruption to the user.
- *Cost-Effective:* Costs can be measured and applied to each user and results can be measured against the incurred costs.
- *Metrics:* eLearning return on investment (ROI) can be effectively measured in terms of knowledge gain and retention.

Portal Technology

Portal technologies supporting open standards can be easily integrated into an organization's existing infrastructure. The portal needs to be operating system and Web-server–neutral so that enterprises can host it on the platform of choice. The portal solution should be deployable and accessible across a variety of platforms and devices. With a platform-, application-, and device-independent architecture, the eLearning portal provides optimal flexibility.

A modular approach provides the greatest flexibility and efficiency for building content, collaboration, and commerce functionality. Moreover, the current business climate and economies demand that enterprise technology have the capability to adapt to changes in the user base and integrate with the most demanding applications. Many eLearning portals have been built from the ground up to be a true enterprise-strength solution. This allows organizations to implement with confidence, knowing that their portal server can accommodate not only thousands, but also hundreds of thousands of users if required.

Next-Generation Portals

The ability to provide mobile, distributed workers with the organized access to the applications, knowledge, and information they need for sound decision-making has become vitally important for businesses striving to be productive, agile, and profitable. The attractiveness of Web-based computing, combined with the need to expedite information access and learning, has fueled the adoption of eLearning portals.

Open technology architecture will enable application access on virtually any device, including wireless and handheld communication devices and information appliances.

Mobile users will be able to move seamlessly from one device to another and receive consistent, personalized learning and knowledge.

Future eLearning portal features coming to market include better process integration, cascading portals, federated portals, business intelligence, and knowledge management. eLearning portals will connect directly and seamlessly with ERP, business intelligence, CRM, and other mission-critical enterprise systems.

Conclusion

The Internet and the Web have marshaled in an unprecedented business and knowledge revolution. A revolution that represents a fundamental shift in the way business is conducted and managed. Over the last quarter century or so, the industrial world has transitioned from being deprived of data to being besieged by it.

With the Internet came speed, connectivity, and intangible value—and the ability to "e-enable" all facets of business, including learning, knowledge, and performance management. But with the e-enabled organization comes stockpiles of data and information—overwhelming the organization and learner.

eLearning portals will drive the evolution from the information economy to the knowledge economy. Moreover, new technologies and the power and connectivity of the Internet will enable eLearning technology, content, and service companies to develop critical learning resources—revolutionizing the way we mentor, train, and learn. eLearning portals will be portable. The learning portal will be positioned as an integration and development platform, not a separate standalone application. The continued knowledge revolution will allow the eLearning portal to bring all information into a distinct, consistent, easily used interface while being fully integrated with other enterprise systems.

Submarine Applications Utilizing Ultra-Long-Reach Transmission Technology

Paul Bullock
Manager, Next-Generation Architecture
Nortel Networks

Niall Robinson
Director, Product and Technology Planning
Nortel Networks

Siraj Nour El-Ahmadi
Vice President, Business Development and Product Planning
Nortel Networks

Introduction

With the recent advancements of terrestrial ultra-long-reach transmission systems, new applications in a relatively untapped market for festoon and regional undersea networks are rapidly emerging. Festooning, a technique for installing unrepeatered submarine systems along a coastline, may be warranted in cases when terrestrial routes are physically impassable, uneconomical, or politically unstable, thus making right-of-way access unattainable. To meet the requirements of service providers operating backbone networks over large geographic areas, the ability to seamlessly complete networks utilizing both terrestrial and submarine technology is becoming critical. To achieve that goal, transmission systems must effectively be able to transport high capacities of traffic all-optically among strategic backbone hubs, sometimes separated by thousands of kilometers. In many cases, the head-end terminations along a festoon route provide excellent access points for transoceanic traffic, thus establishing the single-hop undersea and festoon system as somewhat of a collector infrastructure for global optical networks.

Validated through extensive field experimentation and commercial deployment, ultra-long all-optical distances are achieved utilizing a combination of nonlinear dispersion managed return-to-zero (RZ) transmission, distributed Raman amplification, and strong out-of-band forward error correction coding (OOB–FEC) [1][2]. Borrowing from these same fundamental techniques, it is now possible to support a variety of unrepeatered single-hop festoon and regional undersea applications much more efficiently and cost-effectively than traditionally possible. Submarine adapted ultra-long-haul terrestrial-based systems are advantageous in that they eliminate the need for active equipment in the wet-plant portion of the system. Traditional repeatered submarine systems rely on highly customized undersea technology, including optical repeaters designed to operate continuously and without maintenance activities for as long as 25 years. Such prerequisites command high premiums for the handpicked, high-reliability components required for such applications. In addition, because of the stringent physical packaging and powering constraints of undersea repeaters, they present a bottleneck that keeps undersea transmission systems from reaching the bandwidth capacities of their terrestrial counterparts.

In summary, this paper examines many of the economic and technical considerations surrounding regional unrepeatered undersea applications and how recent advancements in terrestrial transmission adapt to support this emerging market segment.

Regional Undersea Applications

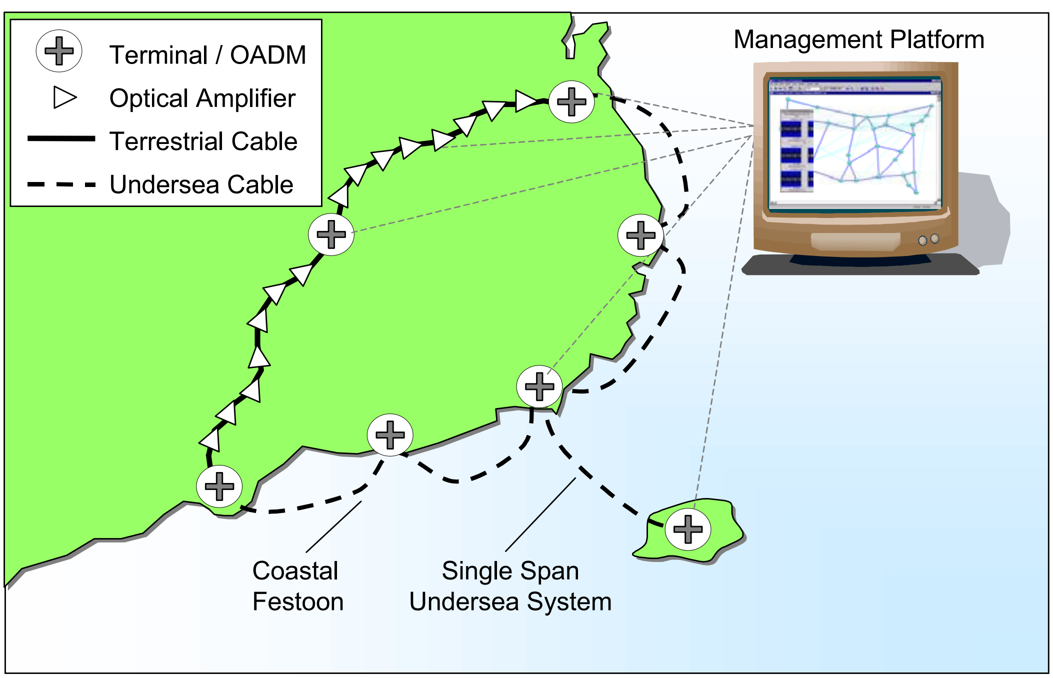
As carriers strive to offer global connectivity, submarine and terrestrial networks continue to converge on utilizing the same technologies. Just as synchronous digital hierarch (SDH) systems have replaced asynchronous equipment and ring topologies have replaced point-to-point (PTP) systems, so too has the recent technological advancements in terrestrial ultra long haul made their way into unrepeatered undersea applications [3]. While submarine carriers have utilized techniques such as OOB–FEC and uniform low-power erbium-doped fiber amplifier (EDFA) deployment to increase system reach, the commercialization of Raman-assisted optical amplification and RZ modulated transmission will further increase the capabilities of such systems. Unrepeatered submarine systems are very similar to terrestrial systems in that all active components are located on dry-land locations for ease of accessibility and routine maintenance. Whenever the interconnecting sites are within reachable proximity, such single-hop systems are always economically preferable compared to traditional repeatered submarine systems. With current technology, it is possible to transport multiple 10 gigabit per second (Gbps) dense wavelength division multiplexing (DWDM) circuits over distances of more than 300 km without the use of remote repeaters.

There are a number of economic and operational benefits gained by utilizing unrepeatered undersea systems over more traditional repeatered undersea systems. Commercial applications for such systems include channel and sea crossings in Europe, island-to-island crossings in the Asia-Pacific and the Caribbean, as well as coastal festoon systems in South America, North America, and elsewhere in the world. With the emergence of commercial ultra-long-haul technology, the same platforms can support both land and submarine applications. Land-based systems utilize the reach capability to eliminate remote electronic regeneration, while submarine systems benefit from the elimination of undersea amplification elements. Both systems are monitored under the same management platform. As shown in *Figure 1*, carriers may utilize unrepeatered systems in conjunction with terrestrial systems to offer route diversity under the same management platform. A coastal festoon hops along a coastline and terminates periodically to accommodate reach constraints or drop traffic. Also, a single-span undersea system is shown bridging the mainland facility with a remote island.

Unlike repeatered undersea systems, each physical cable is actually capable of accommodating hundreds of fiber strands. However, with traditional repeatered systems, the number of active repeater modules that can fit within the undersea housing becomes the limiting factor in overall system capacity. Today, repeatered systems are limited to eight fiber pairs, while unrepeatered systems can accommodate more than 100 fibers, thus allowing for significantly more capacity. Submarine repeaters are made of optical amplifiers packaged in undersea-resistant housings made to withstand sea pressure and other stresses related to laying and recovery. Within these repeaters reside specialized optical amplifiers designed for maximum reliability and an in-service life span of as long as 25 years. Such strict engineering tolerances and customized requirements can drive the price of each undersea amplifier toward U.S.$1 million. The inclusion of Raman pumps in these repeatered undersea systems may help to increase the number of wavelengths supported on each fiber but will also further constrain the overall number of fibers each amplifier housing can accommodate while reducing the system availability by imposing additional active elements into the system. In addition to the physical housing constraints of undersea repeaters, specialized power systems also create a bottleneck for capacity scalability. Active repeaters require specialized power-feed equipment, which provides high-voltage direct current (DC) (as much as 10,000 volts) and regulated current (as much as 1.6 amps). DC power availability may be the limiting factor in

FIGURE 1

Utilizing commercial ultra-long-haul technology carriers can support both land and submarine applications utilizing a common management and operations platform.



the race for ever-increasing capacity. Features include redundancy to withstand component failures or for routine maintenance, safety features to prevent accidental access to high-voltage circuits, and maintenance features to switch power feeds and low-frequency current-modulation capabilities to allow cable-ship repair teams to locate buried cable [4]. With unrepeatered systems, there is no need to take into consideration the physical and reliability constraints of repeaters such as customized undersea housing and strict optical amplifier tolerances. Thus, the elimination of undersea amplification in regional submarine applications dramatically reduces operational costs while significantly improving deployment velocity, thereby enabling carriers to quickly realize revenue.

In addition, by utilizing the extensive optical add/drop functionality of advanced transmission platforms, it is possible, depending on the distance of the undersea span, to employ these capabilities at terrestrial landing sites to further extend the reach of the system and optically integrate with the terrestrial portion of the network. Advancing beyond the first generation of optical add/drop-capable transmission systems, today's platforms, based on the enabling technologies described previously, support fully flexible optical add/drop capability [5]. All-optical branching allows for the re-direction of wavelengths at the landing point to multiple fiber directions without introducing the need for electrical termination. Such capabilities enable carriers with the potential to optically re-direct wavelengths as they glass-through the terrestrial landing site and continue all-optical transmission to the traffic destination sites, which may be several hundred kilometers away. Such flexibility not only reduces electrical termination at the landing site, thus reducing capital expenditures (CAPEX) and operational cost, but also enables rapid service deployment.

Global carriers are finding a number of advantages to utilizing common technologies and platforms for both the terrestrial and submarine portions of their network to simplify operations and management. Fully integrating the regional undersea and terrestrial transmission requirements under a common platform enables simplified training and maintenance procedures along with streamlined network management and system monitoring. Furthermore, without the need for specialized active undersea components, submarine adapted ultra-long-haul systems improve delivery and in-service time frames, which clearly translates into a faster return on investment (ROI) for new projects. *Table 1* summarizes the advantages of extended-reach single-hop systems compared to traditional repeatered submarine systems for regional undersea applications.

Technical Considerations

Unrepeatered systems are typically limited in distance by the need to balance the effects of pulse distortion through nonlinearity induced by high signal powers with optical signal-to-noise ratio limitations of the received signal. Other impairments, such as polarization mode dispersion, polarization dependent gain, and amplifier gain tilt can generally be ignored due to the short length of these systems in comparison to ultra-long-haul terrestrial and repeatered undersea systems.

TABLE 1

Comparison of unrepeatered extended-reach single-span systems and traditional repeatered systems for regional undersea applications.

	Extended-Reach Single-Span Systems	*Regional Repeatered Submarine Systems*
Utilizes active undersea amplifiers?	No	Yes
Customized components required for operation?	No, same as terrestrial system	Yes, route-specific and designed to operate untouched
Specialized power systems?	No, same as terrestrial system	Yes, high-voltage DC with expensive redundancy
Specialized operations?	No, same as terrestrial system	Yes, more difficult to manage, maintain, and repair
Cable-capacity limitation?	As many as 100 fibers	Currently eight fibers
Seamlessly integrates with terrestrial systems?	Yes, optically compatible with terrestrial systems	No, often different systems used for terrestrial and wet plant
Shares terrestrial management platform?	Yes, common management platform and monitoring	No, undersea systems are isolated from terrestrial systems
All-optical add/drop capability at landing sites?	Is possible, depending on reach, to optically branch wavelengths for terrestrial transmission	No, full electrical termination required at landing sites

However, transmission techniques used to extend terrestrial and repeatered submarine systems have a role to play in improving the capacity-reach product of unrepeatered submarine links. At the launch end of the transmission line, self-phase modulation is generally the limiting nonlinearity. However, as capacity levels increase and therefore the total optical bandwidth increases, the signal-to-signal power transfer through the Raman gain process in the transmission fiber will begin to be the limiting factor. Signal-power-level pre-emphasis techniques used to optimize ultra-long-haul systems will be required to combat this effect.

An interesting development of unrepeatered systems is the ability to use different fiber types in the transmission link. The nonlinearity level induced in a fiber is, to an order, determined by the effective area of the optical fiber and the signal-power level. The effective area of an optical fiber is a representation of the cross-section of the optical fiber that is actually guiding the transmitted light. Fibers with small effective areas squeeze the light into a smaller cross-section, therefore increasing the intensity of the light creating a higher nonlinear effect for the same power level compared to a fiber with a larger effective area. These effective-area managed cables [6] often incorporate chromatic dispersion management into the design. An example of an effective-area managed cable might be to use a fiber with a very large effective area at the transmission end of the system to increase the allowable launch power level before effects such as self-phase modulation and channel-to-channel Raman gain become the limiting factor. At the receive end of the link, a section of fiber similar to traditional dispersion-compensating fiber could be used. The advantage here is the combination of built-in dispersion compensation in the transmission fiber and a small effective area that enables large distributed Raman gain to be achieved at relatively low levels of Raman pump power.

Although not new to the world of submarine systems, OOB–FEC techniques can provide several decibels (dBs) of additional margin, some of which could be used to extend the overall system reach. Early synchronous optical network (SONET)/SDH–based error-correction implementations relied on the utilization of normally unused overhead bytes in the transmission frame. Such "in-band" techniques are able to provide 2 to 3 dB of net error-coding gain. However, by manipulating overhead information, such traditional FEC methods are unsuitable for the completely transparent transport of client signals, which may also utilize the same SONET/SDH overhead for proprietary control or messaging information. Current submarine and some emerging terrestrial systems use "out-of-band" FEC at line rates of up to 10.7 Gbps. Such, coding schemes yield a 4 to 5dB net error-coding gain, which is certainly an improvement over the "in-band" technique. Such methods have been commercially utilized in repeatered undersea systems. The most advanced commercially available ultra-long-haul transmission platform increases the normal 9.96 Gbps line rate to 12.24 Gbps to deliver a best-in-class 9 dB net error-coding gain at a 10^{-15} bit-error rate. This out-of-band implementation allows for the completely transparent transmission of client traffic, while also providing critical performance-monitoring capabilities. Such strong OOB-FEC enables coding gains that are higher than those found in repeatered undersea systems. OOB-FEC encapsulation is well suited for a variety of transmission formats such as SONET, SDH, and 10 Gbps Ethernet. The OOB–FEC overhead can also support the optical service channel (OSC) information that would normally reside in an out-of-band wavelength alongside the C-Band window of operation for terrestrial transmission.

In addition to strong FEC, terrestrial transmission systems have commercialized the use of Raman amplification, which has also found its way into the unrepeatered submarine market. With single-span unrepeatered systems, the Raman pump laser is located at the far end of the system and is pumped into the transmission fiber counter—spreading to the traffic-carrying wavelengths to provide a distributed gain along the fiber medium itself. The Raman laser excites the transmission fiber, thus effectively boosting the transiting signal level as it travels down the fiber closer toward the Raman pump source. Here, the ultimate limitation will be determined by the fiber fuse limit of the transmission cable. Fiber fusing is a runaway effect, where the optical power level launched into the fiber is sufficiently high to cause permanent physical damage to the transmission fiber rendering it unusable for transmission.

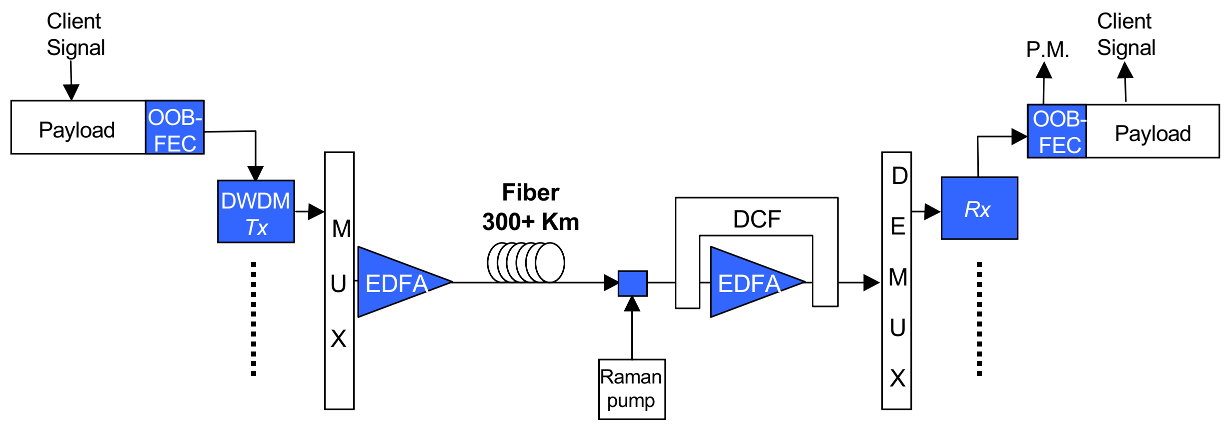
Many ultra-long-haul transmission systems, both terrestrial and submarine, utilize some form of a RZ modulation format. In unrepeatered links, the advantage of traditional RZ modulation is not as evident. Typically, RZ transmission requires a lower optical signal-to-noise ratio (OSNR) at the receiver in comparison to non–RZ (NRZ) transmission. However, with the advancement in potential modulation techniques now available in optical transmission systems such as carrier-suppressed RZ and vestigial sideband RZ, further improvements in system reach or increases in the transmitted line rate may be possible.

As shown in *Figure 2*, the unrepeatered extended reach single-span system encapsulates the original 10 Gbps-client signal in the payload of the out-of-band FEC frame. Error-correcting overhead codes for the client signal are appended, and the entire frame is externally modulated in an RZ format and launched onto the fiber along with a number of other wavelengths. Following propagation through the fiber medium itself, the incoming wavelengths are gradually amplified by the counter-pumped Raman source and discretely boosted by the post EDFA. Each wavelength is demultiplexed, the client signal is decoupled from the error-correction frame, and any errors detected during transmission are monitored and corrected.

The single-span system described could be augmented with remote optically pumped amplifiers (ROPAs) to further improve the reach and capacity of the transmission system. ROPAs are optical repeaters without active elements contained in the underwater housing. A single coil of erbium-doped fiber and associated isolators are housed in a submarine qualified repeater housing spliced into the optical cable. In a ROPA configuration, terminal generated optical pump power is transmitted to the erbium gain block located 80 to 100 km away from the terminal site along the fiber cable so there are no electrically active components in the fiber plant, thus a high-voltage DC power feed is not required. Although ROPA systems are not strictly "repeaterless," because optical signal amplification occurs in the remote gain block, they are not as restrictive as traditional "repeatered" undersea systems. ROPA systems, however,

FIGURE 2

Unrepeatered regional submarine system architecture that enables the transparent transmission of 10 Gbps client signals utilizing OOB–FEC, dispersion managed RZ modulation, and a combination of EDFA/Raman amplification. Only one direction is shown for clarity.



still require specialized physical considerations to withstand undersea conditions and restrictive reliability constraints and thus can create a significant price premium over unrepeatered systems [7].

Market Outlook

Although several coastal festoon and regional undersea systems have been in place for many years, these systems have quite often relied on the use of specialized undersea repeaters, thus they were limited by the packaging and power constraints of active undersea components. With the recent advancements in ultra-long-haul transmission systems, it is now possible for carriers to cost-effectively support these applications, along with many other opportunities. As the reach, capacity, and manageability of unrepeatered systems continues to scale beyond traditional repeatered deployments, the market outlook continues to broaden, as previously cost-prohibitive ventures throughout the world have now become viable business models. Furthermore, by linking with terrestrial systems through homogeneous platforms, a much broader range of applications and potential for long-term growth emerges. According to recent market forecasts, the global market for unrepeatered transmission will grow substantially from 2001 through 2005. More than 300 unrepeatered links are installed or planned throughout the globe, with some 120 additional links targeted for future deployment, scaling the market from a current $2.5 billion to more than $7 billion by 2005 [8].

Conclusion

The global market for festoon and regional undersea systems is new and relatively untapped. Utilizing commercially available ultra-long-reach, terrestrial technology carriers are now able to rapidly and cost-effectively establish presence in a number of markets along and between coastlines. Enabled by strong error-correction coding, Raman amplification, and advanced modulations techniques, it is now possible to transparently support native 10 Gbps DWDM systems to maximize the bandwidth-distance product without incurring the operational and CAPEX of deploying and maintaining specialized undersea optical repeaters. Borrowing from such recently commercialized advancements in ultra-long-reach terrestrial transmission systems, unrepeatered applications can utilize the same techniques to mitigate nonlinear effects to enable native 10 Gbps unrepeatered transmission between landing sites separated by hundreds of kilometers. Seamless integration with the terrestrial plant ensures simplified operational and maintenance procedures, thus reducing the life-cycle cost of the system, while allowing for diverse optical protection switching schemes. This next generation of unrepeatered transmission systems can augment existing network capacity, provide alternate protection routes for land-based systems, or completely obsolete many of the systems currently in use by supporting higher capacities in a more cost-effective manner than previously possible.

Optical Transport Network Recovery through Photonic Switching and GMPLS

Luc Ceuppens
Vice President, Corporate Business Development
Calient Networks

Optical amplification and dense wavelength division multiplexing (DWDM) have fundamentally changed the economics of optical transport networks. Now that these technologies are widely adopted, the bottleneck has moved from the outside line plant to nodal central offices (COs), where the speed of electrical switching equipment has not kept pace. As a result, present networks are carrying terabit per second (Tbps) data streams as 100 parallel 10 gigabit per second (Gbps) or 500 parallel 2 Gbps streams. Each stream is terminated within the CO and carried over individual strands of fiber, creating operational and financial nightmares. This is primarily due to the cost of acquiring and operating the countless optical-to-electrical-to-optical (O–E–O) devices in the signal path inside the CO. While O–E–O technology was (and still is) necessary for the grooming and aggregation of low-speed services onto wavelengths, the transport network has dramatically changed. The inflow of data traffic is threatening to saturate the existing networks, and this requires a dramatic rethinking of how networks need to be planned, designed, constructed, and operated. While today's transport networks carry remarkable amounts of bandwidth, the optical layer of these networks is fundamentally static and provides for only simple point-to-point transport. While efficiently addressing the capacity problem, DWDM alone does little to make the networks smarter. Efficiently managing (i.e., adding, dropping, routing, protecting, and restoring) the growing number of traffic-bearing wavelengths can only be achieved through a new breed of networking element: Photonic switching systems (PSSs) can efficiently execute these functions because they are bit-rate, wavelength, and data-protocol transparent. With their all-optical switch cores and interfaces, PSSs can switch and manage optical signals at various levels of granularity—wavelength, sub-band, full-band, and composite DWDM fiber levels. Though cross-connect systems with electrical switch cores [1] are available, they perform these functions at very high capital costs and operational inefficiencies. This paper examines enabling technologies for the deployment of PSSs in carrier optical transport networks (OTNs) and takes a practical perspective on survivability architecture migration and implementation issues.

The Challenges of Building, Operating, and Managing Optical Transport Networks

For much of the late 1990s and through the early part of 2000, competitive local-exchange carriers (CLECs), wholesale broadband providers, and high-speed Internet companies raced to build new networks and add customers while demand for high-speed services soared. Then, during the second half of 2000, market conditions and a wary investor community caused the large incumbent carriers to restructure their businesses, while many smaller competitors fell by the wayside as capital markets dried up and profits became more important than growth. The telecommunications downturn was precipitated by the suffering stock markets, which led to a shortfall in investment capital as Wall Street and venture capitalists became more restless. Suddenly, instead of focusing on speedy growth, companies were scrambling for enough capital to survive. Those still standing as 2002 arrives are faced with shaking free from the recent carnage, making their new business focuses successful, and renewing investor confidence. The primary trigger for this will be better operating results.

Building and maintaining a network infrastructure is a costly business, and with the markets remaining hostile to new borrowing, communications companies continue to face hardships. Nonetheless, service providers cannot afford not to grow their networks. So, while capital spending is slowing down, the money that is available will have to be spent intelligently and carriers will have to focus on faster, cheaper, and smarter systems. While growing the network, every dollar invested will have to dramatically reduce the operating cost of both new and existing network segments. At the same time, the new infrastructure has to support new revenue opportunities. This leaves service providers with three challenges:

- Reduce and optimize capital expenditures
- Reduce operating expenditures
- Identify and execute on new revenue opportunities

In today's competitive business environment, any technical strategy for network evolution must ultimately provide for competitive differentiation in service delivery. Scaling the network and delivering bandwidth and services when and where a customer needs it are absolute prerequisites for success. The limitations of the existing network infrastructure are hindering a movement to this service-delivery business model. A new network foundation is required—one that will easily adapt to support rapid growth, change, and a highly responsive service delivery.

Photonic switches offer efficient solutions and improvements by providing intelligent optical bandwidth management in support of fluid bandwidth creation and distribution. They provide numerous financial, operational, and tactical benefits by switching signals at the optical level and by providing efficient optical bandwidth management to enable new services and gain operational efficiencies.

Enabling Technologies

Two enabling technologies make large-scale PSSs commercially deployable: 1) the availability of large three dimensional (or 3D) micro-electromechanical system (MEMS) photonic switch components and 2) nearly complete standardization of control plane protocols, which is key to the implementation of PSSs in service-provider networks.

MEMS Photonic Switches

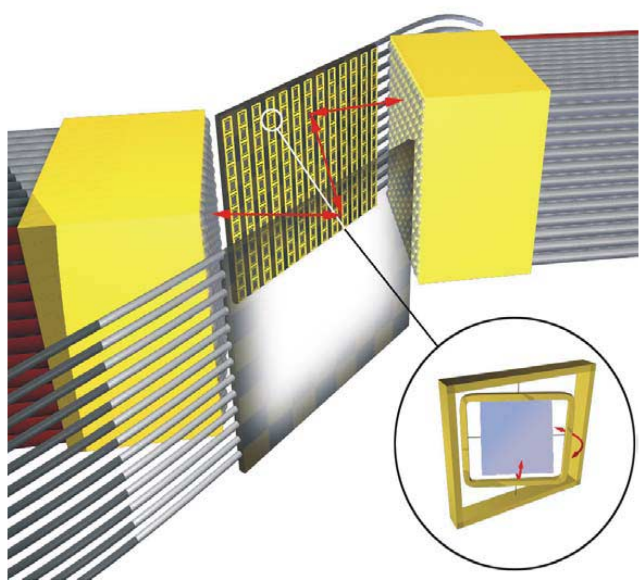
Since 1980, various photonic switching technologies have been developed, including integrated optic, thermo-optic, acoustic-optic, total internal reflection, and liquid-crystal–based switches. These technologies have suffered problems, such as high insertion loss, wavelength and temperature dependency, small scale, and polarization dependency [2], which hamper their adoption in telecommunication networks. 3D MEMS mirror technology is the only photonic switch technology to offer the scalability, reliability, non-blocking operation, fast switching, low insertion loss, low crosstalk, and high serviceability features that service providers require. These switches (shown in *Figure 1*) offer bit-rate, protocol, and wavelength independence between 1260 and 1625 nm. In these large-scale free space switches, light beams are switched with mirror arrays that pivot about two orthogonal axes [3]. As laser beams are spatially and temporally coherent, they do not interact when crossed, hence blocking does not occur. This technology also offers polarization independency with very low polarization mode dispersion and polarization dependent loss.

Generalized Multiprotocol Label Switching

Network protection, dynamic restoration, and real-time dynamic service provisioning of wavelengths can be implemented using generalized multiprotocol label switching (GMPLS), which combines existing control-plane techniques with the point-and-click provisioning capabilities of photonic switches [4]. GMPLS is a signaling and routing protocol suite, with extensions to some existing Internet protocol (IP) protocols. GMPLS is a logical extension of multiprotocol label switching (MPLS), the set of extensions to open shortest path first (OSPF), intermediate system to intermediate system (IS–IS), and resource reservation protocol (RSVP) to support the routing of paths (also known as traffic engineering). Intrinsic to MPLS is the notion of separating the forwarding (data) plane from the control (signaling) plane. Data is transported across the network inside a path. Multiprotocol lambda switching (MPλS) was a concept that said that the MPLS control plane could be leveraged to support routing of lambda paths. After all, there are several synergies between label-switched routers (LSRs)

FIGURE 1

Switching in a 3D MEMS Photonic Switch



and photonic switches, and between a label-switched paths (LSP) and an optical trail. Analogous to switching labels in an LSR, a photonic switch switches wavelengths from an input to an output port. Establishing an LSP involves configuring each intermediate LSR to map a particular input label and port to an output label and port. Similarly, the process of establishing an optical path involves configuring each intermediate photonic switch to map a particular input lambda and port to an output lambda and port. As in LSRs, photonic switches need routing protocols (such as OSPF and IS–IS) to exchange link-state topology and other optical resource availability information for path computation. They also need signaling protocols to automate the path establishment process.

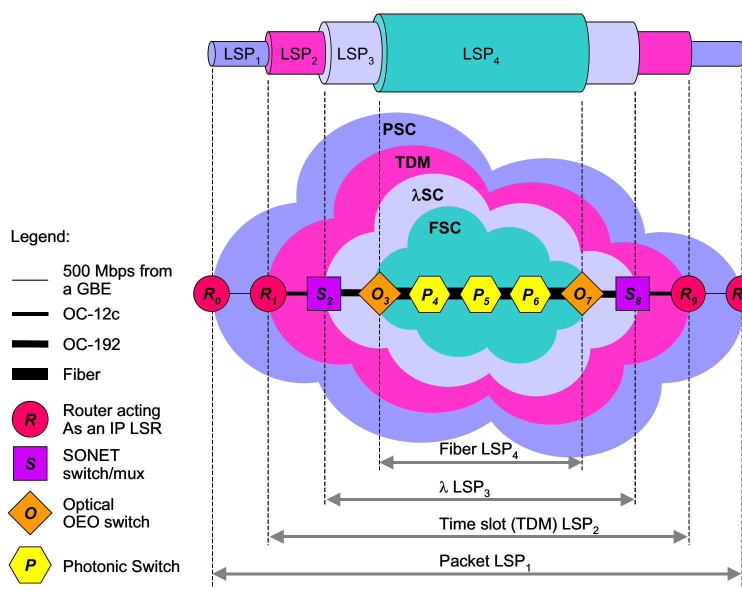
GMPLS is the realization of the MPλS concept, created by extending MPLS to support non-packet paths. GMPLS offers generalized semantics for entities such as packets, timeslots, wavelengths or lambdas, wavebands, fibers, cables, and ducts. A critical component of GMPLS is the link management protocol (LMP), a new protocol that runs between adjacent nodes for both link provisioning and fault isolation [5]. The GMPLS protocol suite enables client-layer data network elements—such as routers, ATM switches, and synchronous digital hierarchy (SDH)/synchronous optical network (SONET) add/drop multiplexers (ADMs)—to dynamically request bandwidth services from the server photonic network layer (consisting of optical network elements such as PSSs and DWDM systems) by using existing control-plane techniques. Beyond simple advertising and the establishment of optical paths through the network, GMPLS includes performance information about the network. Client-layer equipment at the edges of the photonic network uses this information to dynamically request resources (for example, wavelengths) available in the server photonic layer. In essence, GMPLS reduces the network view to just two layers: the OTN server layer and the client service-delivery layer.

GMPLS–Based Network Recovery

GMPLS is a multipurpose control-plane paradigm that supports not only devices that perform packet switching, but also devices that perform switching in the time, wavelength, and space domains. To leverage the natural connection and device hierarchy that exists in real-world networks, GMPLS introduces the concept of hierarchical LSPs [6] (see *Figure 2*), which occurs when a new LSP is tunneled inside an existing higher-order LSP so that the pre-existing LSP serves as a link along the path of the new LSP. The ordering of LSPs is based on the link multiplexing capabilities [7] of the nodes. Nodes at the border of two regions, with respect to multiplexing capabilities, are responsible for forming higher-order LSPs and aggregating lower-order LSPs. As an example, the bandwidth signaled for LSP_1 in *Figure 2* is 500 megabits per second (Mbps); all links traversed by the LSP must be large enough to support the requested bandwidth. R_0 classifies

FIGURE 2

GMPLS LSP Hierarchy



LSP_1 is set up from R_0 to R_{10} for 500 Mbps of bandwidth. LSP_1 is nested in the subordinate LSPs 2, 3, and 4, respectively, as depicted at the top of the figure. If an existing LSP has capacity, the subordinate LSP is added to it; otherwise, the set-up of a new LSP of the appropriate type is triggered. The endpoints of LSP_1 classify packet data and source it into LSP_1. R_1 and R_9 are packet LSRs; S_2 and S_8 are SONET path-level switches. Devices O_3 and O_7 are optical or lambda switched, providing SONET/SDH section-level signals (e.g., OC–192 including all overheads); they also have WDM capabilities between photonic switches P_4 and P_6. The link between R_0 and R_1 is Gigabit Ethernet, between R_1 and S_2 an OC–48, between S_2 and O_3 an OC–192, between O_3 and P_4 a WDM multiplex of 16 OC–192 that which remains intact through to O_7 (P_4 to P_6 are pure photonic switches). The link between O_7 and S_8 is an OC–192, between S_8 and R_9 an OC–48, and between R_9 and R_{10} Gigabit Ethernet.

and maps packets into LSP_1 and shapes the data to 500 Mbps if necessary. The 500 Mbps for LSP_1 will be allocated from LSP_2, which is running at the next larger SONET increment, an optical carrier (OC)–12c. The S_2 switch grooms the OC–12c into LSP_3, which is an OC–192 between S_2 and O_3. The optical switch, O_3, takes this OC–192 and switches it through LSP_4, a WDM channel toward P_4. The OC–192 corresponding to LSP_3 is switched through P_4, P_5, and P_6 to O_7. Continuing in this fashion, O_7 selects the correct lambda and passes the signal to the port adjacent to S_8. S_8 will select the appropriate OC–12c from the OC–192 and pass this to R_9. Finally, R_9 will take the packets from the OC–12c and forward them on R_{10}.

The GMPLS protocol suite broadly encompasses routing (OSPF–TE/IS–IS–TE), signaling (RSVP–TE/CR–LDP), and link management (LMP). These protocols interact in a meaningful manner to provide coordinated hierarchical recovery of connections across multiple layers, something that cannot be achieved if restoration is driven by each layer individually. GMPLS–based recovery provides an answer:

- When Layer-3 rerouting may be too slow
- When Layer-0 or Layer-1 mechanisms may have no visibility into higher-layer operations
- When lower layers may provide some levels of protection (for example, link protection) but no protection against node failures or compute disjoint paths
- To ensure interoperability of protection mechanisms between network elements from different vendors
- To provide a recovery option without an intervening SONET layer when IP traffic is transported directly over WDM optical channels

A key requirement for the development of a common control plane for both optical and electronic networks is the need for features in the signaling, routing, and link management protocols to enable intelligent fault management. Fault management requires four steps: fault detection, fault localization, fault notification, and fault recovery. Fault detection should be handled at the layer closest to the failure; for optical networks, this is the physical (optical) layer. One measure of fault detection at the physical layer is detecting loss of light (LOL). Other techniques based on, for example, optical signal-to-noise ratio (OSNR), bit-error rate (BER), dispersion, crosstalk, and attenuation are still being investigated (see, for example, [8] and [9]). Fault localization requires communication between nodes to determine where the failure has occurred (for example, SONET AIS is used to localize failures between SONET terminating devices). One interesting consequence of using LOL to detect failures in optical networks is that LOL propagates downstream along the connection's path. The LMP [10] includes a fault-localization procedure that is designed to localize failures in both transparent (all-optical) and opaque (opto-electrical) networks and is independent of the data-encoding scheme. Fault notification is the communication of a failure between the node detecting it and a node equipped to deal with the failure. Fast fault notification is essential for rapid recovery. The Notify mechanism [11] is designed to support fast notification of non-adjacent nodes.

Once a failure has been detected and localized, and the responsible node has been notified, protection and restoration can be used to recover from the failure. We make the distinction between protection and restoration by the time scales in which they operate. Protection is designed to react to failures rapidly (say, in less than a few hundred milliseconds) and often involves 100 percent resource redundancy. For example, SONET automatic protection switching (APS) is designed to switch the traffic from a primary (working) path to a secondary (protection) path in less than 50 ms. This requires simultaneous transmission along both the primary and secondary paths (called 1+1 protection) with a selector at the receiving node and uses twice as many network resources as a non–APS protected path. Restoration, on the other hand, is designed to react to failures quickly, but it typically takes an order of magnitude longer to restore the connection as compared to protection switching. This is because restoration typically utilizes pools of shared resources to improve network utilization efficiency. In addition, restoration may involve rerouting connections, which can be computationally expensive if the paths are not precalculated or if the precalculated resources are no longer available.

Protection and restoration methods have traditionally been addressed using two techniques: 1) path-level recovery, where the failure is addressed at the end nodes (i.e., the initiating and terminating nodes of the path), and 2) span-level recovery, where the failure is addressed at an intermediate or transit node. Path-level recovery can be further subdivided into path protection, where secondary (or protection) paths are pre-allocated, and path restoration, where connections are rerouted, either dynamically or using precalculated (but not pre-allocated) paths. Span-level recovery can be subdivided into span protection, where traffic is switched to an alternate channel or link connecting the same two nodes, and span restoration, where traffic is switched to an alternate route between the two nodes (this involves passing through additional intermediate nodes).

To effectively use protection, there must be mechanisms to configure protected links on a span between nodes, advertise the protection bandwidth of a link so that it may be used by a class of traffic that has different availability requirements, establish secondary (protection) LSPs to protect primary LSPs, allow the resources of secondary LSPs to be used by lower-priority traffic until a switchover occurs, and signal protection switchover when necessary. In the remainder of this document, we discuss protection and restoration in the context of GMPLS signaling.

Protection Mechanisms

Protection is designed to react to failures in the fastest timescale and typically involves pre-provisioning protection resources. The level of protection available is a function of the protection resources available for protecting a failed resource:

- *1+1 Protection*
  Two pre-provisioned resources are used in parallel. For example, data is transmitted simultaneously on two parallel links and a selector is used at the receiving node to choose the best signal.

- *1:1 Protection*
  Two resources (1 primary, 1 back-up) are pre-provisioned. If the primary resource fails, the data is then switched to the back-up resource. The recovery path can be used only to recover a specific working path.

- *1:N Protection*
  In 1:N protection, up to N working paths are protected using only one recovery path. N+1 resources (N primary, 1 back-up) are pre-provisioned. If there is a failure on any one of the primary resources, the data is then switched to the back-up resource. At this point, the remaining N-1 primaries are no longer protected.

- *M:N Protection*
  In M:N protection, up to N working paths are protected using M recovery paths. N+M resources (N primary, M back-up) are pre-provisioned. If there is a failure on any one of the primary resources, the connection is then switched to the back-up resource.

  Note that 1:N and 1:1 are special cases of M:N protection.

- *Span Protection*
  A span consists of a number of channels between two adjacent nodes that are grouped together into a single link, often called a traffic engineering (TE) link (see [10]). Span protection involves switching to a protection channel when a failure occurs on a working channel. At the span level, both dedicated (1+1, 1:1) and shared (M:N) protection may be implemented. The protection type supported by a TE link (LPT) is advertised throughout the network so that intelligent routing decisions can be made. The desired protection for a path is signaled as part of the generalized label request in GMPLS signaling. This is needed in signaling if a link supports multiple protection types or if loose routing is used.

  For dedicated 1+1 span protection, each node must replicate the data onto two separate channels (possibly using separate component links of a bundled link or separate ports of a TE link), and the adjacent node must select the data from only one channel based on the signal integrity. This is the fastest protection mechanism; however, it requires using twice the LSP bandwidth between each pair of nodes and the ability to replicate the data on two separate channels.

  For shared M:N protection, M protection links are shared between N primary links. Since data is not replicated on both the primary and secondary links, failures must first be localized before the switchover can occur. LMP can be used for fault localization, and the upstream node (upstream in terms of the direction an RSVP path message traverses) will initiate the local span protection.

- *Path Protection*
  Path protection is addressed at the end nodes of an LSP (i.e., LSP initiator and terminator) and requires switching to an alternate path when a failure occurs. For 1+1 path protection, a signal is transmitted simultaneously over two disjoint paths and a selector is used at the receiving node to choose the better signal. For M:N path protection, N primary signals are transmitted along disjoint paths, and M secondary paths are pre-established for shared protection switching among the N primary paths.

  After the two paths are computed, the source originates two explicitly routed connections with the dedicated 1+1 and unprotected bits, respectively, set in the protection bit vector of the corresponding signaling set-up message. The set-up indicates that these two paths desire shared reservations. For 1+1 path protection, the connection is transmitted simultaneously over two disjoint paths, and a selector is used at the terminator node to choose the best signal. At each node where the two paths branch out, the node must replicate the data into both branches. At each node where the two paths merge, the node must select the data from one path based on the integrity of the signal. For M:N path protection, N different connections are transmitted along N disjoint paths, and M disjoint paths are pre-established for shared protection switching for the N primary paths. An interesting feature of GMPLS is that it allows preconfiguring back-up paths to protect primary paths. These back-up paths, called secondary paths, are used for fast switchover when the primary path fails. Although the resources for these back-up paths are pre-allocated, lower-priority traffic may use the resources with the caveat that the lower-priority traffic will be pre-empted if there is a failure on the primary path. Note that the precomputed back-up path cuts down on the restoration time in the event of a failure.

Restoration Mechanisms
Restoration is designed to react to failures quickly and use bandwidth efficiently, but typically involves dynamic resource establishment and may also require route calculation and therefore takes more time to switch to an alternate path than protection techniques. Restoration can be implemented at the initiator node or at an intermediate node once the responsible node has been notified. Failure notification can be done using the Notify procedures [12] or using the standard RSVP PathError messages.

- *Span Restoration*
  To support span restoration, where traffic is switched to an alternate route around a failure, a new LSP is established at an intermediate node that involves passing through additional intermediate nodes. Span restoration may be beneficial for LSPs that span multiple hops and/or large distances because the latency incurred for failure notification may be significantly reduced and only segments of the LSP are rerouted instead of the entire path.

  If the protected part of the LSP is a single span, then error detection is sufficient to trigger restoration. If, however, protection is required over a series of more than one span, a mechanism is required to notify the point of repair that an error has occurred and that restoration is required.

  The RSVP Notify Request object can be used by an intermediate node to request that it be the target of an RSVP Notify message. Span restoration may break TE requirements if a strict-hop route is defined for the connection. Furthermore, the constraints used for routing the connection must be forwarded so that an intermediate node doing span restoration is able to calculate an appropriate alternate route. This is similar to the problems when establishing/maintaining TE requirements that span multi-areas (see [13] for a proposed mechanism).

- *Local Repair*
  Local repair is a special case of span protection supported by the base RSVP–TE draft [14]. The node that detects the failure may make an alternate routing decision and attempt to resignal the LSP. This approach may be considered too slow since it could rely on convergence of the routing table at the repair node. However, if there is a close link between routing and path computation components, local repair may be equivalent to span protection.

- *Path Restoration*
  Path restoration switches traffic to an alternate route around a failure, where the new route is selected at the LSP initiator and may reuse intermediate nodes used by the original LSP, and it may include additional intermediate nodes. For strict-hop routing, TE requirements can be directly applied to the route calculation, and the failed node or link can be avoided. However, if the failure occurred within a loose-routed hop, the source node may not have enough information to reroute the connection around the failure. The back-up route may be calculated on demand (that is, when the failure occurs) or may be precalculated and stored for use when the failure is reported. This offers faster restoration time. There is, however, a risk that the back-up route will become outdated through other changes in the network—this can be mitigated to some extent by periodic recalculation of idle back-up routes.

Restoration (span or path) will be initiated by the node that has isolated the failure or by the node that has received either an RSVP Notify message or an RSVP PathError message indicating that a failure has occurred. The new resources can be established in a make-before-break fashion, where the new LSP is set up before the old LSP is torn down, using the mechanisms of the LSP_Tunnel Session object (see [14]) and the Shared-Explicit reservation style. Both the new and old LSPs share resources at nodes common to both LSPs. The Tunnel end point addresses, Tunnel Id, Extended Tunnel Id, Tunnel sender address, and LSP Id are all used to uniquely identify both the old and new LSPs; this ensures that new resources are established without double counting resource requirements along common segments. Note that make-before-break is not used to avoid disruption to the data flow (this has already been broken by the failure that is being repaired) but is valuable to retain the resources allocated on the original primary path that will be reused by the new primary path.

Restoration Classes
When the LSP initiator detects that the LSP carrying the traffic trunk has failed, it performs the action specified by the resilience attribute of the trunk. The possible actions are as follows:

- *None*
  No explicit path protection. This means that in failure scenarios, alternate ways have to be found to reroute the traffic.

- *Fallback to Precomputed, Pre-Established Path*
  This option requires that a back-up LSP be pre-computed and pre-established. This provides the fastest path restoration at the expense of wasting the bandwidth reserved by the back-up LSP.

- *Establish a Path Based on the Precomputed Path, and Move the Trunk onto the New Path*
  This option requires that the head-end router precompute a back-up path for the traffic trunk. Since the path is established on demand, there is no need to maintain idle paths. The price for the bandwidth efficiency over the previous option is the additional delay incurred for establishing the new path.

- *Compute and Establish a New Path, and Move the Trunk onto the New Path*
  This option provides the slowest restoration but incurs no bandwidth or processing overhead.

The response time of path restoration is equal to the sum of the following delay components:

- The time it takes for the router closest to the failure to detect it.
- The time it takes for the head-end router to detect the failure (via either an explicit RSVP failure notification or a PathError message).
- The time it takes to compute and establish a new path. Note that if the fallback path is precomputed and/or pre-established, this delay component is partially or completely eliminated.

The currently proposed timing bounds for service restoration for different mechanisms are as follows:

- M:N path restoration with pre-established capacity: 100 – 250 ms
- M:N path restoration with precomputed capacity: 100 – 750 ms
- Path restoration with computation: 1 – 5 seconds
- Local restoration: ≤ 50 ms

Routing Enhancements
The GMPLS extensions to OSPF [15] and IS–IS [16] include the advertisement of the LPT. The LPT field is a bit vector that indicates the protection capabilities that are supported for the link. The LPT field may be configured with dedicated 1+1, dedicated 1:1, shared M:N, and enhanced protection, as well as unprotected. For a link that has dedicated 1+1 protection or is unprotected, this advertisement provides a complete description of the link capabilities and the usable bandwidth. However, a key argument for using dedicated 1:1 or shared M:N is the efficiency gained by reusing the protection bandwidth for lower-priority traffic when the bandwidth would otherwise be idle.

To advertise the protection bandwidth for a link that has dedicated 1:1 or shared M:N protection, a link with LPT field Extra Traffic should be advertised. This indicates that bandwidth can be used by LSPs, with the caveat that any LSPs routed over this link will be pre-empted if the resources are needed as a result of a failure over the primary link.

When a failure occurs on a dedicated 1:1 or shared M:N link, the LSPs routed over the link will automatically be switched to the Extra Traffic link that is protecting it.

To support the routing of secondary LSPs for M:N path protection, new extensions must be added to the current GMPLS routing extensions. In particular, there must be a mechanism to advertise secondary bandwidth, and processing rules must be defined for bandwidth accounting when LSP requests arrive at a node. See [17] for a proposal addressing these issues.

Adoption and Implementation of Photonically Switched and GMPLS–Enabled Networks

As with any new technology, service providers will scrutinize photonic switching and control-plane technology before adopting and deploying it in their networks. The evaluation of these new switching systems goes well beyond technological issues. Service providers need compelling business solutions that improve their financial performance. The combination of scalability, transparency, and intelligence offered by GMPLS–enabled photonic switching translates into four key advantages that allow carriers to differentiate themselves from the competition: reduced capital expenditure, operational excellence, revenue growth, and superior network manageability.

Lab and network trials are currently in progress to evaluate both photonic switching and GMPLS control-plane technology. In the first phase of testing, conducted over the last six to 12 months, carriers have primarily concentrated on evaluating the features, characteristics, and performance of MEMS–based photonic switches, typically in standalone configurations. With the critical optical characteristics validated, some carriers are now looking at deploying these switches under control of their existing managements systems. In this model, photonic switches play a functional role similar to that of today's digital cross-connect systems (DCSs), while exploiting the benefits of optics. Once the DCS has efficiently packed the information in the electrical domain and generated SONET–compliant optical signals, the key role of the photonic switch is to dynamically reconfigure the network—at the wavelength level—for restoration or to accommodate changes in bandwidth demand. As mentioned, network reconfiguration is controlled by a centralized network-management system (NMS), which issues switching commands to each switch individually to create optical paths through the networks.

More recent trials are focusing on the GMPLS control plane and more specifically on the solutions offered by GMPLS–enabled photonic switches. The broad interest in GMPLS is illustrated by the fact that incumbent providers and newer entrants alike are planning these trials and even early deployments, demonstrating that the GMPLS control and management plane provides an adequate answer to the yet-unmet need for homogeneous network control. Beyond photonic switches, most trials involve equipment from multiple vendors, encompassing routers, O–E–O switches, metropolitan and long-haul DWDM systems, and many more.

With the choices that need to be made and the difficulty for some vendors to quickly introduce a standards-based control plane, implementations will likely be phased. This allows gradual education of the service-provider community and their customers regarding the advancements and advantages created by the new "Photonic Paradigm." To accelerate creation of best-of-breed multivendor photonic networks, the following step-by-step approach could be considered:

- *Phase I*
  a) Static configuration of an out-of-band control channel (e.g., Ethernet) between the router and the optical switch to demo MPLS interoperability. This supports LSP creation, using RSVP to set up LSPs via the control plane.
  b) Basic LMP procedures between routers and optical switches to demonstrate the functionality of LMP. This phase includes the use of a control channel between the optical switches and bearer channel initialization and verification. It also facilitates the operation of GMPLS by synchronizing the port mappings for the creation of LSPs using GMPLS.

- *Phase II*
  a) This phase concentrates on optical path redundancy and introduces 1+1 network redundancy to provide fault detection and network restoration at SONET time scales. Other restoration mechanisms include 1:N path restoration and M:N bearer channel protection. This phase also introduces load-balanced path selection, an enhancement to the constraint-based path computation to improve load balancing among equal-weight paths.
  b) The final phase adds support for user network interface (UNI) + network-to-network interface (NNI) signaling and introduces LMP–WDM. This interface allows optical switches and routers to communicate with DWDM transport systems, to retrieve health and status information from the optical cloud, and to make it accessible to edge devices for use in network management and path computation.

The evolution to photonically switched networks will be gradual, as several unresolved challenges still lie between today's networks and purely photonic networks. Among the impediments to true optical transparency are all-optical regeneration, optical performance monitoring, and wavelength conversion. In the absence of commercially viable "all-optical" solutions, some measure of optical-to-electronic conversion should be expected in near-term, practical photonic networking architectures. As this is associated with higher cost, the optimal solution will be one that implements the absolute minimum amount of opto-electronics required to ensure the desired optical signal quality and performance monitoring. Concurrently, this solution has to support an easy migration to all-photonic networking once the technological limitations are removed.

The resulting near-term photonic networking architecture is characterized by transparent photonic segments, bounded by opto-electronics. In the medium term, wavelength conversion combined with all-optical regeneration will allow the conversion and regeneration of any bit-rate or data format. Combined with optical signal quality and performance monitoring, this will lead to the implementation of end-to-end photonic transparency.

The opto-electronic boundaries in the near-term architecture will consist primarily of transponders, which allow systems that were not designed to operate in the tightly controlled WDM environment to operate over these systems. Transponders also provide a common interface between multiple vendors' equipment—a necessary provision, as there are many proprietary DWDM implementations. The third function the transponders provide is interfacing to large routers and switches, since OC–48c and OC–192c high-speed interfaces now enable routers and switches to interface directly into DWDM systems.

Currently, interfaces into the WDM systems are SONET–like. The challenge is to determine how SONET–like they will remain. The bit rates will be common to the SONET rates and will have basic SONET framing and multiplexing. Whatever SONET functions remain, all parameters need to be configurable to allow service providers increased flexibility in their migration strategy. Some service providers will continue to build their SONET network in the same way but will use a photonic switch to interconnect rings. This is a very easy step to take as it preserves the existing ring architecture and restoration techniques (diversely routed 1+1 capacity and SONET ring protocols), while it offers immediate benefits such as simplified service provisioning and management. Additionally, the combined cost of photonic switches and transponder-based DWDM is much lower than that of ADMs and transponder-based DWDM.

An intermediate step toward photonic networking is to build SONET rings over a mesh infrastructure. In the final stage, SONET can gradually migrate to the edges of the network with the photonic switches in the middle, providing the routing and restoration functions. The aforementioned implementations can coexist with existing SONET rings while offering benefits like "point-and-click" provisioning and the ability to introduce class-of-service (COS) networking, allowing a service provider to offer traditional SONET services with 50 ms restoration, mesh reroute restoration services, and unprotected circuits, all on the same network. As these services would be provided at various price levels, customers can balance service quality and cost.

The opto-electronic-bounded photonic network combines the benefits of photonic switching with advances in DWDM technology to create a short-term network architecture that delivers managed multigigabit bandwidth and provides reliable, wavelength-level, traffic-engineered network interfaces to the service platforms. The service platforms include new high-capacity IP routers, O–E–O switches, ATM switches, and SONET ADMs, which are redeployed from the transport to the service layer. The service layer delivers services to users in various forms and relies entirely on the photonic layer for the delivery of multigigabit bandwidth where and when it is needed. SONET transport gives way to photonic transport, and bandwidth is provisioned, not at TDM granularities, but rather at wavelength granularity. To meet exponential growth rates, rapid provisioning is an integral part of the new architecture. While initial implementations of this model will support error detection, fault isolation, and restoration via SONET, restoration will gradually move to the photonic layer.

The premise of photonic networks requires the availability of tools to measure and control the smallest granular component of such networks—the wavelength channel. These functions include the monitoring of amplifiers and switches at add/drop sites, the deployment and commissioning of DWDM routes, and the restoration and protection of networks. This must be accomplished with speed and accuracy and implies that performance measurements have to be done while keeping the channel in optical format. As photonic networks mature, it will be necessary to generate a more detailed picture of the channel "health" in a manner that can be communicated to the network control entities as well as between other network elements. Detailed performance monitoring at the "digital level" will be performed at the service interfaces.

Conclusions

While today's optical networks are highly reliable and carry remarkable amounts of bandwidth, the optical layer of these networks is fundamentally static and provides for only simple point-to-point transport. All channel management, restoration, protection, provisioning, routing, and switching of optical channels is done in the electronic layer. This requires hundreds of millions of dollars in inflexible O–E–O conversions to accomplish basic bandwidth-management functions. New photonic switches, ultra-long-haul DWDM equipment, optical add/drop multiplexers (OADMs), and photonic-layer protection and restoration functions are becoming available to move functionality from the electronic to the optical layer, thereby dramatically reducing the cost of optical networks.

GMPLS will constitute an integral part of next-generation data and optical networks. It provides the necessary linkage between the IP and photonic layers, allowing interoperable, scalable, parallel, and cohesive evolution of networks in the IP and photonic dimensions. The functionality delivered by GMPLS allows network operators to scale their networks well beyond current limitations implicitly created by the segregation of the transport network from the data above. The signaling capabilities of GMPLS will allow service providers to quickly build out high-capacity agile infrastructures that support fast provisioning of connection services. Now that demand for data transport has eclipsed that for voice, it is appropriate that the control-plane mechanism expand to embrace data transport more closely while still serving the incumbent needs of voice transport. Service providers can incrementally deploy GMPLS–based products in existing networks to decrease costs without impacting service quality. Furthermore, the flexible M:N protection and restoration capabilities of GMPLS allow efficient addressing of network survivability, while opening the door to new types of services.

From a service provider's perspective, GMPLS enables three levels of advanced management and control. At the lowest level, flexible and rapid (optical) bandwidth creation and distribution is enabled through signaling, routing, and the link management of wavelengths. At the second level, service creation and management is enabled through the same control plane but now using timeslots, packets, and cells. Since both layers utilize a single set of semantics, service creation, deployment, and provisioning can be accelerated, while the common network knowledge shared between service and transport equipment facilitates a more efficient and faster service restoration, load balancing, and path-performance optimization. At the third level, the GMPLS framework can potentially provide the first unifying management plane for data networks, similar to what signaling system 7 (SS7) does for voice networks. GMPLS allows homogeneous network control, which is not possible today. Substantial impact will be derived from having network-management applications leverage the control plane to collect and correlate service-related data, which can then be applied to applications such as service scheduling, service-level agreement (SLA) monitoring, network-utilization analysis, traffic-flow patterns, connection trending analysis, and planning tools. Through GMPLS–enabled access to network information, operations support system (OSS) and other software vendors can build vendor- and platform-independent applications that run on standalone machines, while the service provider only has to give these applications access to the link-state database (LSD) to bring them on-line. Carriers will greatly benefit from a common set of management semantics to unify heterogeneous optical networks and deliver consistent information across all elements. Lack of such unified management information throttles today's optical networks, limiting performance, cost-effectiveness, and the carriers' freedom to choose best-in-class elements.

Given the challenge of quickly introducing a standards-based control plane, implementations will likely be phased. Calient was preparing to co-launch GMPLS Test Bed activity in 4Q 2001, involving a range of DWDM, gigabit router, and photonic switching players. The goal is to prove that wavelength routing and connection management can be achieved across multiple network elements from multiple vendors. This effort was to be done in concert with the Internet Engineering Task Force (IETF) committee work and constitutes one of the first cross-industry and cross-element collaborative standards implementation efforts.

Architectures for Metro Optical Networks

Joon Choi
Director, Product Management
Mayan Networks

Although the prevalent metropolitan optical networks (MON) consist of the traditional synchronous optical network (SONET) architecture, changes in the MON are imminent. This paper discusses the evolution and challenges of competitive local-exchange carriers (CLEC) and service providers (SP), evaluates existing solutions, and examines the requirements for addressing the emerging challenges.

Evolution

The Telecommunications Act of 1996 was developed to foster more competition in the metro area and in local-loop access. The Act also introduced the first set of metrics used to evaluate the success of CLECs and SPs. The network elements (NE) addressed by the first metrics were the number of fiber miles to which a CLEC or SP had access and the number of buildings to which the fiber had access.

SPs began to provide service based on those NEs, including data services and digital subscriber line (DSL), that were very popular with providers. Eventually the CLECs and SPs formed partnerships with application service providers (ASP) in offering Internet protocol (IP) services. Next they focused on increasing capabilities and seeking ways to bill for service on a usage basis in lieu of offering a monthly flat-rate service charge.

Now the following questions must be addressed:

- How do CLECs and SPs evolve further?
- What are their challenges in terms of the metro edge market?
- How will those challenges be addressed?

Challenges

Some of the solutions addressed by a study in early 2000 were the optical IP, multiservice dense wavelength division multiplexing (DWDM), and the multiservice SONET. The numbers were quite high in terms of projections for 2001 to 2004. On the multiservice DWDM, for example, the number doubled from 2001 to 2002. The multiservice SONET showed a market increase to approximately $6.3 billion in 2004.

Admittedly, this research was done when the stock market was in an exuberant state, so the numbers may have been on the high side, but the following conclusions can be drawn nonetheless:

- Various solutions exist in the metropolitan-area network (MAN).
- SONET as an infrastructure will continue to exist.
- SONET must evolve to provide the performance required by, and meet the criteria of, multiservice.

Current Edge Architecture

At the metro edge, where access exists to the SONET access ring in the MAN, there are multiple service types, such as the following:

- A voice network that requires a fairly delayed, sensitive type of traffic
- A service offering virtual private networks (VPN)
- An enterprise system connection (ESCON)
- Web hosting

Physical interfaces, which are required for the access, are also found at the edge:

- Ethernet interfaces
- Telephone company interfaces; e.g., T1 and T3
- DSL or direct optical interfaces; e.g., optical carrier (OC–3, OC–12, and OC–48)

Riding on the physical interfaces are the protocols for handling various functions:

- A pass-through of time division multiplex (TDM) traffic
- A pass-through of asynchronous transfer mode (ATM)
- IP
- Frame relay (FR)

SONET Optimization

SONET was originally designed to be used for voice, so it is optimized for voice and based on TDM. Consider the case of an SP that offers three megabit (Mb) Ethernet service and provides direct access to the SONET access ring, in this case an OC–3 metro ring. The SP utilizes a legacy add/drop-mix type of equipment which will pass the traffic through, mapping the three Mb service directly onto the granularity of the SONET payload—or the time slot which, in this case, is a synchronous transfer signal (STS)-1 running at 51 Mb per second (Mbps).

Only one third of the entire SONET ring is allocated for three Mb of data stream, the equivalent of a six percent utilization—not an optimum usage of SONET carrying Ethernet directly. Additional grooming and, perhaps, some additional intelligence are required to best optimize the SONET to handle the ever-increasing data-oriented traffic

Solutions

Various solutions, including SONET equipment, ATM virtual path rings (VPR), passive optical networks (PON), wavelength division multiplexing (WDM), dense WDM (DWDM), and gigabit Ethernet (GbE), are currently available. Each solution has its own advantages and issues that must be addressed.

SONET Equipment

Traditional SONET equipment consist of muxes and digital cross-connect (DXC) that all operate at Layer 1. Because there is no higher-layer intelligence, there is no optimization for the data-oriented traffic via the existing SONET infrastructure. SONET also does not scale well and, in the past, the equipment had to be removed and replaced with other types of equipment that might provide better service.

ATM Virtual Path Rings

The ATM VPRs represent another solution, wherein a service layer is added onto the existing SONET infrastructure. Adding a protocol such as ATM provides some guaranteed service, a good quality of service (QoS), and a mixture of different types of traffic, but it also increases overhead.

The biggest issue with the VPR solution is that it is of proprietary nature at this time. Each vendor is required to test and address interoperability with other vendor's equipment.

PON

PON can be a good, cost-effective solution, and it has become popular in the campus-area network as well as the enterprise. Today, however, the PON is still a proprietary solution that requires end-to-end products from a single vendor. The PON also does not offer any edge intelligence; there is no higher layer of processing, such as IP or ATM.

WDM

WDM edge switches and the DWDM edge do aggregate traffic onto the backbone and expand the capacity of the fiber. However, in terms of cost, as the DWDMs in the long-haul area move closer toward the edge and within the access of the MAN, the current price of equipment—not including the bandwidth (BW), at least in nominal cases—is nevertheless still too high for the metro-area edge in comparison with alternative solutions.

Both WDM and DWDM are composed of proprietary solutions, requiring products from either a single vendor or, with a limited interoperability, multiple vendors.

GbE

The GbE started from the local-area network (LAN) side and provides a very good price for BW connectivity. But extending the GbE to the metro access and edge is practical only if the price can remain the same and the product can continue to offer carrier-class reliability and resiliency, which remains a challenge.

The Smarter Metro Edge

The smarter metro edge has four basic ingredients: interoperability, grooming, transport, and provisioning and offer solution to the challenges found in the MON

Interoperability

As the SONET continues to grow and evolve, it is critical for new equipment to be interoperable with the existing equipment, not only at the physical layer but at the signaling and control layers as well. Some equipment must be managed and operated through individual vendors, and multivendor equipment must be managed and operated through the data communications channel (DCC) and other standards-based channels.

Smarter Grooming

One aspect of smarter grooming is providing the DXC all the way down to digital signal (DS)–0 to provide better visibility into the lower-level traffic, which might range up to OC–48.

The other aspect is the ability to provide a distributed grooming capability where, at the entrance of the SONET access ring, the DXC capability can be provided, thereby packing the SONET ring BW more tightly and providing a cost savings.

SONET Transport

To carry data over SONET, the BW must be maximized and efficiently utilized. A small amount of intelligence should be added, while maintaining interoperability and standards over the SONET ring and continuing to provide the maximum utilization of that data BW riding over SONET.

Smart Provisioning

Decoupling the physical interfaces from the protocol or service aspects should enable the provisioning of services on a per-port basis. With a T1 module, for example, each port should be able to provide TDM, ATM, FR, and so on, something only possible with decoupling. A distributed architecture is required for smart provisioning.

DSL and Remote Terminals

Jon Cordova

Directing Analyst, WAN, Internet, and New Metro Access

Infonetics Research

This article discusses digital subscriber line (DSL) and remote terminals, market drivers, deployment models, and market forecasts.

Background on Remote Terminals

Remote Terminal Basics

Remote terminals (RT) are small, weatherproof vaults, huts, or cabinets that were originally used to house digital loop carrier (DLC) systems to provide voice services and pair-gain and to avoid copper home runs. They are usually located within a mile of the final drop to a residence or a small business. Why should RTs be used for DSL deployment? Primarily because the central office (CO) is, in many cases, too far from the user; DSL typically has a three-mile reach from the CO to the customer. In addition, the regional Bell operating companies (RBOC) can leverage their existing DLC RT infrastructure. RTs currently house legacy and generic requirement (GR) 303 next-generation digital loop carriers (NGDLC) and will house new-generation broadband loop carriers in the future. The new-generation broadband loop carriers integrate various combinations of plain old telephone service (POTS), DSL, media gateway, and loop-management functionality.

Remote Terminal Examples

Some examples of RTs are shown in *Figure 1*. The first picture at the upper left is a remote hut. Below that, is a photo of a small vault. The digital subscriber line access multiplexer (DSLAM) at the top right is adjacent to a DLC. Finally, at the lower right is an ordinary DLC with a module for upgrading to DSL services.

Industry Trends

The fundamental consumer demand for DSL remains strong. In North America, DSL providers grew 20 to 40 percent during the first quarter of 2001, ending with 3.9 million subscribers. Cable subscriptions grew 15 to 25 percent, ending with 5.6 million subscribers for the same quarter. DSL providers maintain subscriber backlogs, and prices are increasing in accordance with demand.

Still, a large percentage of households cannot get DSL. The DSL coverage rate for BellSouth is about 60 percent of its customer base, and for SBC it runs at about 50 percent. Verizon and Quest are about the same, at 40 percent. Currently, RTs for the RBOCs are estimated at over 100,000 units. These RTs are serving about one third of residential DSL lines and will probably serve over 50 percent in the future.

Market Drivers

Residential Drivers

For residences, some of the market drivers are high-speed Internet access, video-on-demand, voice over digital subscriber line (VoDSL), distance learning, and home networking.

Business Drivers

The business drivers are telecommuting with virtual private networks (VPN), videoconferencing, VoDSL, distance learning, and, finally, asymmetric digital subscriber line (ADSL) adoption by small offices/home offices (SOHO) and small businesses for cases where ADSL speeds are sufficient to meet their business requirements.

Deployment Models

CO Deployment Model

The most prevalent deployment model in the CO has a DSLAM and a DLC both located at the incumbent local-exchange carrier (ILEC) facility, and the subscriber receives services through a standard DSL modem or router plus a phone set, or, in some cases, a residential gateway (see *Figure 2*). The signal is split at the CO, with the data traffic being sent to the DSLAM and the voice traffic to a local switch.

Next-Generation DLC Deployment Model

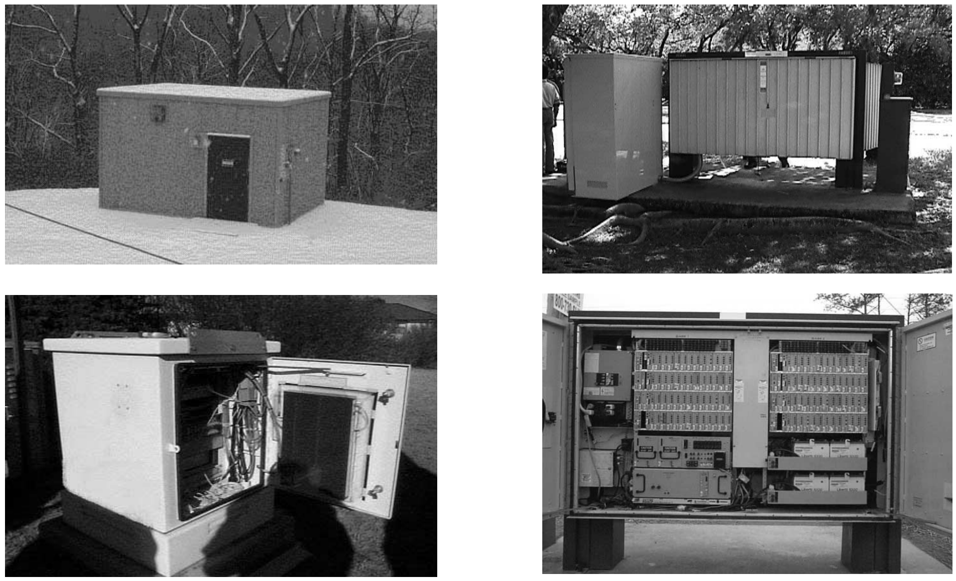
Another deployment model is that of the NGDLC located in an RT (see *Figure 3*). On the left side, the subscriber picture looks about the same. On the right side, the data and voice traffic is split and then sent to the respective data and voice networks. NGDLCs maintain separate ports for POTS and DSL with the splitter typically integrated on the line cards.

Remote DSLAM Deployment Model

The remote DSLAM deployment model calls for both the DSLAM and the DLC to be located in a RT (see *Figure 4*). Here, there is a full-service DSLAM working in conjunction with a DLC, so the ADSL and POTS lines need to be split at the cross-connect before voice and data traffic can traverse their respective public switched telephone network (PSTN) and asynchronous transfer mode (ATM) networks.

FIGURE 1

Examples of RTs



Future Converged Packet-Based Public Network

Of course, the networks' utopia is the future converged packet-based public network (see *Figure 5*). In this case, one broadband loop carrier in the CO or the RT aggregates and distributes all the traffic. On the left side is the typical subscriber customer-premises equipment (CPE). The unique characteristics of these broadband loop carriers are their integrated port and line-card functionality, which includes DSLAM, DLC, media gateway, and loop-management functionality. They require no internal or external splitter, help eliminate truck-rolls, and can be remotely provisioned. Many NGDLCs vendors will likely start to build all of the aforementioned functionality into their products, and both CO and RT deployments will be popular. Broadband loop

FIGURE 2

CO Deployment Model

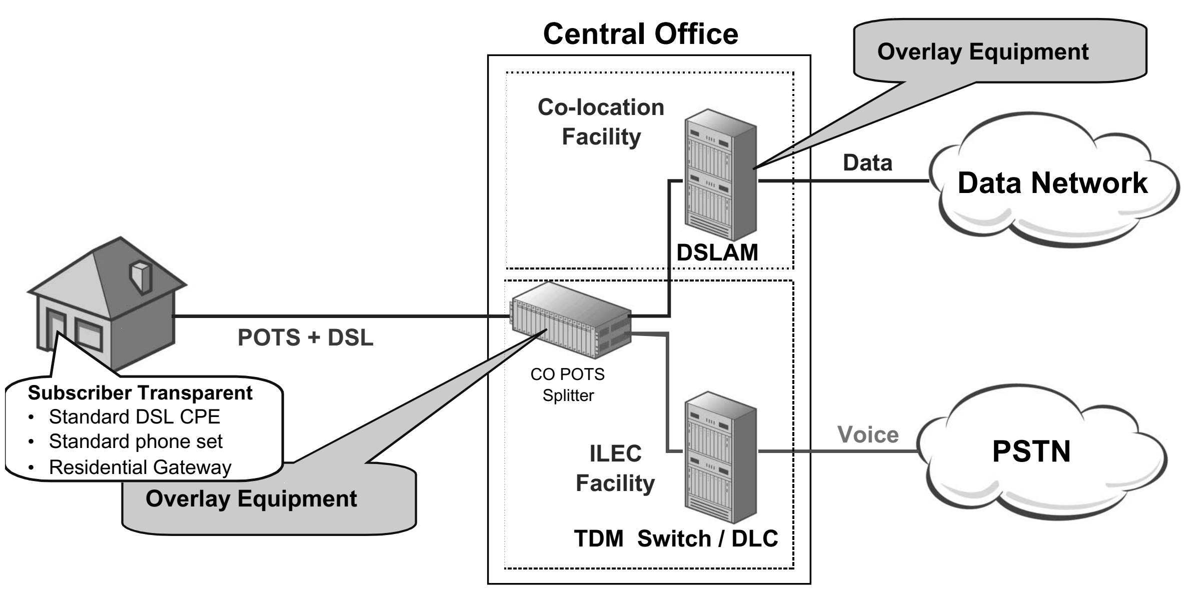


FIGURE 3

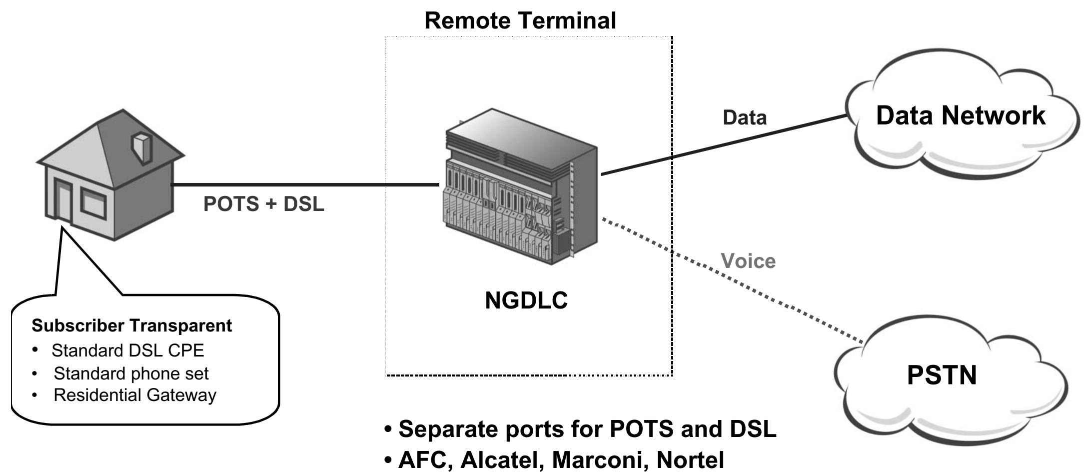
NGDLC Deployment Model



carriers have not gained much traction yet, but are currently in trials with a number of the RBOCs.

Market Forecast and Predictions

Worldwide DLC DSL Line-Card Revenues
Finally, *Figure 6* deals with the market forecast and some predictions for worldwide DSL line-card revenues. This market is expected to grow from about 300 million at the end of 2001 to about 750 million by the end of 2004. However, this does not include the broadband loop-carrier revenue, nor does it include any chassis revenue or revenue from deployments in COs. It is a very simple, realistic forecast.

Forecast Factors and Assumptions
Some of the factors and assumptions used in the forecast are important to understand.

- SBC has approved Alcatel and AFC platforms for Project Pronto, which aims to cover about 80 percent of the customer base with over 17,000 RTs by 2003.

FIGURE 4

Remote DSLAM Deployment Model

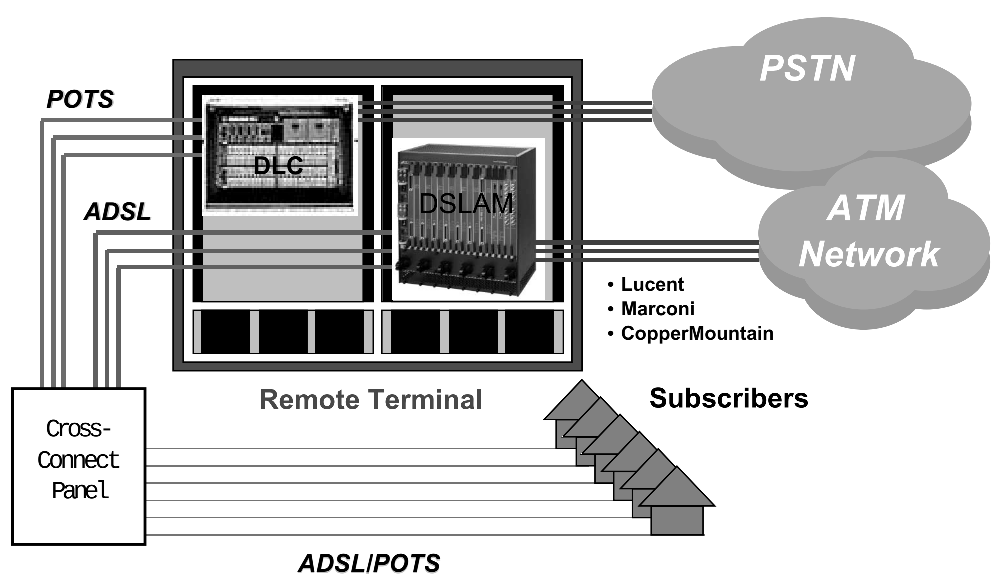


FIGURE 5

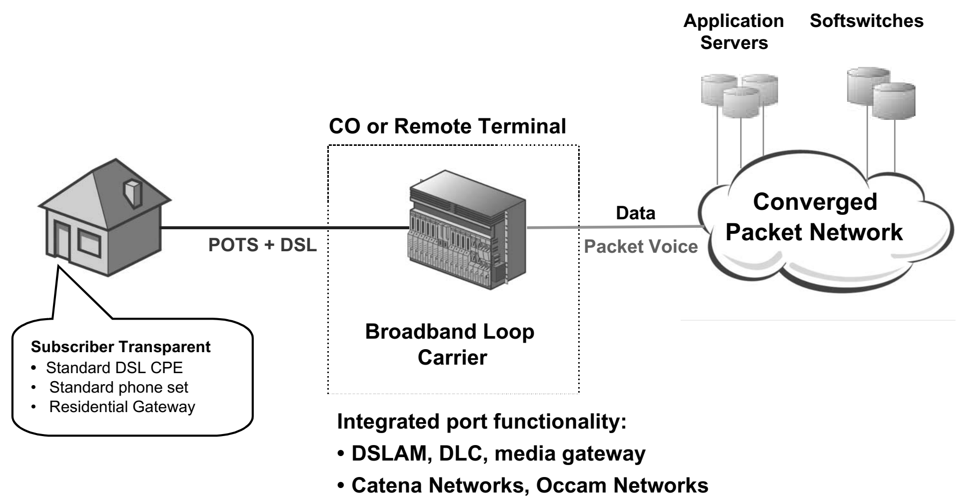
Future Converged Packet-Based Public Network



- Lucent announced an agreement to provide Stinger DSLAMs in Qwest RTs that will add about 6 million DSL–capable customers by the end of 2002.
- BellSouth and Verizon are a little bit more on the fence. They have talked about some different deployment models, and BellSouth has indicated it will deploy Marconi DSL remotes in 2001 that would add 100,000 new DSL–ready households per year. Verizon has reported interest in AFC, Alcatel, and Lucent solutions, but has not committed to remote DSL deployments because of unbundling requirements and uncertainty about how regulatory legislation will unfold.
- The last, and most important, factor is that the RBOCs will have much more incentive to modernize their access networks and gain return on investment if the Internet Freedom and Broadband Deployment Act of 2001, which is also termed the Tauzin-Dingle Bill, is passed. If it is not, there will probably continue to be deployments by the RBOCs, with waivers in some regions and some competition from the competitive local exchange carriers (CLEC) and the inter-exchange carriers (IXCs) as well. However, this bill is key to the RBOCs getting very aggressive with their deployment plans.

After the DSLAM: From CO Magic to Service Provisioning

Ed Cox
Director, Business Development
Santera Systems

This article discusses changes inside the central office (CO) and what needs to happen within the switching environs for broadband services to be delivered while supporting the legacy voice work.

Disruption in the Service Provider's World

A lot of things are going on in the market that cause disruption in the service provider's world, particularly within the last year (see *Figure 1*). Technology is changing rapidly. Service providers have the ability to introduce new things and implement new services, but they are saddled with old architectures, meaning that the previous generation of technology has a shorter life cycle, putting more strain on the network's ability to absorb it. Standards and protocols are constantly changing, making more customer and employee training necessary. The market is disrupted by missing market-entry barriers, bandwidth hunger, and challenges caused by convergence. There is widespread confusion as well as competition. And of course, in all of this there are the financial issues that go with the more rapid adoption of technology—how to use it, how to quickly recover from it, and what services can be provided while it is in the network.

Access Demand Cannot Find the Network

The access network continues to grow and diversify (see *Figure 2*). There is bandwidth improvement within the core of the transmission network as well, whether it is digital subscriber line (DSL) or cable modems on the access side, or any of the dense wavelength division multiplexing (DWDM) types of things that are being done in the core. But nothing has happened to date in between those two, which is the switching equipment that connects all of that high-bandwidth access with all the high-band transmission work going on.

Public-Switching Evolution

The public-switching evolution started out in the 1900s, and about every 25 years or so there have been major changes (see *Figure 3*). The last major change that happened within the switching environment was the move from analog to digital. That has lasted the telecom industry for about 30 years, but in the move from the circuit-based world, with pure voice, to the packet-based world, where voice is just one of many different application bases, some major changes need to happen. IBM learned this lesson very painfully in the move from a monolithic computing model to a distributed model. The question, then, is whether, as they move from a circuit- to a packet-based world, the legacy vendors and carriers are going to realize how upside-down current business practices are actually going to leave them.

Size of United States Replacement Market

There are a number of switches from a voice perspective, with over $50 billion in replacement value, that are either discontinued with no support or in their last year of support (see *Figure 4*). If one looks at the numbers and starts to add them up, even with the next-generation switching dollars, there is a lot of change that needs to happen within the next 5, 10, and 15 years. There is a large amount of switching equipment out there that has been the workhorse of the service-delivery model for the voice-only world. Now, with the move into a packet world, not only is different equipment needed, but the equipment that the industry has relied on is not quite as confident a continuation.

Transition Network

The current transition network (see *Figure 5*) is introducing a variety of different gateways to the softswitch to control those gateways that handle the operation and interoperation between the different routers, asynchronous transfer mode (ATM), frame switches, and the digital subscriber line access multiplexers (DSLAM) themselves; the different voice types of equipment (seen on the right hand side between the Class 5 and the Class 4 switch); digital loop carriers (DLC); and the like. This is, of course, introducing many boxes with many networks and many headaches. The more network elements involved in providing service, the more networks a carrier has to maintain and the more difficult it is for them to move quickly, nimbly, or maybe even at all and the more difficult it is for them to offer those services in some kind of a cost-effective manner.

FIGURE 1

Disruption in the Service Provider's World

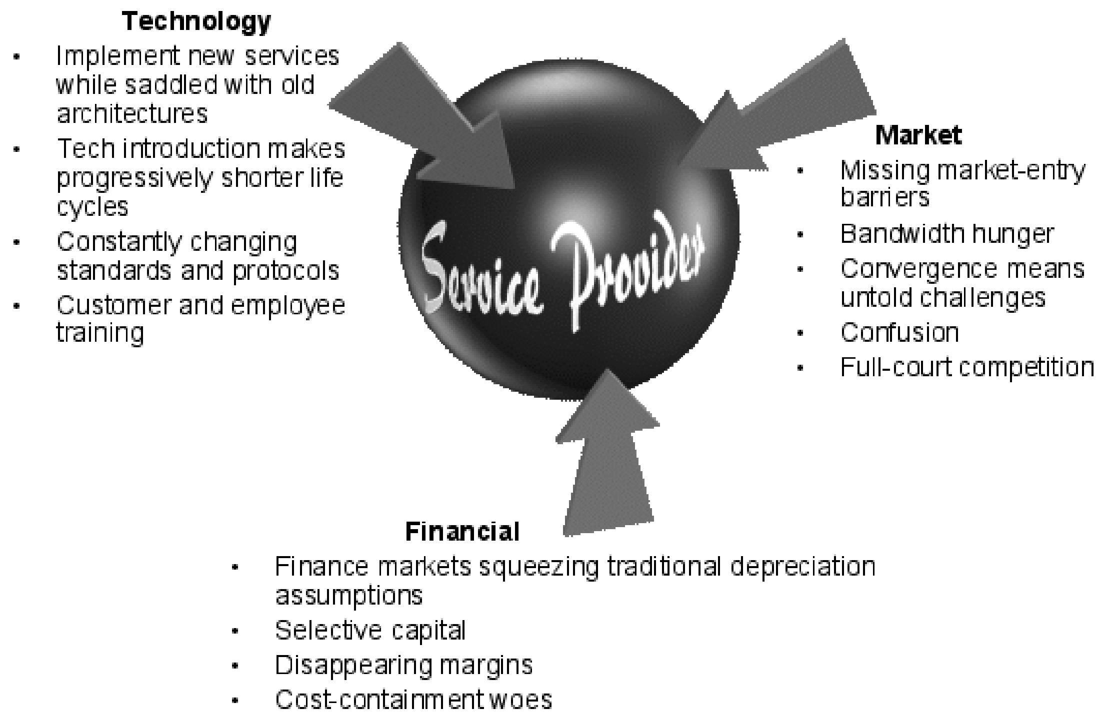

FIGURE 2

Access Demand Can't Find the Network

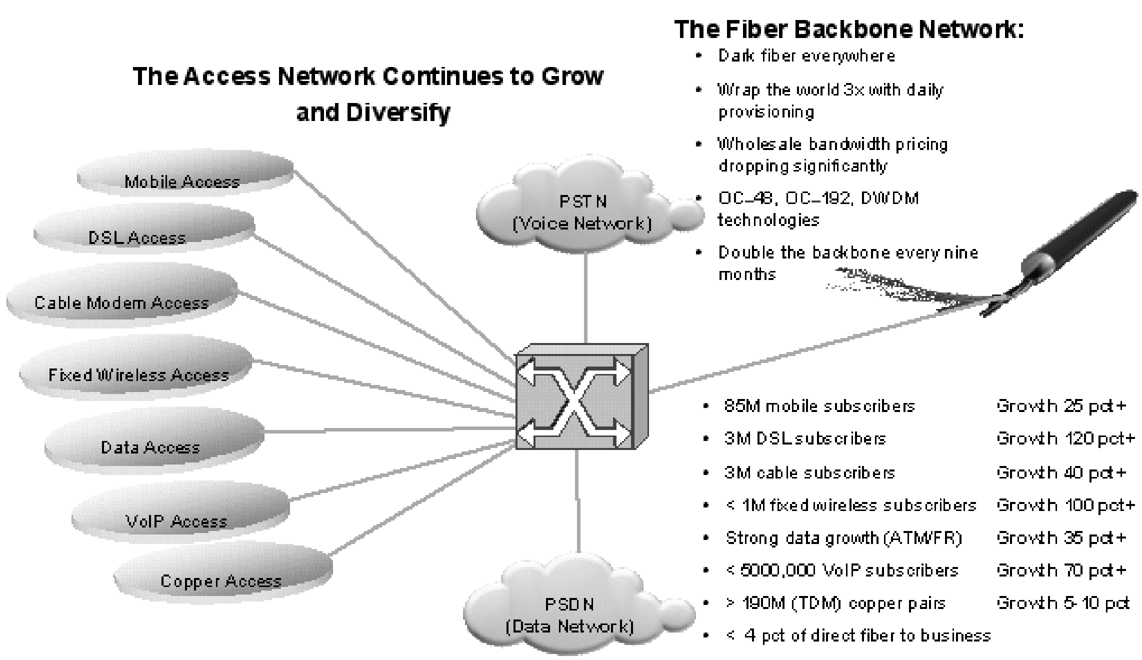

FIGURE 3

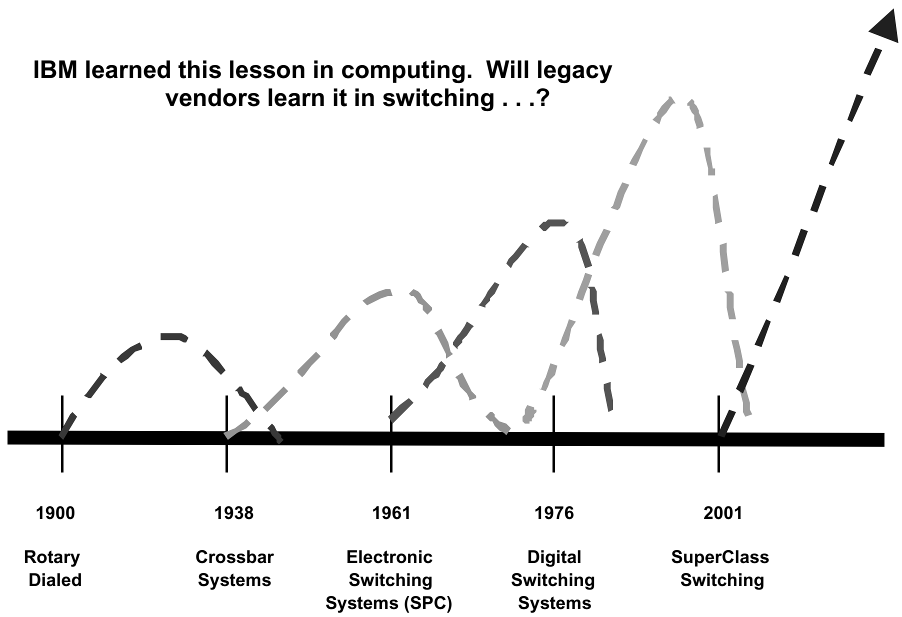
Public-Switching Evolution



Integrated Network

The fully integrated network (see *Figure 6*), when it arrives, will have the ability to put the softswitch and the media gateway together as a superclass switch, or the next switching element, so that all the pieces and information flows that come from the optical-transport network can be interconnected and so that they get down to the customer-premises equipment (CPE) with the switching, adaptation, and services treatment that needs to happen. In doing this combination of functionality, many features will have multiple functions and many opportunities as the service-delivery equation is simplified greatly.

Sustainable Architecture

This needs to be done on a sustainable architecture, where the media gateway is able to provide a variety of traffic types in and out, with the ability to scale and work within different types of bandwidth requirements with different applications in the broadband network. That media gateway will be controlled by the softswitch, which has continued to increase in its definition and importance within the network. At one time the media gateway only included the call control. Now it not only controls the media gateway controller (or softswitch or call agent) but also serves as the repository to run the software functions of the signaling gateway; the application server, if there is one on board; and the element-management system in order to work with all of the different provisioning and management systems. Third, because no single vendor is going to be able to write all the software in the telecom space, the platform needs to be able to provide access to third-party application servers and to continue to increase the value and the number of services that are provided and supported by that particular platform (see *Figure 7*).

DSL Services: Current Transition Network

DSL services in the transition network are a complex challenge (see *Figure 8*). There are a number of network elements involved in providing the service, whether extracting the voice off of a voice gateway or using a plain old telephone

FIGURE 4

Size of United States Replacement Market

Switch	Status	Number of NA Switches
Ericsson AXE–10	Discontinued No Support	Over 80 switches
Lucent 1A	Discontinued No Support	>300 switches
GTD–5	Last Year of Support	>1,900 switches
Siemens EWSD	Current Engineering Only	>1,600 switches
Nortel DMS 100	Last Year of Support	>8,300 switches
Lucent 4ESS	Current Engineering Only	140+ switches
Nortel DMS250	Current Engineering Only	>950 switches
Lucent 5ESS	Current Engineering Only	10,000+ switches
Nortel DMS–10	Discontinued No Support	>4,800 switches

Over $50B in Replacement Value

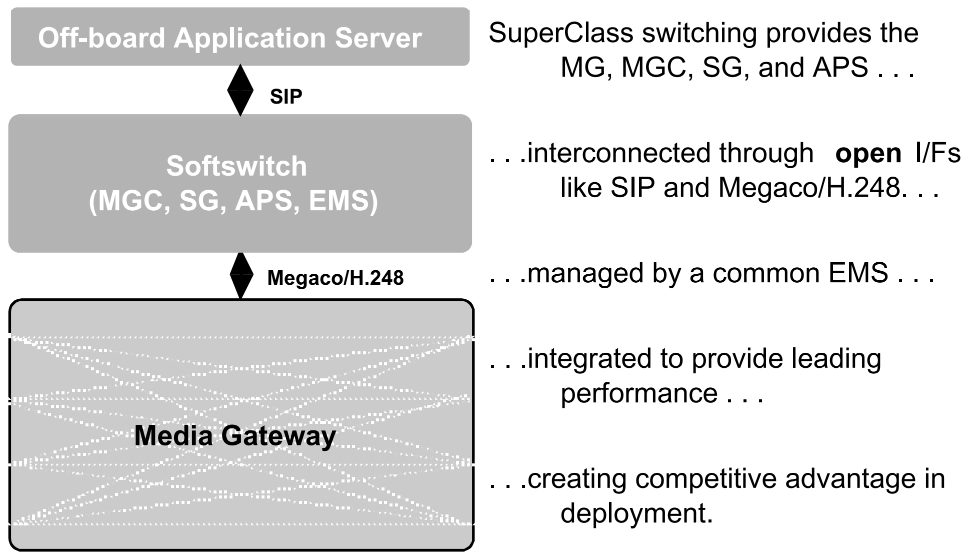
Sustainable Architecture



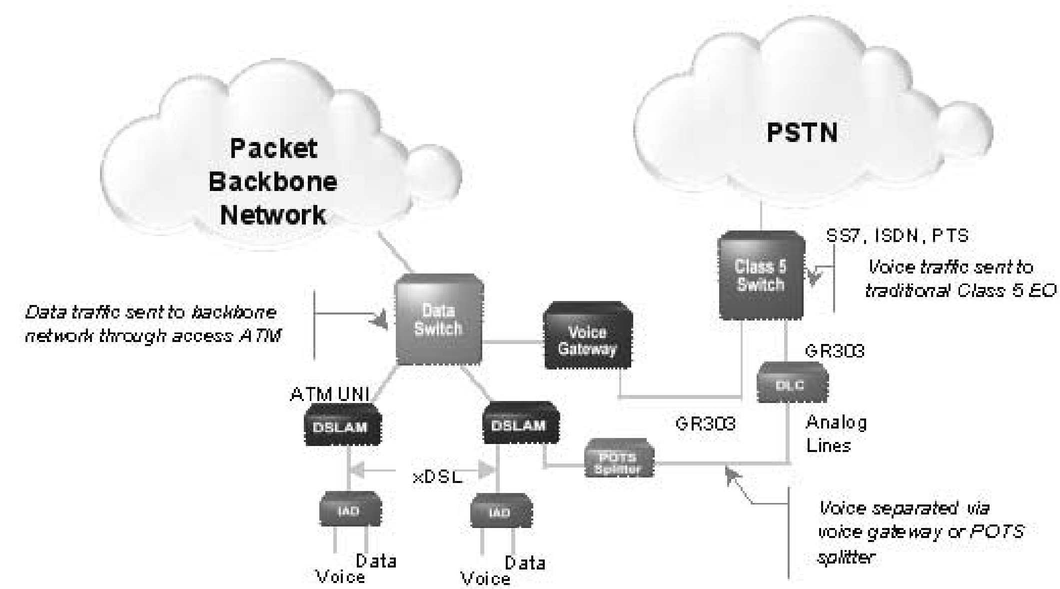
service (POTS) splitter to communicate with the DSLAM and/or the data switch. A long-term service option to supply 7 million lines of voice-over-broadband servers in a single metropolitan area really is a difficult situation to manage. It is a complexity as far as management is concerned. It has lower reliability because it has so many points involved in the total end service and a higher cost to provision.

DSL Services: Integrated Network

Ultimately, next-generation network switching needs to provide an aggregation of functions and to take the traffic directly in from the DSLAM. It needs to take that traffic and switch it, provide services treatment at wire speed, and, depending on the type of service and how that line is provi-

FIGURE 8

DSL Services—Current Transition Network



sioned, to determine whether that traffic then needs to be switched off onto the packet backbone network (regardless of whether it is frame relay, IP, or ATM based) or whether to go back into the legacy environment and continue to support the backbone or the POTS world with equal ability (see *Figure 9*).

Putting Brawn and Brains in the CO

Brawn and brains need to be put back into the CO. DSL is just one example of what next-generation switching must do in order to serve as the switching vehicle over the long term, like the time division multiplex (TDM) switching has done for the last 40 years. This next-generation platform must be put in the network with the knowledge and confidence that it can be counted on for a great period of time. As the industry moves to the packet world, the legacy switching is either dying or dead. The number of switches that are in their last year or have been discontinued in terms of service and support may leave some vendors aching for a cure—but nevertheless, CO switch expectations need to increase. The vendors providing this space need to deliver to that new level of expectation. The industry needs to set the hurdles for vendors to be able to jump over.

The decision then becomes, if vendors are actually performing to spec, should the industry look at a point solution that solves the problem for today by switching within transition networks to solve bottlenecks? Or should it look at a platform decision to really get at the switching needs from a long-term perspective, supporting graceful migration by switching within integrated networks? If it does that, the industry will be able to provide a platform that allows the carrier a variety of different vehicles.

Greenfield, replacement, or cap and grow all follow same architectural design—SuperClass switching. This new SuperClass-switch concept can support the voice as well as the data world, and all the services and points in between.

Introduction

The data over cable service interface specifications (DOCSIS) 1.0 and 1.1[1] define the physical-layer radio frequency (RF) interfaces for data-over-cable systems. With the success of DOCSIS–based broadband access to homes and businesses, the demand for greater symmetric capacity is growing rapidly. This paper discusses the physical-layer enhancements developed to increase the effectiveness of transmission in the upstream or return-path direction in which cable modems send data in time-division multiple access (TDMA) mode to the cable-modem termination system (CMTS) at the head end.

Advanced TDMA Proposal Summary

The key parameters of advanced TDMA[2] are summarized in *Table 1*.

Trade-Offs Leading to Advanced TDMA

TDMA versus S–CDMA and OFDM
Three technologies have been considered for advanced upstream transmission: advanced TDMA, synchronous code division multiple access (S–CDMA), and optical frequency division multiplexing (OFDM). For each technology, the access method during initial registration and station maintenance is TDMA. In addition, in each of the considered technologies time slots are assigned to different users, so all three schemes include TDMA burst transmission and TDMA media access control (MAC). Thus, all three schemes require a TDMA burst modem, with varying synchronization requirements. S–CDMA and OFDM can be viewed as extensions of TDMA transmission to two-dimensional (2D) framing: time/code in the case of S–CDMA and time/tone in the case of OFDM.

Impulse Noise Sensitivity: With 2D schemes, multiple codes or tones are transmitted simultaneously. Hence, individual symbols are lengthened in time by a factor of the number of codes or tones. The longer symbol duration provides an advantage in the presence of weak impulse noise, because the impulse energy is spread among the concurrently transmitted symbols. However, this advantage turns into a disadvantage if the impulse energy exceeds a certain threshold. Then more symbols are affected in these schemes than in pure TDMA.

Figure 1 illustrates the corruption of a single TDMA symbol (or a few such symbols) by a short, but strong, burst of noise, whereas the same noise event affects all concurrently transmitted CDMA or OFDM symbols.

Narrowband Ingress Sensitivity: With TDMA, agility in modulation bandwidth and carrier frequency can be used to avoid RF bands with known severe interference. Remaining narrowband interference can be mitigated by adaptive ingress cancellation. With S–CDMA, cancellation technique can in principle be employed at the chip rate. However, the large decision delay due to the inherent chip-to-symbol conversion process prevents instant availability of reliable decisions. Other estimation and subtraction techniques of much greater complexity must be employed[6,7].

TABLE 1

Key Parameters of Advanced TDMA Physical Layer

Category	DOCSIS 1.0/1.1	Advanced TDMA
Modulation	QPSK, 16-QAM	QPSK, 8-QAM, 16-QAM, 32-QAM, 64-QAM
Symbol rates (Mbaud)	0.16, 0.32, 0.64, 1.28, 2.56	0.16, 0.32, 0.64, 1.28, 2.56, 5.12
Bit rates (Mbps)	0.32 –- 10.24	0.32 – 30.72
FEC	Reed-Solomon, T = 0 to 10	Reed-Solomon, T = 0 to 16
Interleaving	None	RS byte; block length may be adjusted dynamically to equalize interleaving depths
Equalization	Transmit equalizer with 8 T-spaced taps	Transmit equalizer with 24 T-spaced taps
Ingress mitigation	Vendor specific	Receiver ingress cancellation
Preamble	QPSK or 16-QAM; length ≤ 1024 bits	QPSK-0 (normal power) and QPSK-1 (high power); length ≤ 1536 bits (≤ 768 T)
Spurious emissions	Sufficient for 16-QAM	Generally 6 dB tighter to support 64-QAM

TABLE 2

Cable-Plant Impairments and Mitigation Techniques

Impairment	Mitigation Techniques
AWGN	Minimize implementation loss (see *Figure 3*)
Impulse/burst noise	FEC and interleaving (see performance section)
Narrowband ingress	Ingress cancellation (see *Figure 5*), frequency avoidance
Common path distortion[3]	Same as ingress
Micro-reflections	Transmit equalization
Hum modulation	Receiver tracking loops

To cope with dynamically occurring narrowband ingress, S–CDMA can use spreading as a form of signal repetition, trading bandwidth efficiency for robustness against narrowband noise. For example, spreading by a factor of 10 leads to a 10 decibel (dB) processing gain at the expense of a 90 percent loss of capacity—an unattractive trade-off.

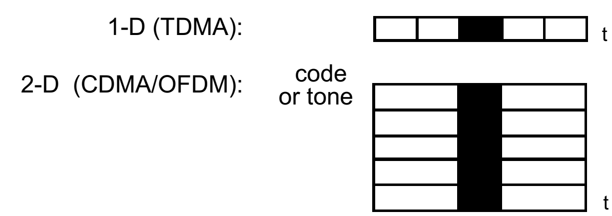
In an OFDM system, narrowband interference can be avoided by not using the affected tones. Frequent tone reassignment is then required for both cable modems and the cable-modem termination systems (CMTS) to avoid dynamic ingress noise, making the protocol complicated and less efficient. OFDM is also more sensitive to unrecognized low-level narrowband interference than TDMA.

Synchronization Sensitivity: The 2D schemes require much tighter timing synchronization and lower carrier phase noise/frequency offset to maintain code or tone orthogonality. For instance, the synchronization accuracy requirement for uncoded 64-QAM is +/– 3 ns for S–CDMA, compared to +/– 250 ns for TDMA, a factor of more than 80. Thus, the timestamp-messaging scheme currently used to control DOCSIS TDMA slot timing would have to be modified. To prevent degradation of code orthogonality (the tendency of codes to interfere with one another if not perfectly synchronized and equalized), the S–CDMA system requires preshaping to flatten the band. Achieving sufficient flatness to support high-order constellation formats can be a challenge in the presence of equalization and ingress cancellation as well as imperfect synchronization among many modems spread over the cable plant. The result can be a self-inflicted noise floor due to inter-code interference.

MAC Impacts of 2D Schemes: Complexity and compatibility with the MAC and transmission convergence (TC) layers of DOCSIS 1.0/1.1 represent major hurdles for the integration of a 2D scheme. Bandwidth allocation is more complex because the scheduler must be able to schedule in time for

FIGURE 1

Strong Impulse Noise (Vertical Black Band) Affects a Larger Number of Symbols in 2D Schemes



DOCSIS 1.0/1.1 modems and time/code or time/tone for advanced physical-layer (PHY) modems. This requires a change to the MAC/PHY interfaces and tight coupling between the MAC and PHY. Otherwise, there may be unused codes/tones, causing capacity loss. Because 2D schemes require block-based processing based on frames, the latency is increased, which can pose a problem for delay-sensitive applications such as voice over IP (VoIP). Some versions of OFDM utilize dynamic bit loading per tone, requiring modifications to the fixed mini-slot format (i.e., constant bytes per time interval) in the DOCSIS MAC.

Fidelity Requirements versus Implementation Complexity

An important element of advanced TDMA is its tighter specifications on spurious emissions. To a first approximation, with 64-QAM operation on the plant, cable modems must provide 6 dB higher suppression of out-of-band emissions than with DOCSIS 1.0/1.1, which uses at most 16-QAM transmission. Otherwise self-noise could limit system performance. The spurious emissions requirements were tailored to the performance achievable with practical low-cost power amplifiers. Similarly, carrier phase noise and transmitter modulation error ratio (MER) were tightened to preserve performance for 64-QAM while weighing implementation complexity and the availability of low-cost oscillators.

System Implementation

Figure 2 illustrates a typical upstream transmitter.

Figure 3 shows a typical burst receiver. The receive equalizer may include an adaptive ingress canceller. The analog front end may include a high–sampling-rate analog-to-digital converter (ADC), which allows direct digital sampling of the entire upstream band (5-42 or 5-65 MHz). Channel-quality–monitoring capability utilizing an FFT can be integrated into the receiver to support spectrum management and provide the ability to detect, characterize, and avoid interference[5].

FIGURE 2

Block Diagram of an Upstream Transmitter

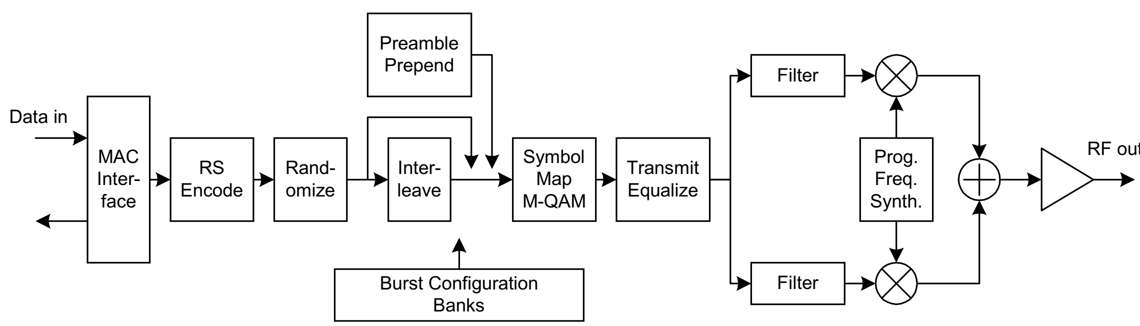


FIGURE 3

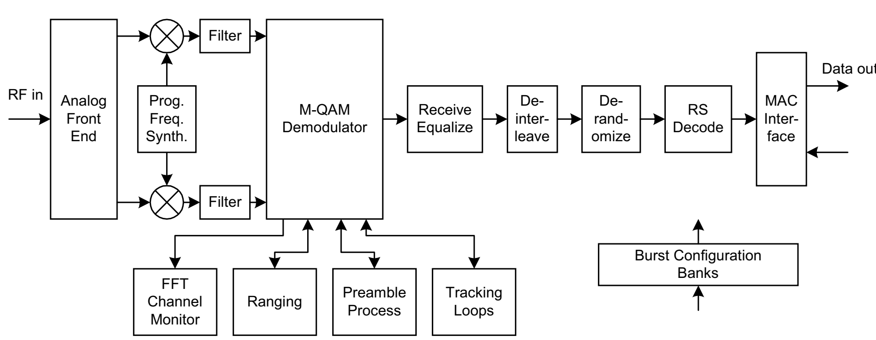
Block Diagram of an Upstream Burst Receiver



Performance

Measured Packet Error-Rate Performance

Figure 4 shows measured performance of an advanced TDMA burst receiver in AWGN with 64-QAM modulation and short packets RS(99,73). The theoretical curve for an ideal continuous receiver with RS(99,73) forward error correction (FEC) is shown for reference. The performance reflects the use of modern digital receiver design techniques and a high level of very–large-scale integration (VLSI).

Measured Ingress Mitigation Performance

Figure 5 displays measured samples of a 64-QAM Advanced TDMA signal with four narrowband interferers. The receiver ingress canceller removes the interference.

Impulse/Burst Noise Performance

The advanced TDMA physical layer adds interleaving as an important mitigation feature against burst noise, used in combination with FEC. DOCSIS contains a great deal of flexibility in burst parameters such as modulation, preamble, and FEC, which permit a trade-off of receiver processing complexity versus robustness. In this section, we consider only interleaving and FEC, since they are defined by the transmission waveform and provide a performance bound.

Specification and Measurement of Burst Noise: Burst noise is characterized statistically by its level, duration, and interarrival time.[4] Some sources of burst noise are quasi-periodic—for example, AC-line–based noise. Performance is often specified and measured in practice using a periodic burst noise model.[5] The burst noise level can reach C/I = –10 dB in the signal bandwidth. The duration is normally 1 us or less, with infrequent isolated occurrences up to 50 us, and an average interarrival time of about 10 ms (100 Hz repetition rate). System performance is measured by the packet error rate (PER) versus FEC code rate (k/n in the RS codewords). To characterize performance in the presence of burst noise, we ignore fragmentation and concatenation and settle on two payload sizes: 74 bytes (for a typical short packet) and 1528 bytes (for a long Ethernet packet).

Performance: *Table 3* shows the performance of advanced TDMA interleaving/FEC in the presence of burst noise for Reed-Solomon T = 16. The analysis assumes the corruption of all symbols coincident with the noise burst plus an additional symbol before and after the noise burst.

Figure 6 is a graphical presentation of the data in *Table 3*. Each point is a bound on the burst noise duration and repetition rate that can be corrected by the selected settings for the interleaver, FEC, and modulation. Hence, any duration and repetition rate of burst noise less than these values can be corrected. This results in a rectangular region to the left and below each point. Case "E" is selected as an example in the graph. The region of typical burst noise that occurs in real cable plants is also depicted; considerable margin is available in most cases. Actual performance, including acquisition effects, will approach these bounds but should lie below them.

FIGURE 4

Measured 64–QAM Packet Error-Rate Performance for Short Packets

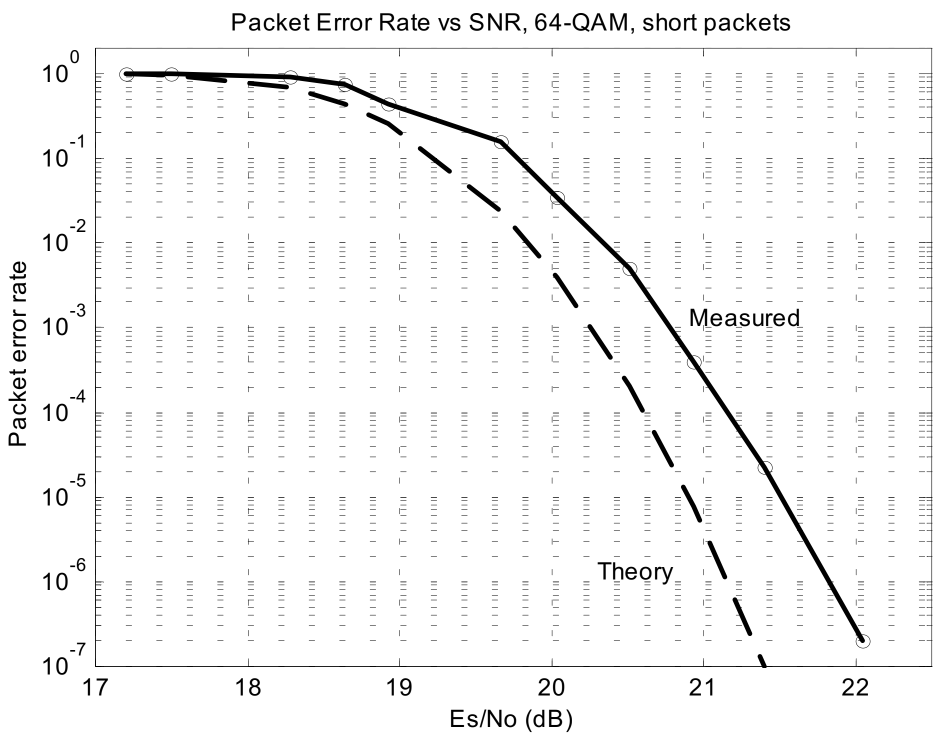


FIGURE 5

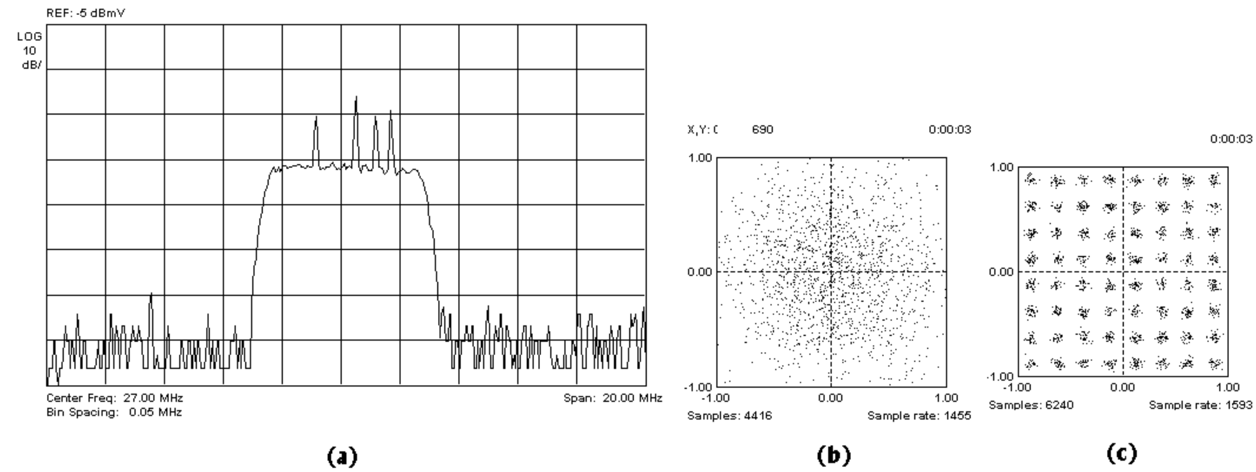
Cancellation of Narrowband Ingress. (a) FFT monitor display showing 64–QAM signal with four narrowband interferers. (b) Signal constellation at slicer input before ingress cancellation is enabled. (c) Signal constellation with ingress cancellation enabled.



Conclusion

The proposed enhancements to the DOCSIS physical layer for upstream transmission provide increased capacity in the return path of data-over-cable systems. The approach is to extend the successful DOCSIS system in an evolutionary manner for both higher throughput and increased robustness. Attention is given to backward compatibility with 1.0/1.1 modems, coexistence between advanced TDMA and legacy modems, and specifications to permit interoperability between multiple vendors that will implement the enhanced waveform. Advanced TDMA modems employ digital techniques to mitigate worst-case plant impairments. This permits the use of portions of the upstream band that were previously unavailable due to strong impulse noise or narrowband ingress. The result is expanded capacity of data-over-cable systems in support of new broadband services demanding higher symmetrical throughput, including voice, video telephony, videoconferencing, and distributed servers.

TABLE 3

Interleaver/FEC Performance in Periodic Burst Noise

Case Label	Modulation Format	Symbol Rate (Msps)	Packet Length (bytes)	Number of Interleaved RS Codewords	Maximum Correctable Noise Burst Length (usec)	Maximum Correctable Noise Burst Repetition Rate (kHz)	FEC Code Rate (%)
A	64-QAM	5.12	74	No interleaving	3.3	35.7	69.8
B	64-QAM	5.12	74	2	7.4	27.7	53.6
C	64-QAM	5.12	74	4	15.2	18.9	22.4

IBM Microelectronics Division

Abstract

In this paper, we review some of the technology trends and directions in fiber-optic data communications, including wavelength multiplexing and storage networking, and discuss applications of this technology, such as disaster recovery solutions and grid computing. We identify key hardware components that enable next-generation data centers, including wavelength agile lasers, optical switching, and parallel optical links. Related trends in self-managed computer networks and emerging industry standards such as InfiniBand are also presented.

1. Introduction

In the past decade, the computer and data-communications industries have witnessed far-reaching changes in both the architecture of large, enterprise-class computing and the fiber-optic networks that are used to interconnect servers with clients, storage, and each other. With the widespread adoption of fiber-optic technology, network bandwidth may have surpassed even processor speed as the most critical element in evaluating the utility of large computer systems. As modern data centers have come to rely on the Internet, which in turn has come to rely on optical communications, various technologies and applications have emerged that are expected to drive future growth in these areas. In this paper, we describe a few of the most important trends in this field, including wavelength multiplexing for metropolitan-area networks (MANs), storage networking, grid computing, automated network management, the emerging InfiniBand standard, and others.

2. Wavelength Division Multiplexing

Wavelength division multiplexing (WDM) is emerging as the preferred technology for the optical data center of the future. It takes advantage of the fact that different wavelengths or colors of light will not interfere with each other when they are carried over the same physical optical fiber. The concept is similar to frequency multiplexing used by frequency modulation (FM) radio, except that the carrier "frequencies" are in the optical portion of the spectrum (around 1550 nanometers wavelength, or 2 x 10^{14} hertz). Thus, by placing each data channel on a different wavelength (frequency) of light, it is possible to send many channels of data over a common optical fiber [1]. Using optical amplifiers, DWDM networks can be extended to well over 100 km distances, making them well suited for disaster recovery applications. More data channels can be carried per fiber if the wavelengths are spaced closer together. In this manner, WDM systems may be classified as coarse, wide-spectrum, or dense WDM (DWDM), as shown in *Table 1*. Successive generations of DWDM equipment have supported more wavelengths and thus more channels over a common fiber link. Current industry standards ratified by the International Telecommunications Union (ITU) establish a minimum spacing of 0.8 nm (100 GHz) and accommodate about 32 wavelengths per fiber. Each wavelength today has a typical capacity of 2.5 gigabits per second (Gbps), which is expected to increase to 10 Gbps in the near future. Systems are emerging that are expected to handle hundreds or even thousands of wavelengths at less than half the current wavelength spacing.

The next generation of DWDM involves more than simply increasing the number of channels, however. New network topologies are also being enabled by the capability of third-generation and higher DWDM systems to support meshed or nested rings with dual redundant paths, self- healing at the physical layer, data regeneration, and more advanced survivability or path protection than currently available. By contrast, conventional telecommunications networks have deployed asynchronous transfer mode (ATM) over synchronous optical network (SONET) rings with separate overlay networks to accommodate Internet protocol (IP) data and other kinds of traffic. These overlay networks are optically transparent but remain service specific. Since data traffic has different characteristics than voice traffic, overlay networks cannot make efficient use of the available bandwidth as they scale to multiple, concatenated rings. Consequently, optically transparent overlay networks are being replaced by a service-transparent DWDM core capable of allocating bandwidth on demand. This offers the advantages of a highly scalable, low-cost, protocol-independent infrastructure and may be the first step toward all-optical networks (AONs). Unlike first-generation DWDM, more recent technology allows wavelength multiplexing networks to be cascaded together, because they act as a complete "3R" repeater (Retimes the signal to remove jitter and improve clock/data

TABLE 1

Types of Wavelength Multiplexing Systems

Type of WDM	*Number of Wavelengths (Channels)*	*Wavelength Spacing*	*Notes*
Coarse (CWDM)	2–4	Very wide (typically 1300 nm and 1550 nm)	Very limited applications
Wide Spectrum (WWDM) also known as Sparse (SWDM)	Up to 16	No standard defined; typical spacing of 1 to 30 nm have been used	Four-channel systems are under consideration for emerging 10 Gbps Ethernet[1]
First-Generation DWDM	8 – 10	ITU grid[2]	Example: IBM 9729
Second-Generation DWDM	Up to 16	ITU grid	
Third-Generation DWDM	Up to 32	ITU grid	Largest systems commercially available for datacom Example: IBM 2029
Fourth-Generation DWDM (Ultra-Dense)	Up to 64	No standard defined; smaller than ITU grid (0.4 nm proposed)[3]	Not commercially available

recovery, Reshapes the signal to removes pulse distortion caused by dispersion, and Regenerates the signal to insures that there is sufficient optical power to reach its destination). Full protection switching at the physical or transport layer is available on a per-channel basis to restore service in the event of either a fiber break or failure of a hardware component in the system; a properly designed DWDM network would have no single points of failure [2].

The historical trend of growth in aggregate system bandwidth is likely to continue for the near future. However, this approach will require the service layer to upgrade more than twice as fast as the transport layer, or roughly double capacity every six months (some estimates have shown the service layer growing more than 70 times by 2003). A more realistic approach is to have the transport and service layers evolve together, although this still requires service-layer capacity to double on a yearly basis. To keep pace with bandwidth growth, future DWDM systems may employ ultra-dense fourth-generation DWDM systems. The desire for efficient bandwidth management is also likely to drive the use of sub-rate multiplexing or the combination of multiple time division multiplexed data channels within a single wavelength on a DWDM network as the most cost-effective way to increase the total number of channels in a DWDM network. As the capacity of the network grows, there are a number of key DWDM components that must keep pace. For example, this past year saw the introduction of the first DWDM devices to employ both electrical and optical backplanes as an efficient means to handle the huge volumes of data being routed within networking equipment. These optical backplanes are also being extended to adjacent equipment racks using parallel optical interconnects, or ribbons of optical fiber four to 12 channels wide, capable of supporting up to 2.5 Gbps/channel. Related technologies, such as all-optical switching and routing, are also being developed to keep pace with bandwidth demands in the network. As the number of wavelengths is increased, there is also a need for optical sources that can be quickly tuned to different wavelength bands to provide more flexible optical add/drop capability and reduce the number of components required for servicing the network. Currently, the mismatch between laser center wavelengths and optical filters in a DWDM network can result in 3 dB to 4 dB or more of excess attenuation, effectively limiting the supported distance that can be achieved without using optical amplifiers. Tunable laser sources would also alleviate this problem. The current state of the art for tunable lasers [3] involves changing the laser wavelength by tightly controlling its temperature, often using some form of feedback to a thermoelectric cooler or a specially designed laser structure. This approach is commonly known as wavelength locking. Currently available systems exhibit fairly slow tuning times, stability concerns over long periods of operation, a limited tuning range, and high cost. Future advances in this area are expected to be a key enabler in lowering the cost and increasing the flexibility of DWDM networks.

Previously, features such as quality of service (QoS), guaranteed message delivery, protection switching, and others have been provided over the legacy telecommunications infrastructure. Indeed, SONET–based traffic is already carried over a physical layer that uses DWDM optical fiber interfaces. However, the growth of IP traffic has led to a complicated arrangement with up to four separate transport layers (IP over ATM over SONET over DWDM). In an effort to simplify this approach and streamline the data flow, there is a clearly emerging trend toward elimination of the ATM and SONET layers and toward the direct transmission of IP or grid data over DWDM. This new model requires the DWDM layer to assume many of the traditional functions associated with ATM over SONET, such as protection switching. In particular, two standards efforts are currently under way to link data packets directly to DWDM optical wavelengths so that the optical network can take some advantage of the intelligence imbedded in IP traffic. This so-called "optical IP" effort could eventually allow grid users to dynamically request portions of a fiber cable's bandwidth for a particular time or service. One such standards effort is the Optical Domain Service Interconnect (ODSI) coalition—a loose connection of vendors providing optical transmission equipment, access services, terabit routers, switches, and network provisioning software. ODSI seeks to define common control interfaces between optical or electrical physical layers and IP media access layers of the open systems interconnect (OSI) model. This work may ultimately rely on derivatives of the Internet Engineering Task Force (IETF) multiprotocol label switching (MPLS)—a means of defining IP flows that is already widely used in the electrical signaling domain. ODSI will propose low-level (below Layer 3) control plane standards that must be met by vendors of both optical transmission equipment and broadband IP switches/routers. A separate but complimentary effort, also based on MPLS, is being drafted within the IETF itself. Known as multiprotocol lambda switching (MP_S)—lambda refers to switching by native wavelengths—this effort has proposed methods to link optical cross-connects and high-bandwidth routers through a Layer-3 switching methodology. Operating at a higher level than ODSI, this proposal has the advantage of not requiring a new set of protocols for QoS and bandwidth control

3. Storage-Area Networking

Today's strategic business initiatives are inexorably linked to network bandwidth for storage applications. Simply put, a business can only grow as fast as information can be retrieved, exchanged, and acted upon. A recent University of California study [4], having estimated that the entire human race has accumulated about one exabyte (10^{18}) of information to date, goes on to predict that the second exabyte will be generated within the next three years. This abrupt growth spurt in storage requirements after a fairly long period of incremental growth parallels the growth pattern of the Internet, and its implications are just as fundamental. It has been estimated that by 2003 the Fortune 1000 companies will add more than 150 terabytes of storage capacity and that more than half of all fiber-optic traffic in their data centers will be feeding storage systems. Storage services are growing at more than 120 percent per year, and are projected to be an $8 billion market in 2003 [5]. Loss or even temporary unavailability of mission-critical data is unacceptable. In the event of a disaster at their primary data center, large companies can easily lose millions of dollars. In this environment, storage-area networks (SANs) have become a vital part of the e-business infrastructure.

With the growing amounts of network bandwidth that must be dedicated to storage applications, it makes sense to separate the storage traffic from the rest of the network to improve performance and simplify network management. This is the basic principle behind a SAN. The concept of SANs is not new. More than 10 years ago, enterprise data centers used Enterprise Systems Connectivity (ESCON™) protocols over a dedicated, switched fiber infrastructure as a replacement for copper cables. Optical networking quickly became the preferred means to interconnect mainframe servers and storage devices. More recently, Fibre Channel protocol (FCP) has become the preferred means of building a SAN because it offers higher bandwidth and improved performance at extended distances (beyond 10 km) for disaster recovery applications. This is the technology currently being deployed by many service providers for storage over a wide area and metropolitan area. Examples of this approach include the recently announced GeoMax℠ service from Qwest and the Ultravailable Broadband Network℠ from AT&T, both of which are based on DWDM technology.

In addition to offloading storage traffic and minimizing server-to-server traffic to improve network performance, SANs are typically optimized for large blocks of data transfer (streaming video or terabyte back-ups with many sequential read/write operations). SAN management is centralized (thought it may not be done from the data server), and many suites of storage-management tools are available. Storage resources can be dynamically re-allocated and shared across multiple servers in a SAN. This allows heterogeneous SANs to be constructed that are still able to take advantage of policy-based management, workload balancing, and similar functions (the cost of network management can be 3 to 10 times greater than the SAN hardware cost). An important alternative to FCP–based SANs is the Fibre Connection (FICON™) protocol [1], originally developed for enterprise servers and currently being standardized by the American National Standards Institute (ANSI). FICON is implemented in essentially the same way as FCP, below Layer-3 protocols, and includes enhancements above Layer 4 that improve data integrity. Through various design features, FICON channels maintain their maximum data throughput over distances of at least 100 km.

A complimentary approach to SANs known as network attached storage (NAS) relies on IP protocols such as Gigabit Ethernet to interconnect application servers with storage appliances. NAS does not segregate storage traffic from other types of IP data and is typically optimized for smaller data packet transfers, using file protocols rather than block protocols (the maximum data block size for Gigabit Ethernet is 9 kilobytes using jumbo frames). The principle benefit of NAS is its flexibility and ease of installation. Storage appliances are designed to "plug and play" on existing local-area networks (LANs) with a minimum of effort. The difference in complexity is apparent; while you install a NAS device, you implement a SAN infrastructure. Thus, NAS architectures can vary from shared nothing (each server accesses storage independently with no clustering, load balancing, or failover capabilities) to shared everything (any server can concurrently access any storage device). Various types of SAN/NAS gateways are available to merge the two approaches and groom storage data traffic, for example the IBM TotalStorage product family.

Storage applications over IP are generating interest because of their ability to use existing IP network infrastructures over MAN or wide-area network (WAN) distances. Although transport of Gigabit Ethernet over DWDM has been demonstrated to distances greater than 1,000 km [3], performance at such long latencies remains to be determined. There are currently three major ways to transport storage data over IP. First, iSCSI (SCSI over IP) uses a software agent on the server to encapsulate SCSI data into an IP packet, and then tunnel that encapsulated packet through the transmission control protocol (TCP)/IP stack. The data is unwrapped at the other end of the link. Second, storage over IP (SoIP) converts Fibre Channel to IP outside the server and bypasses the TCP/IP stack in the host, eliminating stack overhead in the process. Finally, the Fibre Channel over IP (FCoIP) specification is a proposed standard that allows routers to connect a Fibre Channel SAN to an IP network (note that similar options for Fibre Channel over ATM are also available). Of these options, iSCSI has attracted attention recently because of its handling of block input/output (I/O) protocols and ready integration with embedded storage (iSCSI appliances) or gateways to an existing SAN or NAS. As a block transfer–based network accessible over an IP network, iSCSI has the potential to offer the advantages of both SAN and NAS environments.

The fundamental building blocks of a SAN include the server, optical transport fabric (gateways, hubs, wavelength multiplexers), switches or routers, storage devices (disk control units or tape libraries), management software, and deployment service offerings. Steadily increasing server performance has driven the requirement for increased network bandwidth and storage capacity. In the past decade alone, the cost per megabyte of disk storage has fallen by an order of magnitude to less than 50 cents. Data density on a storage medium has been doubling annually since 1997, growing faster than Moore's Law. Although optical storage is becoming more common, magnetic storage continues to grow due to recent advances in material science [6] that are expected to enable 100 gigabits/square inch by 2003—a level previously thought impossible (this would enable a laptop PC to hold 200 gigabytes, enough to accommodate 200,000 books or 300 CDs). There is also a significant opportunity to improve the optical transport fabric technology. For example, DWDM has emerged as a cost-effective way to extend storage networks over the MAN and WAN and is expected to form the backbone for future storage service provider offerings. SONET backbones will likely co-exist with Ethernet encapsulation for many years to come, especially in the MAN. This in turn has driven interest in very high-speed (nanosecond) all-optical switches and cross-connects. These technologies are among the critical elements of the future optical data center.

Today's storage environment is a combination of multiple SAN and NAS environments, typically with little attempt at global optimization. In the future, storage networks will evolve through the use of gateways, modular storage, and hybrid approaches such as iSCSI into a shared pool of intelligent storage devices accessible from any server, anywhere. Efforts are under way toward storage virtualization, which separates a single, logical view of storage resources from the physical device configuration. However, a standardized approach has yet to be established. Intelligent storage devices are expected to automate storage administration, making it simpler, less expensive, and continuously available. With the growth of DWDM as a cost-effective means to implement disaster recovery over extended distances, storage networks are spreading into the MAN and WAN. Given the recent surge of interest in business continuity solutions, this trend toward geographically dispersed SANs is expected to continue and represents a significant market for storage application providers.

4. Grid Computing

Grid computing involves many thousands or millions of small, distributed computing devices, linked together in local or regional networks that are in turn interconnected on a global level. The grid functions as if it were one giant virtual computer, with very close integration of servers, storage, and other resources. Everyone connected to the grid is able to share these resources in a very fast, efficient manner. Grids can be used to address so-called "Grand Challenge" problems, including advanced genetics research, modeling global weather patterns, or global air traffic control. This class of high-risk/high-reward problems is also known as "Deep Computing." While they hold the potential to be the next disruptive technology in the computing industry, the concept of grid computing isn't new. It can be traced back to early experiments with distributed, parallel processing, and so-called "lightweight grids" such as SETI@home, which uses free software downloaded over the Internet to scavenge a computer's spare processing cycles to analyze signals from the Arecibo Radio Telescope. There are currently more than 1.6 million SETI@home subscribers in 224 countries, averaging 10 trillion operations per second and having contributed the equivalent of more than 165,000 years of computing time to this project. This is arguably the world's largest distributed supercomputer, interconnected over the existing Internet. Small-scale grid models have been under investigation for years by the University of Southern California, Argonne National Laboratory, and the National Aeronautics and Space Administration (NASA), among others, and commercial applications have recently begun to attract the attention of major corporations [7]. Grids are still in their infancy; however, the ultimate goal is so-called "heavyweight grids"—much larger and more powerful systems linked on a national or international scale. Today, heavyweight grids are under development in several countries, including the United Kingdom's National Grid and The Netherlands. Recently, IBM was selected to build the Distributed Terascale Facility (DTF), which would be the world's most powerful computing grid capable of 13.6 trillion calculations per second and a storage capacity of more than 600 terabytes of data, or the equivalent of 146 million full-length novels. The Terascale Facility, with $53 million in funding from the National Science Foundation (NSF), is a joint undertaking of the National Center for Supercomputing Applications (NSCA), the San Diego Supercomputing Center (SDSC), Argonne National Laboratory, and the California Institute of Technology. Including some of the world's fastest supercomputers and high-resolution visualization environments, this grid will enable thousands of scientists around the country to share computing resources over the world's fastest research network in search of breakthroughs in life sciences, climate modeling, and other critical disciplines.

These systems are based mainly on protocols, standards, and software tools under development by Globus, an open source community led by Dr. Carl Kesselman at the University of Southern California Information Sciences Institute and Dr. Ian Foster of Argonne National Laboratory and the University of Chicago. In the same way that the Linux™ community has become a major part of open standards, Globus is working with the grid movement to help various standards and technologies to reach maturity; this includes tools to enable remote sharing of massive computing and storage resources, sophisticated resource management, scheduling and scalability routines, privacy and security tools, and other software functionality. Emerging software standards such as UDDI (universal description, discovery, and integration) are important to this effort, as well as natural languages to analyze unstructured data such as Web pages, hypertext markup language (HTML), video, and MP3 audio files. Utility pricing, or pay-as-you-go, is one of the features that make grid computing attractive to large businesses; the increased flexibility that this model affords could save billions of dollars alone. This approach is different from capacity-on-demand models, in which companies own or lease servers and pay an additional, fixed charge when they activate excess processing capacity. By contrast, in the utility model, the company doesn't own anything, but rather simply pays for its use of servers, storage, and disk capacity. These resources are metered through software measurement tools and can be billed in various ways, usually either on a per-user or per-processor basis. Either way, the cost per user goes down as the server utilization rises. This approach avoids one of the major pitfalls of today's information technology (IT) systems, namely capacity planning. Many corporations have difficulty accurately forecasting their demand for IT resources, and this has become more obvious during the recent economic slowdown, when anticipated revenues fail to materialize and overbuilt IT capacity becomes a burden that most companies would prefer not to bear. Since utility pricing directly ties cost to revenue, it should allow companies to weather fluctuations in the market better by amortizing costs over time.

5. Autonomic Computing

The cost of ownership for servers is already being driven upward by management and maintenance fees. In fact, some feel that the management of ever-growing networks constitutes a looming crisis in the Internet data center. The rapid growth of SANs, DWDM networks, and grid computers has only accelerated this trend. For these systems to succeed, both resource and network management must be highly automated. The future of optical network management depends on a core of intelligent middleware that is capable of handling most networking decisions without human intervention. This is the concept of autonomic computing, named after the body's autonomic nervous system that allows human beings to adapt to any number of situations by unconsciously adjusting things such as your heart rate, breathing, body temperature, or pupil dilation. An autonomic computer is self-managing and self-healing, responsive to changes in its environment, and always accessible. This is accomplished by middleware needs to be platform agnostic, supporting a heterogeneous mixture of access devices ranging from conventional PCs to network appliances, embedded devices, kiosks, or cell phones. In addition to network management, middleware may also perform functions such as data caching to improve performance, directory and security control, QoS enforcement, and transcoding (changing data structures to take on the characteristics of the end user's access device).

A leading example in the field of self-managed computer systems is IBM's project eLiza, announced in April 2001 [8]. This refers to the first artificial intelligence program to permit natural language conversations between a human and a computer, written decades ago by Professor Joseph Wiezenbaum. The symbol for the eLiza program is a lizard, which refers to calculations done a few years ago using assumptions in Ray Kurzweil's book "The Age of Spiritual Machines," in which researchers estimated the processing power of the chess-playing Deep Blue supercomputer as roughly equivalent to a lizard's brain. While it may seem odd for such a simple creature to need so much brainpower, the lizard actually has a far more complex task than a single purpose computer. While the computer's environment is completely controlled and comparatively predictable, the lizard faces a constantly changing jungle environment requiring instantaneous responses to new demands and dangers. Enterprise computers have their own jungles to contend with, complete with totally unpredictable demands from unknown amounts of users, sudden threats from predators, and frequent natural shocks that stress the system. Like the lizard, computers require intelligent self-management skills to survive in this environment. A self-managed computer could, for example, update and maintain its own software at the latest release levels, actively protect itself against attacks by malicious computer hackers, monitor its health and perform limited acts of self-repair, correct inadvertent human management errors, and guard against unexpected problems or acts of nature. In this way, an eLiza system would insure its own survival and stability. It would also continually self-optimize, eliminating the need for constant tweaking by network administrators, and adjust by itself to changes in the server loading. For example, an eLiza server running the stock market could detect sharp upsurges in trading and adjust quickly to meet the higher demand. In addition to providing the means to control systems that are orders of magnitude larger than any existing today, it is hoped that these systems would be significantly lower in cost to own and maintain. While eLiza is still under development, some important related steps have already been taken—for example, the z/OS™ 64-bit operating system automatically shifts server capacity between logical partitions in response to high-priority workload spikes. This is expected to be a great productivity boost for IT staff, freeing them from the more mundane tasks to focus on other areas. It may also help alleviate projected shortages in trained IT staff. (Some analysts estimate that in five years, the world will be short at least a million qualified IT administrators. Others have noted that a network of one billion users would require about 250 million skilled people, almost the entire population of the United States) It is widely recognized that there are some things that computer systems cannot do for themselves, and although their job descriptions may change, systems administrators are not going to disappear. However, if eLiza succeeds, the end result could be a global computing network that will be as easy to control as a kitchen appliance.

6. The InfiniBand Standard

Features that used to be associated exclusively with mainframe computing—continuous availability, serviceability, high reliability, redundancy without single points of failure, clustering, logical partitioning, and greater I/O bandwidth—are slowly becoming commodity requirements in today's e-business environments. This had led to an increasing focus on the limitations of current system architectures, in particular widely used standards such as the peripheral component interconnect (PCI) bus. While microprocessor and memory subsystems have advanced at a rapid pace during the last decade, high-performance I/O has traditionally been reserved only for large mainframes or enterprise servers, which implemented direct channel attachment for I/O devices. In an effort to develop new industry standards in this area, the InfiniBand Trade Association (IBTA) grew from a combination of two previous industry consortiums, Next Generation I/O (NGIO) and Future I/O. In August of 1999, the IBTA was founded by a core group of companies that form its steering committee and current board of directors, namely IBM, Intel, Hewlett-Packard, Compaq, Dell, Microsoft, and Sun Microsystems. They were joined by many companies representing virtually every aspect of the computer and networking industry, including sponsoring members such as Agilent, Cisco Systems, Brocade, 3Com, Adaptec, EMC, Fujitsu, Siemens, Lucent Technologies, Nortel Networks, Hitachi, and NEC. At the end of 2001, there were 226 member companies participating in the IBTA. The initial InfiniBand Architecture Specification was released to the industry on October 24, 2000, at the second annual InfiniBand (IB) Developers Conference. Since then, there have been more than 100 product announcements for silicon chipsets, adapter cards, switches, software, cables, and test equipment. The value proposition of InfiniBand lies in a combination of performance improvement and better reliability (at least for entry-level and midrange systems) in a scalable, low-cost architecture. IB is a bottoms-up design for high-performance interconnects, suitable for many different server platforms and applications ranging from SANs to server clustering. Originally conceived as a replacement for PCI–type data buses, IB has broadened its focus to encompass client-server communications, server clustering, and storage. IB provides a message passing fabric in which data is shared between a host and target channel adapter. One objective of the IBTA was to introduce an I/O subsystem with significantly higher performance than conventional shared bus architectures, with characteristics inspired more by the enterprise server environment. This approach brings with it improvements in reliability, error detection, and fault isolation. For example, fault zones in the IB fabric insure that a failure on an IB–attached I/O device will not compromise the rest of the server, as in a shared bus architecture. Redundant IB fabrics and transparent multi-pathing may also be configured for high-availability applications. Although data delivery is still on a best-effort basis, similar to IP or Internet messaging, it also offers selectable QoS features that can be provisioned by specified service levels, automatic failover, and virtual lanes. IB performance is also more scalable than its predecessors; it can readily accommodate faster, higher-performance I/O devices, and performance of the IB subsystem is not reduced by the addition of extra storage or networking capacity. It is designed to reduce high TCP/IP stack latencies between transaction servers, database servers, and load-balanced Web servers, as well as between servers and storage in future Internet data centers. InfiniBand is the first standard to incorporate parallel optical data buses to increase bandwidth and distance beyond the capabilities of traditional copper buses. Duplex IB link speeds can scale from 500 megabytes per second to 6 gigabytes per second, per link [1]. By contrast, PCI–X offers a peak burst bandwidth of 1 gigabyte per second half duplex at 64 bits, with next-generation plans for 2 to 4 gigabytes per second still in the process of being defined. There can be thousands of subnets in an IB fabric, each in turn serving thousands of nodes (servers, storage, switches, routers, network analyzers, and other devices). In contrast to other transport protocols such as Ethernet or SCSI, InfiniBand allows for the adaptation of packet sizes and transport characteristics to a given application, such as block I/O or data streaming with large or small packet sizes. There have been a number of IBTA–hosted meeting and industry trade shows featuring demonstrations of the IB fabric running Linux-based clustered server and storage applications.

7. Conclusions

There are a number of key trends currently driving the next generation of computer networking technology for the optical Internet data center. The recent exponential growth rate of storage applications, coupled with a renewed interest in disaster recovery, has accelerated deployment of fiber-optic DWDM networks for both long-haul and metropolitan-area networks. This technology functions as a protocol-independent channel extender and allows network capacity to grow without the expense of installing new fiber. This has enabled applications that were previously not economically feasible, such as multi-terabyte and petabyte SANs or mainframe clustering in a Parallel Sysplex architecture. Optical networks are also expected to play a role in emerging grid computers—massive interconnections of servers over long distances that offer computing power on a utility-based or pay-as-you-go model. As networks scale to ever-larger dimensions, some form of autonomic management or self-healing is required to address practical problems with management overhead. These advances in networking have led to interest in new industry standards to improve performance and reliability for commodity-based computers. One very promising effort is the InfiniBand standard, which functions as a replacement for the legacy PCI data bus and also enables server clustering and storage networking. The synergistic combination of these trends is expected to create new market opportunities for service providers as well as traditional computer companies capable of providing end-to-end service and support of increasingly complex networks.

A Multiservice Applications Platform

Kevin Duffy
Business-Development Manager
IBM

An overriding concern in the telephony industry is the ability to develop and deploy value-added applications to ensure the loyalty of the subscriber base and to generate revenue. One way to provide this ability is through a multiservice platform that resides in the network. IBM has produced one such product, called the IBM Resource Manager. Instead of a monolithic item that would run one service when placed in the network, the Resource Manager is a set of components that can be pulled together in different ways to provide different services, depending upon the provider's needs. This paper outlines the way different services can run on this platform and will illustrate what this type of distributed architecture can accomplish within a network. Three services are discussed here that the Resource Manager enables: integrated voice command, calling/conferencing services, and operator redirect.

Integrated Voice Command

One service that can be deployed through the multiservice Resource Manager platform is integrated voice command, the ability to pick up the phone, speak a command, and have the command carried out. *Figure 1* illustrates how this service works. One obvious application for voice command is voice-activated dialing. The user shown in *Figure 1*, for example, can simply say, "Call Wally," and the application will connect him to the requested party.

This application brings value to the network in and of itself, but it is only the tip of the iceberg in terms of possible value-added voice services. The advent of new voice portals today means that a wealth of information is available from the network by using voice. And as commands move to the edge of the network, appliances will allow access to this network information. People have become very comfortable using their phones. The next step is to be able to make requests of the phone as the user in *Figure 1* does: "Tell me about my stock portfolio," or, "Tell me if my plane is on time." This architecture provides the capability to fulfill those requests.

Wireless applications have been driving development of voice-activated services and probably will continue to do so. This is especially true as concern grows about people dialing their cell phones as they are driving; indeed, legislation is in the works in some areas to regulate such cell-phone usage. Other applications of voice-activated services are as rich as one's imagination. Among them are personal or corporate dialing services, financial services, weather reports, and sports updates.

Voice command can be activated by an off-hook trigger for a wireline phone or a star code sequence in a wireless environment. Activation leads to a flat menu structure. Most voice response unit (VRU) applications today tend to be extensions of old customer-service applications that used a structured way to get information from a customer and to reply with an answer. Flattening the structure provides an intuitive interface that allows specific questions and quick responses. This interface provides a common look and feel for all services and thus facilitates the introduction of new services.

Voice-activated services were tried five or six years ago with limited success. Why should the situation be any different today? The major difference is that the technology has come a long way. Voice-recognition software is now speaker independent, whereas in the past the name had to be recorded and recognized. In that case, if a dog barked in the background during the recording, it had to bark for every call or the software would not recognize the name.

The current implementation of voice-activated services is through a cellular code division multiple access (CDMA) network. It can synthesize speech, so it does not require programming. The data interface is self-provisioning through the Web—any personal digital assistant (PDA) or similar device can upload it. It can then be maintained through the Web, a process with which most people are now very comfortable. The information can thus be shared by anyone else that a user designates. In an office environment, for example, an administrative staff person can maintain an office address book that allows everyone to pick up the phone and request a specified person without having to look up the correct number for that person. The Web interface makes maintenance easy and practical.

A result of this approach will be less reliance on an actual physical unit. With integrated voice command the network is the repository for personal data, not the device itself. Thus, users will not have to program a device. The average cell-phone user now upgrades phones about every 12 months. If all pertinent information is maintained on the Web rather than in the phone, the user is spared many of the problems associated with changing.

FIGURE 1

Integrated Voice Control

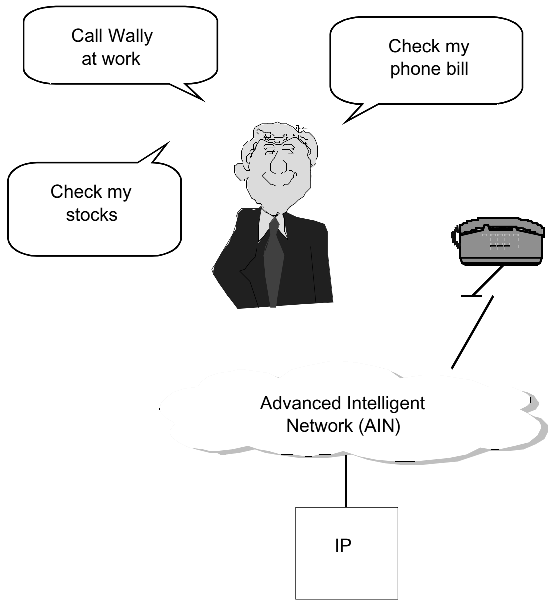

FIGURE 2

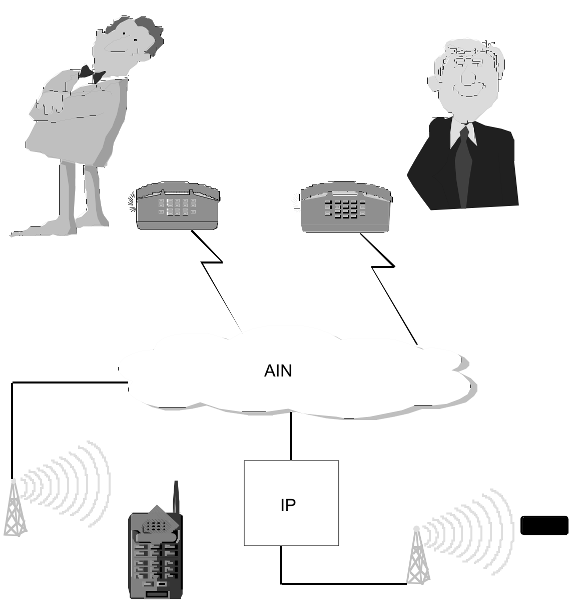
Meet-Me Calling/Conferencing



Voice-activated services bring value to the customer, which in turn increases customer loyalty. Increasing customer loyalty decreases churn, an expensive problem for telephony providers. In addition to saving money by keeping customers, voice-activated services facilitate usage of premium services and many more minutes of service, two ways for providers to generate additional revenues.

Meet-Me Calling/Conferencing

Another type of value-added service has been developed in prototype but has not yet been implemented. This service enables users to meet in the network for conferencing. Businesspeople who have been involved in a conference call and found that they needed to bring in someone else, but were unable to do so, will appreciate this service.

Meet-me calling allows two or more people to meet in the network (see *Figure 2*). The service is initiated with a series of special dual-tone multifrequency (DTMF) digits that page the parties or with a Web transaction that e-mails the people. Either way, the required parties receive a message requesting that they join a conference. The message provides a dial-in number and a personal identification number (PIN) for access. The application can dynamically add or drop parties as needed instead of maintaining a specified number of ports as required with current conferencing methods.

An example will show how the service works. Say that Randy receives a page requesting his presence at a conference. He calls the number given and enters the password. He can then communicate with Mark, who paged him, using Internet protocol (IP). After speaking with Mark, Randy may decide he needs some help from Oliver to solve Mark's problem. He enters a special series of DTMF digits, which places Mark on hold, and sees a menu that allows him to page Oliver.

Operator Redirect

The first two services outlined were revenue-generating services. The third, on the other hand, is a cost-avoidance service. With all the deregulation in the industry, the operator that a subscriber reaches is not necessarily the operator who can answer that person's questions. When people pick up the phone and dial out, in most cases they are connected to their local service company's operator. That operator has to spend time to understand what the caller really wants and to redirect the person to the proper place. This is a time-consuming and expensive process, and saving operator minutes can amount to significant cost savings. Thus, a service that can prevent such calls is of particular interest to the old regional Bell operating companies (RBOC).

Faced with this problem, one customer implemented an application using the multiservice platform that intercepts calls to the operator (calls dialed "0"), prompts the caller for a specific call request, then routes the call to the local operator if that is the proper person to answer the request (see *Figure 3*). Eliminating operator time to route requests for information has generated significant cost savings.

Conclusions

Many applications are currently being developed and implemented, and the three outlined here illustrate how they can generate revenue or save money while keeping subscribers committed to the service. In these ways, such value-added applications will keep telephony providers competitive in a very competitive industry.

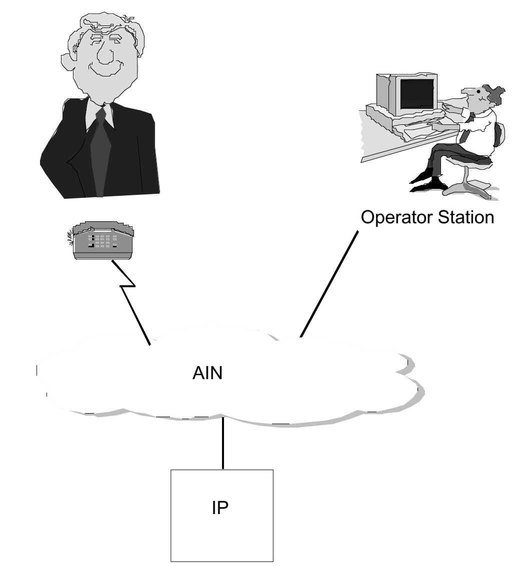
Operator Redirect



Optical Ethernet: Stirring the Imagination

Stephen Garcia
Director, Optical Ethernet Marketing
Nortel Networks

Eric McDonald
Senior Manager, Optical Ethernet Marketing
Nortel Networks

What if all corporations could connect buildings thousands of miles apart as easily as if they were just connecting two floors of the same building? What if every access and metro network was as simple, fast, and reliable as a local-area network (LAN)? What if metropolitan-area networks (MANs) and wide-area networks (WANs), with their multiple handoffs and protocol translations, physical distance, and hundreds to thousands of users, were as simple to manage as a single LAN today? Can you imagine the possibilities? Wouldn't it be revolutionary? The revolution is spelled OPTICAL ETHERNET.

Today's Corporate Networking Objectives and Challenges

According to a recent survey by Forrester Research[1], sixty-eight percent of Global 2500 corporations are looking for their information technology (IT) networks to provide competitive advantage. IT networks can provide corporations with competitive advantages in a variety of ways, including faster delivery of information, better access to customers and suppliers, support for next-generation applications, enhanced employee collaboration and productivity, and improved resource utilization

Corporations, however, face a variety of networking challenges when pursuing these objectives. Network complexity is increasing daily with the addition of new users, new nodes, and new network links. As traffic traverses the network from source to destination, it often undergoes a series of protocol translations, each of which adds complexity to the network. Network complexity represents the number-one networking problem faced by the Global 2500 today, as indicated in a recent report from Forrester Research[1].

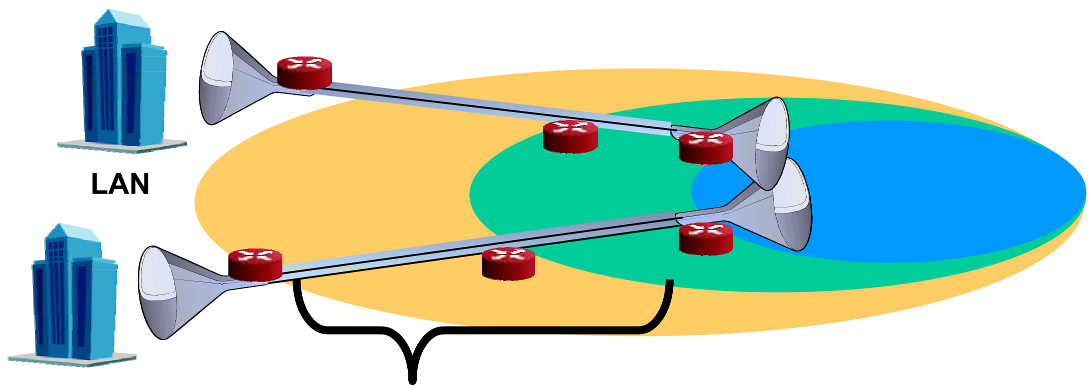
The scarcity and expense of access bandwidth in today's networks represents an additional challenge for corporations (see *Figure 1*). Today, corporate LANs run at hundreds of megabits per second (Mbps). Similarly, WANs, built on optical systems capable of terabit speeds, are blazingly fast. Unfortunately, connections between the LAN and the WAN are extremely limited and have created the equivalent of an access bandwidth bottleneck. The average corporate site today uses a fractional T1 (64 kilobits per second [kbps] channels), a full rate T1 (1.5 Mbps) or, at best, a T3 (44.8 Mbps) to connect their LAN to the WAN. While 44.8 Mbps may sound like a lot at first, consider the case of a corporate network with 100 desktops. Assuming 80 of the 100 desktops use a full-duplex 100 Mbps Ethernet network interface card (NIC) and that 75% of the traffic generated by those 80 desktops is destined for the WAN, 12 Gbps can converge on the business' access link at the same time. While this represents an extreme example, even 10% of the traffic, 1.2 Gbps, represents far more than a T3 can provide. Compounding the problem of the access bandwidth bottleneck are the long provisioning times required for turning up new links—typically measured in months—and the inflexible nature of the service. Corporations are unable to scale their bandwidth linearly, and instead must scale their bandwidth in increments of T1s or T3s.

Network complexity and the access bandwidth bottleneck lead to a third challenge: poor network performance. Every time a packet undergoes a protocol conversion or requires a Layer-3 look-up, latency, jitter, and unpredictability are introduced into the network. Similarly, the access bandwidth bottleneck creates the need to throttle back the number of packets-per-second and to establish queues that add additional latency and jitter and degrade network performance. For existing applications and current networking paradigms, this level of performance may be acceptable. For chief information officers (CIOs) implementing new applications or trying to consolidate network resources in the WAN, today's network performance represents a critical obstacle.

A fourth challenge confronting corporations is the issue of IT staffing. As networks have become increasingly complex, the skills required to run the network have become more and more specialized. Whereas, in the past, network generalists could perform the majority of network jobs, today corporations must recruit, hire, train, and retain network specialists with detailed knowledge of specific network functions, such as security or the operations and maintenance of each specific technology used in the network—e.g., Internet protocol (IP), asynchronous transfer mode (ATM), and frame relay (FR).

FIGURE 1

Bandwidth Bottleneck



Optical Ethernet: Meeting the Corporate Challenge

Optical Ethernet allows corporations to overcome their networking challenges and utilize their networks to gain the competitive advantage that they desire. Fundamentally, optical Ethernet represents the combination and extension of two existing technologies, Ethernet and optics. This marriage takes the best of both Ethernet and optics and magnifies their capabilities to create a paradigm shift in networking and service models for both corporations and service providers. Whether offered as a managed service by a service provider or operated as a private network by the corporation, optical Ethernet transforms the corporate network into a key competitive advantage.

Today's Ethernet

The first personal computer (PC) with an Ethernet LAN adapter was shipped in September of 1982. Ethernet originally ran over thick coax and provided users with a shared 10 Mbps bandwidth connection. Ethernet soon progressed to running over unshielded twisted pair and offering dedicated 10 Mbps connections using switches. Today, Ethernet enables dedicated 100 Mbps to the desktop with 1 Gbps trunks, and, within a few years, industry experts predict 1 Gpbs to the desktop and 10 Gbps trunks. In the nearly 20 years since the first Ethernet shipment, Ethernet has become a widely standardized plug-and-play technology that is used in more than 90 percent of corporate LANs. Clearly, Ethernet has come a long way.

Today's Optics

Not to be outdone, optical technologies have come as far as Ethernet in arguably a shorter amount of time. It has been said that the advances in optical componetry are outstripping Moore's Law by eight times! Optical transmission speeds have grown from tens of megabits per second to 40 gigabits per second, and vendors have recently demonstrated the ability to put 1.6 terabits per second on a single optical fiber, using dense wavelength division multiplexing (DWDM). Optics' tremendous capacity as well advances in all-optical, or photonic, networking that eliminate the need for electrical regeneration have secured optics as the preeminent, lowest-cost-per-bit transport technology.

More than the Sum of Its Parts

Optical Ethernet, however, is more than the just Ethernet plus optics. Industry standards bodies as well as vendors have been developing optical Ethernet solutions that are higher in performance, more reliable, and more secure than merely running Ethernet over optics. Several standard bodies and industry alliances are working, for example, to create specific policing, traffic management, quality of service (QoS), and security mechanisms for optical Ethernet.

As a Layer-2 connectionless technology, optical Ethernet removes the addressing and other network complexity issues seen with IP and ATM–based networks (see *Table 1*). In addition, because it spans the LAN, MAN, and WAN, optical Ethernet removes the need for multiple protocol conversions that create significant management headaches for network operators. Furthermore, this simplicity extends into the provisioning and re-configurations of the network. No longer will businesses have to wait weeks or months for an additional T1 or spend time reconfiguring the network every time a change is made.

In addition to simplicity, speed is a key attribute of optical Ethernet. With the deployment of optical Ethernet, the bandwidth bottleneck is broken. Optical connectivity allows for access speeds of 10 Gbps—orders of magnitude faster than today's T3s. Bandwidth is also available in more granular slices. No longer are IT staffs made to jump from a T1 to a T3, when all they really need is another megabit of bandwidth. Optical Ethernet access links can be increased in 1 Mbps increments to deliver bandwidth from 1 Mbps to 10 Gbps or anywhere in between.

Optical Ethernet also greatly improves network performance. Because optical Ethernet is Ethernet end to end, it removes the need for multiple protocol conversions that introduce latency and jitter into the network. Lab tests conducted by Nortel Networks reveal that optical Ethernet reduces latency by more than 30 percent and reduces jitter by more than 90 percent when compared to traditional routed networks.

TABLE 1

Key Network Attribute	Today's Networks	Optical Ethernet
Complexity	High: • Layer 3 • Multiple protocols from LAN to WAN • Fixed design	Low: • Layer 2 • Ethernet from LAN to WAN • Flexible design
Access Bandwidth	• Fractional T1s, T1s, T3s • Weeks to months to provision • Don't scale linearly	• Up to 10 Gbps • Hours to days to provision • Linear scalability
Performance	• Unpredictability • Latency • Jitter	• LAN performance end to end
Staffing	• Network specialists for each protocol	• Network generalists

Moreover, optical Ethernet topologies enable much greater reliability than today's access networks can provide. For example, an Ethernet over resilient packet rings (RPR) solution provides less than 50 milliseconds of delay in event of a catastrophic failure, such as a line cut. This high availability guarantees up time in networks that deliver mission-critical applications. The reduced latency and jitter in an optical Ethernet network also delivers the performance necessary to run time-sensitive, multimedia applications such as videoconferencing.

Finally, optical Ethernet is significantly less expensive than today's networks. The cost of an Ethernet interface card, for example, is a fraction of the cost for an ATM or packet over SONET (POS) interface card. In addition, the optical Ethernet's Layer-2 simplicity allows network operators to eliminate multiple private virtual circuits and reduce staffing levels. Nortel Networks, which is converting its own internal network—a network that spans six continents and supports more than 50 million voice minutes and 1.3 petabytes of data traffic per month—estimates that its cost savings from optical Ethernet will be between 30 and 40 percent.

Why Now?

The convergence of multiple factors has created the market discontinuity that optical Ethernet is now exploiting. First, as was mentioned, corporations are continuing to choke on the increasing complexity of their IT demands. Second, competitive price pressure is forcing service providers to move up the value chain away from undifferentiated products and services and toward value-added services. Third, several critical optical Ethernet technologies have matured to the point that optical Ethernet is now ready for commercial adoption—Ethernet has become carrier-grade, and the availability of fiber in access networks has increased[2]. Fourth, the Internet has become a trusted business tool.

Together, these factors are driving significant demand for optical Ethernet. The Yankee Group recently forecasted a cumulative $5 billion market and a compound annual growth rate of 90 percent for optical Ethernet equipment between 2001 and 2004 (see *Figure 2*).

Building an Optical Ethernet Network

There are three basic building blocks that can be used to construct an optical Ethernet network, whether private (corporate) or public (service provider). Each of these building blocks delivers its own set of advantages. Specific optical Ethernet network topologies will vary depending upon the needs of the network operator and in many cases may include more than one type of building block (see *Figure 3*).

Ethernet over Fiber

The first building block is Ethernet over fiber. This implementation is simple electrical-to-optical translation over non–SONET–based fiber. Only Ethernet services are available with this type of implementation (no time division multiplexing [TDM] services), and these services are somewhat limited to campus-type installations because of a less than 70 km distance restriction but can also be used in hybrid optical Ethernet solutions. This implementation is a very low-cost alternative because all interfaces are Ethernet only.

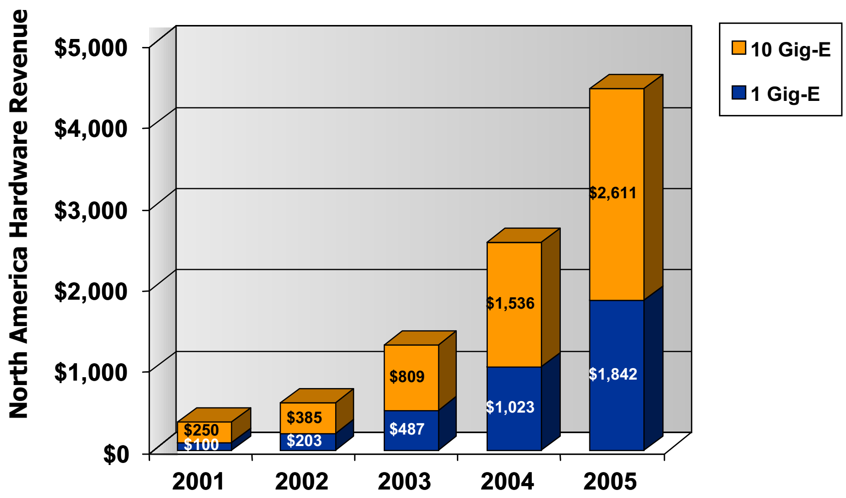
Ethernet over Resilient Packet Ring

A second optical Ethernet building block is Ethernet over RPR. While RPR standards are still being developed, many customer specific implementations are carrying traffic today. Ethernet over RPR requires the availability of SONET infrastructure but solves the traditional problem of SONET bandwidth "waste" because in Ethernet over RPR the SONET ring's bandwidth is utilized in both directions instead of only one. Ethernet over RPR carves up a portion of the SONET ring to create a multiservice ring allowing for pure Ethernet services as well as TDM, ATM, and IP traffic. Ethernet over RPR takes advantage of SONET's link-layer protection and provides less than 50 millisecond fail-over. The RPR can span thousands of kilometers and hence provides a flexible optical Ethernet solution for any number of implementation scenarios.

Ethernet over DWDM

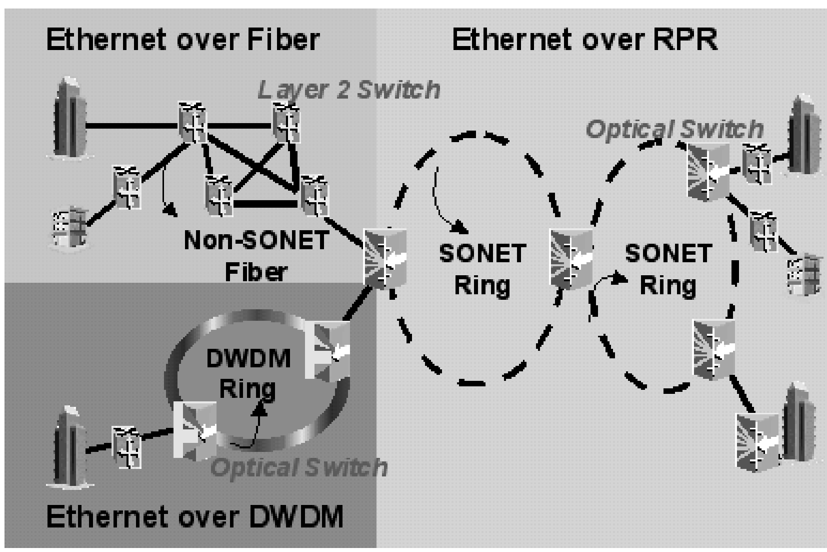
Ethernet over DWDM utilizes DWDM as its core transport versus SONET. It delivers massive bandwidth. This implementation is by far and away the lowest cost per megabyte solution and is most appropriate where the application(s) dictate very high bandwidth requirements (such as storage-

FIGURE 2



Source: Yankee Group, 2001

FIGURE 3



area networks [SANs] and data centers) or in areas where SONET is not available or where fiber availability is limited and must be most effectively used. Ethernet over DWDM is bite-rate and protocol independent, which allows it to work in almost any network scenario.

Benefits to Corporations and Service Providers

Corporations and service providers will derive a number of tangible benefits from the adoption of optical Ethernet. Corporations that adopt optical Ethernet will immediately benefit from improved network performance (more bandwidth, reduced latency and jitter, greater network predictability, and network utilization) and reduced capital and operational costs. Moreover, because optical Ethernet creates LAN–like performance in MANs and WANs, corporations that deploy optical Ethernet will be able to consolidate network infrastructure and applications, thereby realizing significant cost savings. Let us assume for example that Corporation XYZ has two primary sites, one in Boston and one in New York. In all likelihood, Corporation XYZ is maintaining a separate data center and a separate Internet service provider (ISP) connection for each corporate site. By deploying optical Ethernet, Corporation XYZ can consolidate both data centers and ISP connections at one site, e.g., Boston. Employees in New York will still have access to all the same applications, at the same levels of performance, by connecting over the corporations' optical Ethernet network. The corporation, however, will save significantly by eliminating the cost of a data center and ISP connection.

For service providers, optical Ethernet represents the opportunity to continue the evolution of their services up the value chain. At the end of 1998, service providers' wholesale bandwidth prices were falling by 50% every 18 months. Since the middle of 2000, prices have been dropping by 50% every six months.[3] Not surprisingly, service providers are looking for new services to increase their revenues, expand their customer base, and deliver competitive differentiation in their service offerings. Optical Ethernet enables these capabilities.

Optical Ethernet services generally fall into two categories, connectivity and value-added services. Connectivity services look very much like services that service providers are offering today—services such as private line, aggregation and backhaul, and LAN extension. While connectivity services may cannibalize service providers' existing revenues in the short term, optical Ethernet's decreased operating expenses will help to offset this effect and maintain service providers' margins on these services. Moreover, optical Ethernet connectivity services lay the foundation for service providers to offer differentiated value-added services.

The market for value-added services is large and growing (see *Figure 4*). Not surprisingly, service providers are racing to offer these services. Unfortunately, today's networks are capable of only the most basic value-added services, such as Web hosting. Optical Ethernet, however, provides the network-performance improvements necessary to make value-added services a reality for service providers. Decreased latency and jitter, and better network predictability makes offering real-time and mission-critical services such as voice over IP (VoIP), storage-area networking, and disaster recovery true possibilities for service providers. Furthermore, service providers will be able to differentiate their services with better service-level agreements (SLAs). Tests conducted by Nortel Networks show that optical Ethernet improves SLA response times over ATM by 44 percent.

Summary

Optical Ethernet delivers today what could only be imagined yesterday. By combining the ubiquity and reliability of Ethernet with the speed and economics of optics, optical Ethernet creates a networking paradigm shift. Optical Ethernet solves the critical challenges faced today by corporate IT managers and service providers. Optical Ethernet's simplicity is found in its easy network management and provisioning. Additionally, optical Ethernet removes the complexity of multiple protocol translations that can add latency and jitter into the network. Optical Ethernet is not only fast; delivering speeds from 1 Mbps to 10 Gbps, but it also provides for linear, predictable bandwidth management. It removes the limitations seen in many of today's access and metro networks that can bottleneck bandwidth availability in the network. Finally, optical Ethernet delivers mission-critical reliability in fail-over times, physical security of fiber, and enabled reliability in disaster and recovery and network-area storage applications. The coming optical Ethernet revolution will be limited only by our imaginations, eclipsing the changes that Ethernet or optics ushered in and delivering, in one solution, a fast, simple, and reliable network.

Understanding the Design Challenges for Residential Gateway Chips

Bernard Goffart
Product-Line Manager, Gateway Products
Alcatel Microelectronics

Abstract

Key customer-premises equipment (CPE) gateway chip design issues include technology choices, interoperability, and cost reduction. Designers have choices in determining which local-area network (LAN) and digital subscriber line (DSL) access technology to use and how to integrate the needed functions at the lowest possible cost. This paper will cover how chip designers can enable interoperability between different mediums from residential gateways to peripherals; how voice, data, and real-time video digital content can be transported reliably and securely; and how home LANs can use existing cabling plus ease of set-up, configuration, and management. Finally, the reader will gain an understanding of how the design of gateway chips enables upgrading to the integrated access device (IAD), allowing the delivery of future value-added products from service providers. As the IAD become increasingly sophisticated, the addition of new functions and additional capabilities will not only fuel the installation of home gateways, it will also stimulate the provision of many new services to the home user.

Introduction and Overview

Networked homes of the future are becoming closer to reality in large part due to breakthroughs in gateway technology. The day when appliances, security systems, telephones, computers, and entertainment systems are connected will soon be here. As rapidly increasing numbers of households with multiple computers and Internet access demand higher levels of telecommunications speed and data capacity, DSL connectivity is entering the residential space. At the same time, in response to market demand, satellite and television cable operators have launched data over cable service interface specifications (DOCSIS) digital communications systems to offer fast Internet access. Access technology previously reserved for business applications is streaming into the home.

Connecting the home of the future presents challenges unlike those found in the business environment. The average household will not have a staff of systems professionals available for maintaining a network and resolving complex problems. Legacy equipment will need to be refined for ease of installation, configuration, use, and maintenance as well as affordability. Furthermore, the diversity of applications and systems found in the home makes demands on a network unlike those of a business. Residential gateway products capable of supporting residential requirements have started to enter the market, and many more are expected to enter the market over the next several years.

Example Applications

The Telecommunications Industry Association (TIA) has identified initial residential gateway applications to include the following:

- Telecommuting
- Internet access
- Distance learning
- Telemedicine
- Video telephony
- Home appliance management and integration
- Security systems management
- In-home power regulation and management
- Automated meter reading
- Neighborhood cordless roam phones
- Video delivery and distribution
- Virtual videocassette recorder (VCR) and video on demand (VOD)
- Video intercom
- Compact-disc (CD) jukebox
- On-line advertising and electronic catalogs

Given that the home market is known for being price sensitive, the first-out products will likely not be the highest bandwidth-consuming products that could be connected to the LAN for the aforementioned applications. As semiconductor technologies continue to provide more integration opportunities and improved circuit performance at lower costs, these products will become available and be joined by even more practical applications. The design engineer is therefore best advised to consider application flexibility with the design so that additional product functionality and value may be added over time.

Gateway Design Characteristics

Future gateways will not depend upon personal computers (PCs) and will be able to offer the 99.999% availability that telecom service demands and PCs cannot provide. The mainstream residential gateway will not be dependent upon a PC. Rather, it will be a standalone box able to route information at high speeds and provide hub services with always-on Internet access. Therefore, it requires Internet isolation and protection functions to avoid hacking. The residential gateway will be designed to be durable, with a 10-year life span, low failure in time (FIT), and recovery procedures in place. It will need to support a remote management capability. It will support multiple services starting with telephony and VOD. These gateways will be portals to a number of new applications based on the high-speed on-line connectivity.

Example of Expected Broadband Piping Improvements

We use asynchronous digital subscriber line (ADSL) as the example (see *Figure 1*). The most exciting feature of ADSL is that it provides an "always available" data channel to the home or office. And with asynchronous transfer mode (ATM), it is designed to handle multiple channels with varying quality of service (QoS). ADSL allows for the development of services that were previously uneconomical. Push as well as pull applications are becoming available. The main interface box between the broadband pipe and home networks will be the residential gateway or IAD when multiple services are enabled.

The ATM–based multimedia pipeline is positioned to provide expanded services. There is great opportunity to deploy exciting new applications, but there is room for ADSL broadband pipe design improvements to support expanded services and customer satisfaction.

A few examples will be given. DSL deployment and troubleshooting must be improved. For the DSL service provider, this includes automated logistics for deployment, line, and service qualification. Additionally, the user is provided remote monitoring and diagnostics capabilities for cases where there is difficulty during installation or during later operation. This supports user self-install and eliminates the need for on-premises presence for installation or maintenance support. Remote CPE and central office (CO) operations, administration, and maintenance (OAM) and diagnostic tools will be applied. Eliminating the plain old telephone service (POTS) line splitter helps to simplify self-installation, avoiding the need for additional equipment to be installed at the customer premises. Unfortunately, performance quality of the POTS line is achieved only by inserting a micro filter in front of each phone. With anticipated future deployment, an all-digital loop approach will help to reduce the deployment costs. In this case, the POTS line is replaced with ADSL service, providing for all-digital transportation of the voice conversation.

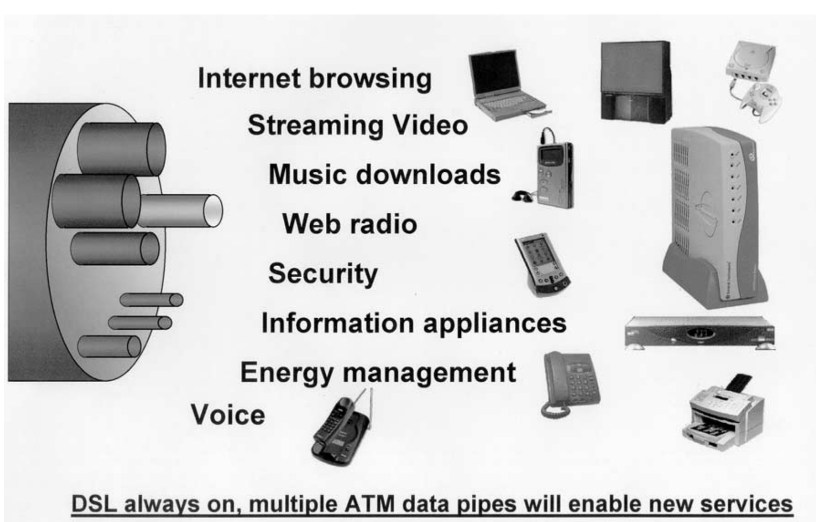
Forthcoming improvements are expected for the ATM/ADSL multimedia pipeline infrastructure in radio frequency (RFI) robustness. To improve the operation of ADSL with HomePNA, and where multiple lines in the same bundle are used, enhancements will include better-controlled impedance and spectrum management. Residential gateway designers will welcome such improvements in the ATM/ADSL multimedia pipeline infrastructure.

Vision of the Evolution of Gateway Functions

IADs will need to evolve substantially over time to meet the gateway needs of residential users. Today's IAD consists of a PC network (for example, PC–to–PC) that includes shared Internet access, a printer, and possibly a firewall to the public Internet. Access to the Internet may be via an analog dial-up modem or a broadband modem. As reported by Kinetic Strategies, more than nine million homes in the United States have broadband access at this time. Early adopters are using voice over Internet Protocol (VoIP) Web phones and streaming audio for music, infomercials, and video for train-

FIGURE 1

ADSL Multimedia Pipeline



ing programs. There has been little demand for a residential gateway and LAN.

In phase two, however, the basic PC IAD will begin to transition to a dedicated IAD capable of processing integrated data and voice as well as managing a home network. Early adopter residential users will begin to access high-definition television (HDTV) broadcasts via the Internet, watch high-quality videos on-line, and have brown goods such as the television, VCR, and stereo equipment connected. Phase two will have a mix of residential users—some still using the PC as the IAD, but a growing segment of users becoming dependent upon a dedicated IAD and residential LAN.

Phase three is predicted to start within about five years from this writing and will see the rapid ramp-up of fully integrated services that provide universal connectivity, with a port available on all types of devices. Home security will be integrated and white goods (appliances) and brown goods (e.g., entertainment) will be connected, and mobility integrators will offer new products. The delivery of services from vertical suppliers—such as monitoring services, security services, and financial applications—are expected to have wide acceptance. Applications that extend the office workplace into the home will likely be the initial applications that are sufficiently compelling to make the residential gateway and LAN investments. Home control systems, security, medical support, and home entertainment distribution follow.

During phase three, providers of residential gateway products will find users requiring a range of performance and capability depending upon the application. At the high end of residential gateway hardware, the small office/home office (SOHO) will include a multi-host DSL router with eight to 24 lines of voice over DSL (VoDSL). This model will allow a number of users to be attached to a single server. The strictly residential model will provide VoDSL via a low-end router with two to four lines. For those households wanting only data services, a DSL router capable of connecting more than one computer directly to a DSL line, with integrated management and security features, will provide a moderate level of features. Future IADs will also include VoIP services at this level. The single host PC platform will no longer need a gateway, with a DSL modem operating from the internal peripheral component interconnect (PCI) bus or bridged externally to a universal serial bus (USB) or Ethernet.

Phase four will be the maturation phase similar to how we now consider PCs—not an every-home item but quite pervasive. Existing homes will have been retrofit with the preferred LAN technologies, and nearly all SOHOs and new homes will be built with the residential LAN. Users will have many choices of services and activities accessible via the residential gateway. They will be able to choose from many microprocessor-operated home appliances plug-and-play ready to be networked via standard interface ports.

Introduction to Design Challenges

Complexities of the interworking of wide-area networks (WANs) and LANs make the design of products for residential applications an interesting challenge. Exchange of information must be processed between two different worlds, the wide-area access network and the local network. On the access side, a number of protocols must be addressed. Today, telecommunications companies, mainly incumbent local-exchange carriers (ILECs), are ATM–centric. They and Internet service providers (ISPs) are adopting Internet protocol (IP)–based solutions. Since these technologies are used in different segments of the data path architectures, technologies for addressing both IP and ATM framing characteristics are needed. These technologies are known as encapsulation techniques. Thanks to several interoperability initiatives, the stabilization process is currently underway. Access authentication and administration is also done with varying technologies. Most deployed methods are using the legacy point-to-point protocol (PPP) developed for dial-up access. Methods are adapted to Ethernet (PPPoE) and ATM (PPPoA). The addition of new voice-over-packet services, such as VoDSL or VoIP, is also adding new dimensions to the interworking of networks. Within two to five years of this writing, it is expected that new services will be added that will extend the IAD with voice, data, and video capabilities. The impact of the introduction of IP version 6 (IPv6) into the backbone network should be taken into account. Mobile devices are expected to be the first to make use of IPv6 to the terminal. The evolution of Ethernet to the last mile will significantly impact the residential gateway architecture.

Residential Gateway Design Issues and Solutions

Connectivity support for residential gateways requires working in two worlds, ATM and Ethernet. The transportation mechanism is ATM while the payload is Ethernet requiring interoperability between the two. There are also multiple alternatives for session control—namely PPP and virtual private network (VPN). The flavors for broadband (ATM and Ethernet) can be compared.

PPPoA (PPP over ATM) uses one virtual circuit (VC) per session on an ATM adaptive layer (AAL)–5. Powerful ATM QoS tools may be leveraged. Point-to-point tunneling protocol (PPTP) for remote session set-up is required. Multiple sessions require support for multiple VCs.

For PPPoE (PPP over Ethernet) one VC for an unlimited session number is used. There is RFC1483 encapsulation over ATM, and only a best-effort QoS is supported. ATM is used as a transport mechanism between the CPE and DSL access multiplexer (DSLAM).

Guidelines for access service provisioning include an allowance for a simple set-up process and provisions for authentication, authorization, and accounting (AAA). Compatibility should be maintained with a layered approach, depending upon the country, with regulatory plus network service provider (NSP) mapping on installed layer two. We also recommend bandwidth shaping with differentiated capability for QoS and that proper security features be provided. The design should be based upon ubiquitous access technology as close as possible to V90 dial up or broadband.

Quality of Service

The control of the QoS over the entire chain access, gateway, and LAN will promote the emergence of new applications sensitive to latency and throughput (audio, video, conferencing). It is known that compression and echo-cancellation audio algorithms, and the data packetization process, require intensive signal-processing support. Particular attention must be paid within the CPE to minimize the impact on the overall delay. Jitter must also be controlled. For example, telephony over packets (VoIP, VoDSL) is transported over a dedicated bus general control interface (GCI) or a combination of pulse code modulation (PCM)/serial port interface (SPI). The signal is passed over a classical pair of subscriber line interface circuits (SLICs) and audio-processing circuit devices that implement the digital signal processor (DSP) functions and allow for the interface to the legacy analog telephony equipment. Home LAN support of QoS will eliminate the need for POTS interfacing. As an illustration of this concept, telephony can be transported over a LAN network with specific LAN phones placed on the line. These phones will interface directly with a set of loudspeakers and microphones connected to a LAN medium after digitization, coder/decoder (CODEC) echo cancellation, and packetization; or they interface through an RF link to a cordless phone. Furthermore, the all-digital loop path DSL gateway may eliminate the need for the dual POTS/DSLAM equipment at the CO side by relying on the voice-over-packet transport to the LAN phone.

All-digital loop refers to the access technology where all information, including the telephony signals, is transmitted as digital data up to the customer. For ADSL or VoDSL, this implies that, in contrast to the traditional "overlay scenario" where POTS or ISDN are transported "out of band," the telephony signals are transported in-band. The telephone signals are digitized on the CPE such as on the LAN telephone and forwarded to the access node through the broadband access network.

Network Isolation and Security

Network isolation and security encompass IP network access translation (NAT) or port access translation (PAT), encryption, and a firewall kit. Support for specific applications is mandatory. Typical solutions are providing application language gateways (ALGs) that support specificities for approximately 30 to 35 applications. To understand the complexity of a NAT/PAT, one needs to understand that for many applications, local IP addresses are included with the payload of IP packets. Examples are H.323 and Netmeeting. To make proper NAT, the tools must be capable of making address substitution within the payload. Other functions included in the firewall kit are a standards-based packet-filtering engine, proxy server, socks server, stateful multilayer inspection (SMLI), and compliance with International Customer Service Association (ICSA) firewall certification. For CPE applications, the code size must be managed.

Other considerations for firewall engine security are access policies/access restriction and protocol disabling. Remote login user configuration should be supported.

Local-Area Networks

There is a plethora of wire and wireless LAN implementation technologies in consideration for becoming the preferred residential LAN. Some of the technologies, such as Ethernet and Firewire, listed in *Table 1* are broadly applied, while many others are in an early stage of development. The table shows advantages and disadvantages that can be expected from the technologies if used for residential LAN applications. Some of the quantitative information is somewhat fluid in that new versions of standards are in development. For example, a new version of the standard for HomePNA is in development for 32 Mbps, as well as a new version for IEEE 1394 for 1,600 Mbps and a 1,000-meter range.

LAN Medium

The distribution and communications medium will likely include wire and wireless. The choices for use of existing wire are the home phone line, supported by the Home Phone Network Alliance (HPNA) or power line supported by the HomePlug Alliance. Typically requiring new wiring would be Ethernet (IEEE 802.3) unshielded twisted pair (UTP) Cat 5 cable, Firewire (IEEE 1394), or structured cabling where multiple wire types are within a cable. Wireless standards viewed as having the highest chance of wide acceptance for residential application are HomeRF, IEEE 802.11b, and Bluetooth. With respect to the transmission speeds for wireless that are shown in *Table 1*, they are reduced as distance increases, but wireless provides the greatest flexibility for users.

Ideally, the overall guiding principles for the design of the connectivity medium infrastructure would be to use the existing cable as is. Deployment of new cabling for home networking is costly. The goal is also to achieve simple setup procedures and to support QoS tools such as opening the LAN to real-time or near–real-time applications.

LAN routing traditionally has been limited to business applications. The building of LANs is a complex task. Its maintenance is usually expensive in that it requires highly technical personnel. The services rendered in a business environment justify the investment. For a home application, the same level of cost is not affordable. A number of efforts are underway to improve the ease of configuration and maintenance.

The data-transmission capabilities of existing cables in homes have been investigated. Several methods are used for deployment. The industry has initiated standards. For example, the HPNA makes use of the phone network, HomePlug makes use of the power-line network, and wireless solutions—such as Bluetooth, IEEE 802.11, HomeRF, and HiperLan—are either already in use or anticipated for home application. LAN hardware must be designed for easy deployment, configuration, and maintenance of the home network.

The diversity of appliances destined to be hanging on the home LAN is increasing. LANs need to be able to support new types of applications and new types of services. Typically the "best-effort" philosophy of Ethernet protocol is a major limitation for streaming applications as well as for applications requiring latency control.

The availability of residential gateways capable of supporting future services will depend upon their ability to respond to the challenges described. The diversity of data media inside the home brings new challenges for system partitioning. Integrated micro switches, including media access controller (MAC) and physical (PHY), are available on the market for Ethernet unshielded twisted pair (UTP). The availability of these components justifies a system interfac-

TABLE 1

Alternatives for LAN Networks

Technology	*Performance*	*Advantages*	*Disadvantages*
Wired Medium			
HomePNA	1–10 Mbps	Compatible with POTS and ADSL	Insufficient number of phone jacks in typical home
HomePlug	10–14 Mbps	Typically sufficient outlets available	Resolution needed with some local regulations that forbid modulation in the required band.
IEEE 802.3 Ethernet	10–100 Mbps	Readily available	Most cases need new wiring; cost
IEEE 1394 Firewire	100–400 Mbps	Throughput needed for multimedia; isochronous	Limited to 5 meters
Wireless Medium			
HomeRF	1.6–11 Mbps	DECT–like (already shipping); access up to 127 devices	Limit of four simultaneous handsets; 2.4 GHz radio band is noisy
IEEE 802.11a Wireless LAN	24 Mbps	Throughput; up to 1,000-foot range	Cost; power consumption
IEEE 802.11b Wireless LAN	11 Mbps	Throughput; up to 1,000-foot range	2.4 GHz radio band is noisy
Bluetooth	1 Mbps	Cost; low-power transmission	Throughput; only 10-meter range; dial-up to use piconet; radio band is noisy
HiperLAN	20–54 Mbps	Throughput	Power consumption

ing at the media independent interface (MII) level. Another justification to interface residential gateways at this level is the evolving consensus among the industrial community to develop PHY devices for alternative home mediums at the MII level. For instance, there are such devices on the market for standards such as HPNA, 802.11, HiperLan, Bluetooth, and HomePlug. After a consolidation period, the range of media and standards will narrow, and residential gateways will embed the PHY part.

Protocols

The broadband pipeline infrastructure supporting a multiplicity of standard protocols for packet transmission is first described. This is followed with an example of software architecture appropriate for a residential gateway system.

There are various methods used for voice-over-packet technology (see *Figure 2*). These include using an ADSL PHY with VoIP or voice over ATM (VoATM). Some are still working on voice over T1 (VoT1) via AAL–1. Another method is channelized VoDSL (CVoDSL), and then the familiar lifeline bus over copper line. In the context of the example provided in this material, only the VoDSL and VoIP will be covered.

In this example architecture, voice and data information are entering from the DSL physical layer through the Utopia interface block, with the traffic being ATM cells. After segmentation and re-assembly two ATM channels are separated. The AAL–2 channel is used for voice (VoDSL) and the AAL–5 channel is used for data. For the AAL–5 traffic, after decapsulation of the ATM cells' content, the resulting Ethernet frames are sent to the client target using the MII interface. This interface transfers Ethernet frames generated by the MAC to the physical device that will send packets to the home network. One will note that VoIP traffic is captured within the transmission control protocol (TCP)/IP stackware and sent to the audio processing part. The VoDSL traffic, being separated at the ATM level, is directly sent to the audio-processing part.

Audio processing and call processing set up the telephone calls and maintain the session throughout the call. Depending on the type of technology in use (VoDSL or VoIP), different technologies and standards are in use to implement the required functions. Referring to the left side of *Figure 3*, signal processing–intensive functions are performed. These functions include adaptive echo cancellation (AEC), voice compression, signal mixing, activity detection, and others. The system services are depicted on the far left and include entities such as the management information base (MIB) and the CTRL–E to drive the ADSL chip.

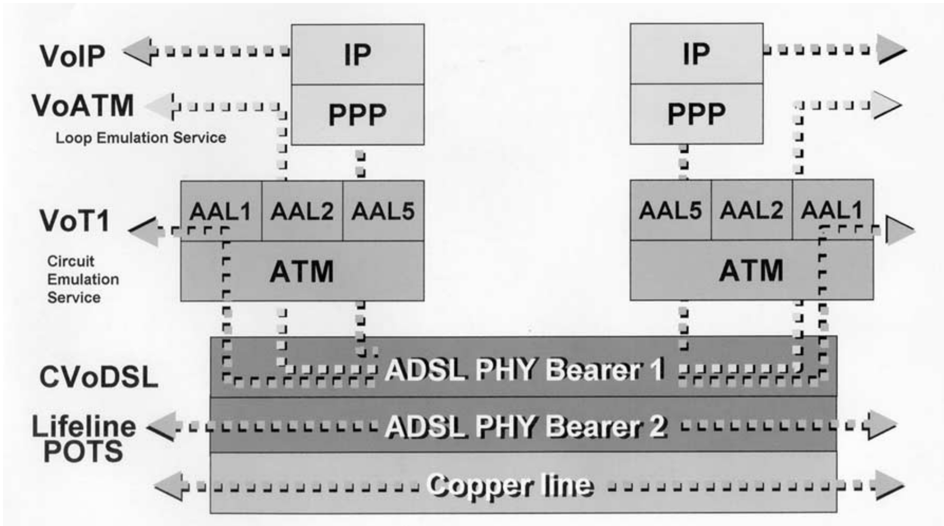
To allow device customization and application integration, a number of application program interface (API) functions are provided. These API are providing access to various elements of the device architecture.

Gateway Application Support and Integration

A residential gateway product is not complete by just addressing the protocol requirements. Application drivers and software must be available for a complete solution (see *Figure 4*). There are a number of companies specializing in

FIGURE 2

Voice-over-Packet Technology



software product development for residential gateway applications, and such companies can provide these products. However, the chip and system developer must plan and test for interoperability of all components of the system.

An example block diagram for a design implementing home audio/video interoperabilty (HAVi) architecture is shown in *Figure 5*. The API is established for some of the applications with native binding and others for Java binding. A Java-based virtual machine provides a framework for the integration of service- or device-specific applications. While residential gateways may initially be called upon to service a very limited set of applications, standard interfaces promulgated by the open services gateway initiative (OSGI) and implemented in the system software architecture will allow for future applications to be added such as illustrated in *Figure 5*.

Design Implementation

At the board level, the goal should be to eliminate external components for cost reasons. Try to simplify board routing and use cheaper printed circuit board material with the reduction of board-level high-frequency signals. Consider using modules to simplify manufacturing.

Solutions at the chip level can help the design meet such goals with the integration of interfaces such as PCI/USB/

FIGURE 3

Software Voice plus Data Architecture

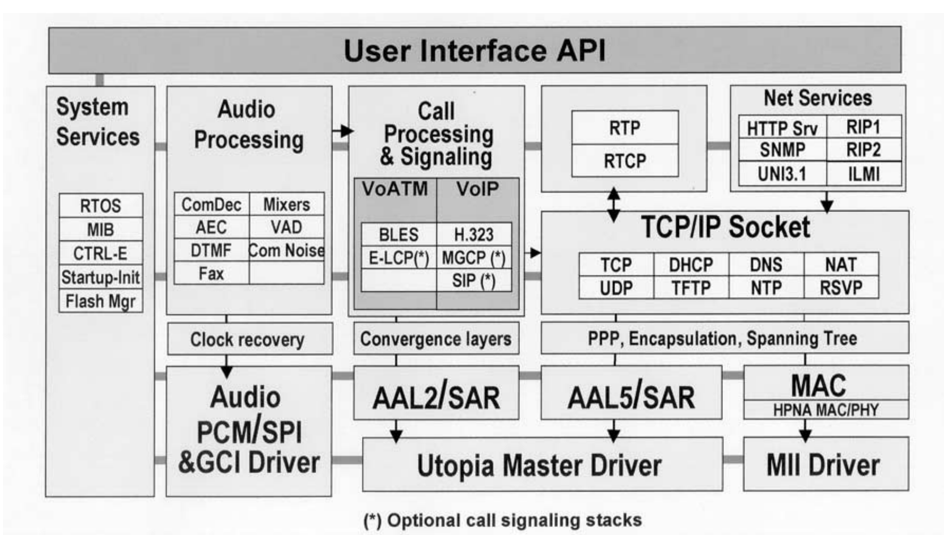


FIGURE 4

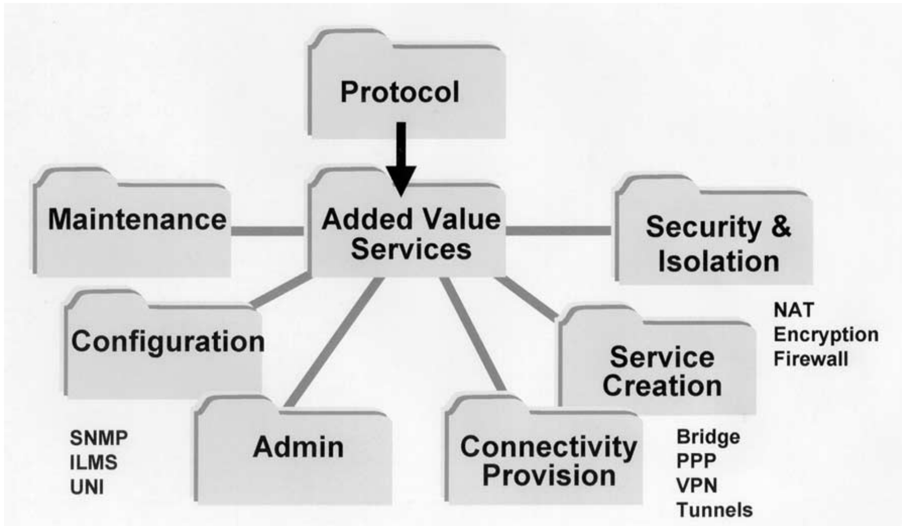
System Solution with Software



ATM/MII, integration of the access and LAN PHY, memory, and external filters. We see silicon integration occurring in four phases as illustrated in *Figure 6*.

The first phase is the exploratory phase, where the gateway is designed around the PCI bus with standard components. Application-specific integrated circuits (ASICs) have been used for glue logic and the PHY. While the standards are settling out, this phase would be used for the definition and check-out of interworking and software closure. This phase was to be followed by the availability of application-specific standard products (ASSPs) for the access modem and include the application of communications and network processors. During phase two, standards are reaching maturity, allowing developers to see stabilization of interworking protocols. Feature evolution is made possible by allowing for software plugs and API standardization.

Phase three is anticipated to be the mass production phase with complementary metal oxide semiconductor (CMOS) technology providing for further integration opportunities. Actually, the complete system will be integrated on a single chip. This system-on-chip (SoC) ASSP will include processor, access modem, and an embedded LAN PHY. In this phase, open architecture definition will expand application support from third-party software developers.

FIGURE 5

HAVi Device

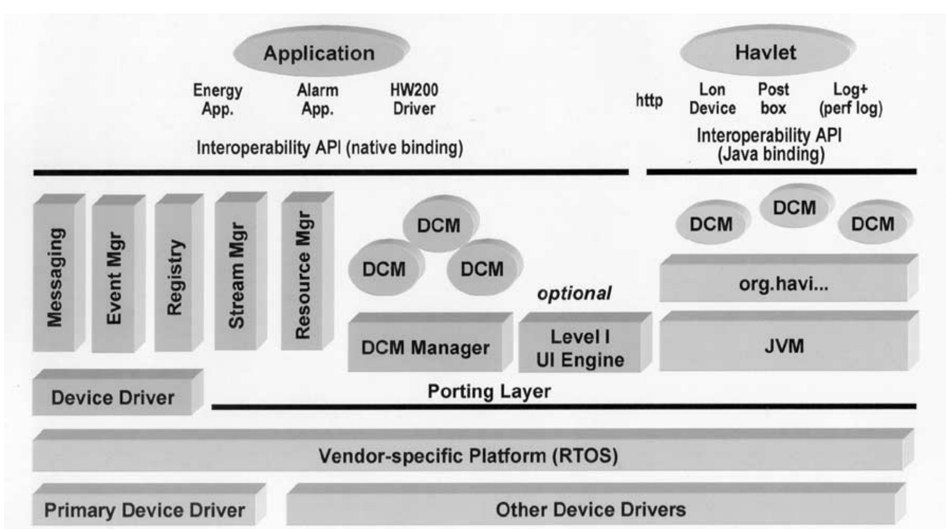


FIGURE 6

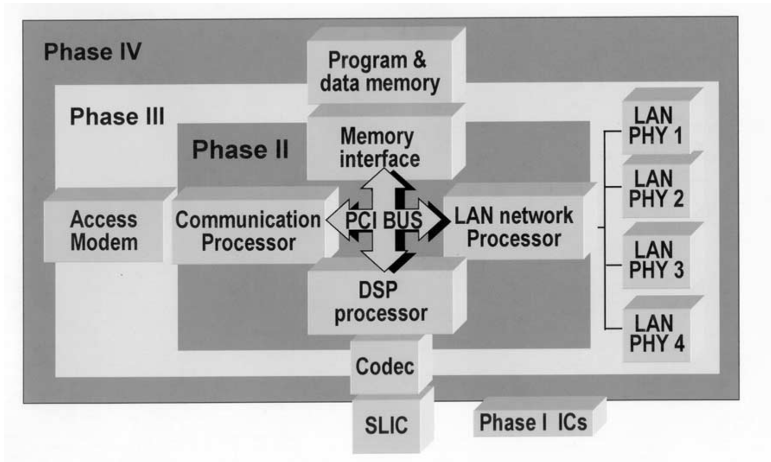
Hardware Architecture Evolution



More cost reduction will be called for in phase four, with an integrated circuit (IC) in 0.13 or 0.11 CMOS technology that includes a modular architecture with communication ports, multiprocessor integration, phase-three external component integration such as glue logic, memory, and multi-PHY on-chip support. This design will be optimized over the phase-three design with low-cost software stacks.

A reliable semiconductor supplier will provide a complete development solution consisting of not just silicon, but also a reference design board with schematics, software drivers, evaluation software, documentation, full customer support, and a design example based upon the reference board.

Examples of a gateway design are shown in *Figure 7*.

Conclusion

To successfully address the large residential gateway market opportunity, we have concluded that it will be best to leverage legacy telecommunications access, evolving new LAN technology, and the potential of the Internet.

We have described the design issues and solutions for complex technological challenges of sophisticated interworking functions and multiple services in an environment of tough commercial targets. To achieve worldwide interoperability, industry-wide collaboration is mandatory. To facilitate system design with ever-changing standards and the advancement of product functionality, the silicon solutions must prove flexibility for system adaptation. A silicon-only solution is not a complete and flexible solution. A complete design kit solution is called for that includes much of the system software.

The Light Ahead: Integrating Optical Components on Silicon

Robert Green
Vice President, Business Development
Bookham Technology plc

Despite the recent slowdown in the global economy, the pressure for innovation in the communications industry has not abated. The demand for bandwidth is still growing, but the challenge no longer ends there. The competitive communications market of today is calling for minimized capital expenditure, but more importantly, it is also asking for increased flexibility in the networks on which it relies to generate revenue, and hence increased returns on its investment. Network providers want greater functionality; they need this to be able to deliver bandwidth at the right price, in the right place, and at the right time. These factors require that the infrastructure be used to its maximum potential. In the quest to satisfy the increasing demand for greater network capability, fiber-optic cable has been deployed aggressively and the push is now on to make maximum use of that investment, particularly in the current difficult climate.

The solution to these pressures is increasingly being found in increasingly integrated optical components, an area of the industry where the most noticeable advancements are emerging. This market has always been customer-led, but the nature of customers' demands is changing and creating greater competition. To meet the criteria for greater flexibility, the industry is leaning toward customized products with greater functionality. By integrating many optical functions as closely as possible, device manufacturers are beginning to offer themselves as one-stop solutions shops, not only producing components, but also a range of customizable optical subsystems.

Today, the optical components industry has solved the production and manufacturing problems of old by directly applying techniques from the semiconductor industry and, in the process, has benefited from the billions of dollars of investment already made in this area. The technology that is enabling integration, and this new drive toward network flexibility, is already available. The answer lies with the use of silicon as an optical material.

The Successful Platform

Before considering the attributes of silicon as an optical material, it is worth taking some time to define what constitutes a successful and flexible integration platform. Essentially, we are looking for an over-arching technology that will allow us to deliver, through network infrastructure providers, what network operators are demanding.

The most important attribute for a component technology is *functionality*. This is the ability of the chosen platform to perform all (or at least, most) of the tasks (generation, routing, conditioning, and detection of light signals) required by engineers working in optical networking. Such tasks fall broadly into two categories: active functions and passive functions.

These two categories of function can in their turn be realized by two different methods. The first of these is true "intrinsic" integration, which involves building structures within the material of the optical device itself. The chosen material and production system therefore needs to lend itself to this kind of manipulation.

The second method is hybridization—attaching discrete devices directly to the surface of the optical substrate. This technique is valuable because it allows the integration of functions that, for one reason or another, cannot be implemented within the optical material that forms the basis of the device.

Whilst functionality is important in the current context, an integration platform needs several other attributes. Its *performance* will decide whether the resulting components can reach, and if possible exceed, the performance benchmarks required within the industry. Despite economic slowdown, it is important for industry to keep pace with technological development. Indeed, times of economic instability could even encourage the development of faster, stronger, and cheaper components.

Another important feature is *reliability*. This relates both to reliability in-service and to two other key parameters: *manufacturability* and *manufacturing yield.* Components that can be reliably produced by well-understood, repeatable, automated processes will generally produce superior manufacturing yields (that is, less manufacturing defects resulting in rejected parts) and thus be more economically viable. They will also be less likely to fail in the field. Service providers expect to be able to control their networks, and this can boil down to reliability—in theory it should be easier to control and monitor one multifunctional device rather than several linked via fiber.

Service providers also have to deal with the high expectations of their customers, who are unforgiving when faced with a failed system. In the communications industry, reliability is essential to ensure that reputation remains positive.

Physical size and *power consumption* are factors that must also be considered. Smaller components are desirable not just because they take up less space in the final application, but also because with more devices per wafer, production yields can be radically enhanced. Miniaturization also goes hand-in-hand with integration; it is easier to incorporate more functions on each device if the space required for each function is smaller. Additionally, by integrating functions, fewer components are needed, which has a knock-on effect on the interconnections. The fibers connecting various chips take up a huge amount of space, and therefore the number of components used is directly linked to the amount of fiber used. Fewer components lead to a reduction in the amount of fiber, which leads to less bulk and less floor-space cost for the network operator.

Infrastructure vendors are increasingly asking for quick, reliable production of a number of product variants. They want *customized* products that can be sold at different specifications all over the world. In essence, this is another argument for integration.

Bookham Technology's ASOC® technology is a good example of the new breed of component integration technologies which are rising to satisfy these demands.

Based on single-mode rib waveguides (see *Figure 1*) formed on silicon-on-insulator substrates, ASOC uses the fact that silicon is practically "transparent" at telecommunications wavelengths to produce waveguides with low losses (less than 0.2 dB/cm). The refractive index of silicon is high (3.5), allowing compact optical circuits to be made.

The fundamental passive elements of a waveguide-based integration platform include, for example, bends, couplers, and fiber-waveguide interfaces, and these need to be easily combined to produce the desired optical functions, preferably via easily used computer-aided design (CAD) models. A key early stage in the development of ASOC as a successful integration platform was the development of such a set of passive elements that could be assembled into practical integrated optics devices.

The engineering investment in ASOC as a large-scale optical integration platform began to pay off in 1999, as the company began to build a suite of products based on its arrayed waveguide grating (AWG) offering. The AWG is at the core of many dense wavelength division multiplexing (DWDM) functions, performing the key task of combining many wavelengths of light for transmission along a single fiber and splitting those wavelengths at the receiving end.

In volume production, silicon AWGs yield non-adjacent channel crosstalk levels of below –45 dB, enabling worst-case specifications of –23 dB for 40-channel Gaussian devices and eliminating the need for "clean-up" filters. The small-dimension ASOC waveguides were combined with 2D mode expanders to achieve insertion losses of less than 8 dB for flattened devices and less than 6 dB for a Gaussian.

For Bookham Technology, the "building-block" approach has been supplemented by a further step toward higher-level integration within a single device. Doping and injecting charge into silicon waveguides enhances the range of optical functions available through intrinsic integration, rather than by hybridization. Charge injection changes both the refractive index and linear absorption coefficient of the material and allows an electrical signal to be used to attenuate the light traveling through the silicon waveguides. This is a valuable capability since it points directly to other functions commonly used in DWDM networks—signal attenuation and channel balancing—and is a major benefit of using silicon waveguides, as this technique has yet to be proven in other waveguide materials such as silica.

FIGURE 1

The Basic ASOC Waveguide Structure

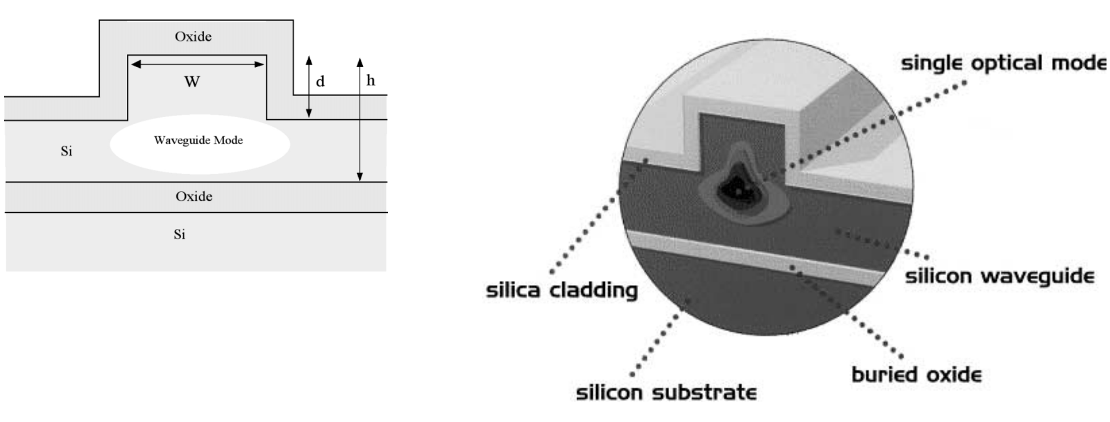

FIGURE 2

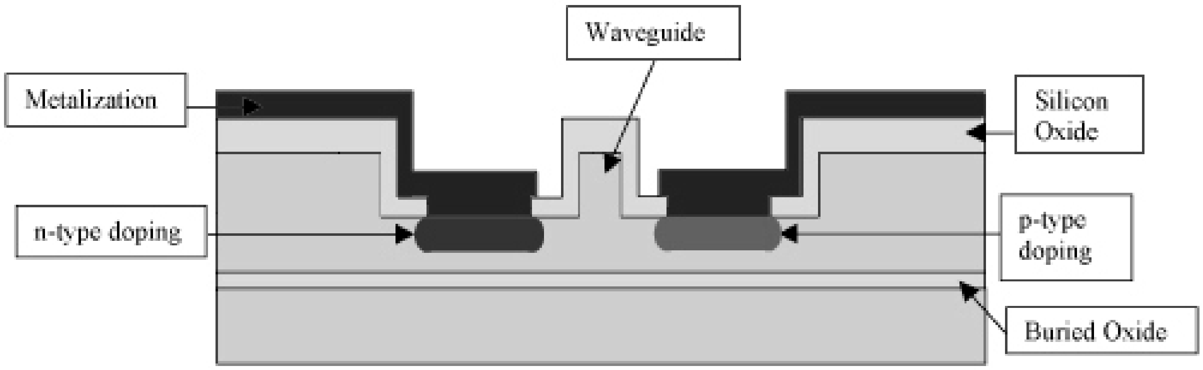
Doping and Charge Injection Enables More Complex Functions



The ASOC absorption attenuator structure (see *Figure 2*) uses a monolithically integrated pin diode to inject both electrons and holes into the waveguide region. The resultant variable optical attenuator devices have a switching speed in the order of megahertz—three orders of magnitude greater than that available in other technologies. By integrating several attenuators on a single chip, Bookham Technology demonstrated an early capability to perform parallel integration (i.e. multiple "copies" of the same function on a single chip) within a silicon platform.

This approach to producing attenuation can also be applied in implementing the switching functions that have always been intrinsic to communications applications. The ASOC attenuator is so fast, and produces of such a high level of attenuation, that it can effectively be used as a 1x1 (on-off) switch—a fundamental building block in communications systems.

We have noted that a wide range of functionality is a key attribute for successful integration and that hybridization is an important capability that radically increases the range of functionality. This was a key initial attraction toward the use of silicon: Mounting other semiconductor elements, such as lasers, on the surface of the silicon device can be done via established processes (see *Figure 3*). Unlike alternatives such as silica, there is little thermal mismatch between the hybridized device and the silicon substrate, and reliability is not compromised. There is also a good match between the refractive indices of the various semiconductor materials, easing the task of coupling light from one material to the other. Lasers, for instance, can be located in etched holes in the silicon, allowing the laser stripe to be positioned against the waveguide facet. Since the waveguide and laser location holes are defined in the same semiconductor etch process, placement accuracy using automated pick and place equipment in high-speed assembly processes is assured.

If we consider a simple end-to-end DWDM system (see *Figure 4*), we can see the importance of this range of functionality. The lasers that are used to generate the light traveling through the system are active devices: The light is multiplexed together using an AWG or similar passive functional block, which is preceded by a set of attenuators that balance the optical power in each wavelength of light. Depending on the span length of the optical link, there may be several optical amplifiers between the sending and receiving end, where a range of demultiplexing, switching, and attenuation functions are required. There is also the need to perform system monitoring, not only to ensure that the system is up and running, but preferably also to provide "trend" information that will allow the network operator to perform predictive maintenance.

Infrastructure makers, under pressure from their customers, want to reduce the complexity of their task. This increases the attractiveness of buying as many functions as possible within an integrated subsystem, in which the various compatibilities and performance trade-offs have already been understood and accounted for.

FIGURE 3

Hybridization Radically Increases the Range of Optical Functions

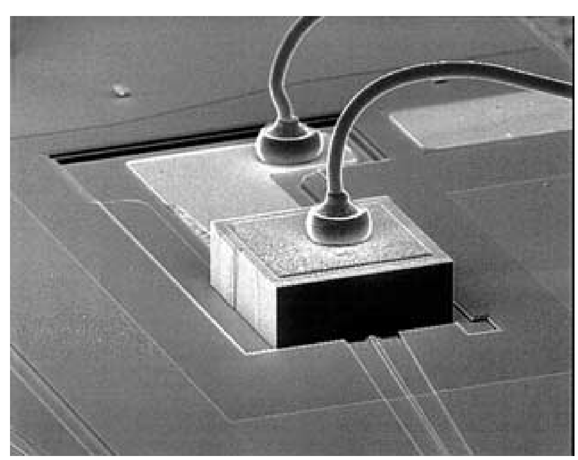


FIGURE 4

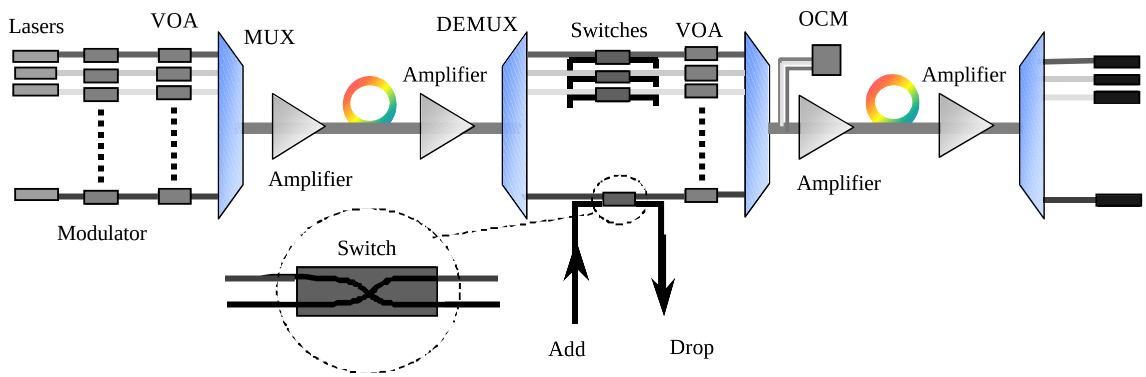
Even the Simplest DWDM System Requires a Wide Range of Functionality and Integrated Monitoring



On-chip channel monitoring offers a clear example of how integration can work. Bookham Technology's optical spectrum analysis module (OSAM) with switching input is specifically designed to provide a much more cost-effective way of monitoring power levels in DWDM systems. It reduces the costs of testing from hundreds of dollars per port to tens of dollars. The OSAM checks wavelengths and powers in multiple locations, and this is the best way to cut cost. By putting a switch at the front end of the monitoring system and monitoring different wavelengths sequentially, the need for several traditional channel monitors is integrated into a single chip. The OSAM has successfully demonstrated that increased functionality, switching, demultiplexing and detecting is available in a single package. The market already offers integrated switches, but this is the first time that switching has been fully integrated with other functions on a single chip, without the need to link several tasks via a fiber.

Another example is the integrated multiplexer and variable optical attenuators (Mux–VOAs, see *Figure 5*) and Demux–VOAs, which for the first time are commercially available components that fully integrate the functions of a 40-channel multiplexer/demultiplexer with 40 variable optical attenuators onto a single, compact silicon chip. The list of benefits includes excellent channel uniformity, up to 20 dB attenuation with no degradation of optical performance, very high attenuation accuracy, fast warm-up time, space saving, and low power consumption.

The current environment continues to be difficult, and future visibility remains unclear. However, the challenges posed by the new environment mean that there is light ahead in the optics world, and there will always be a demand for solutions that reduce time and cost and increase network up-time. The opportunities for silicon-on-silicon–based solutions, such as ASOC, will continue. This is a solution with the highest potential to be the industry standard for high-level integration.

Let's Recount the Votes on All-Optical

Clifford Holliday
President
B & C Consulting

Dense wavelength division multiplexing (DWDM) has brought us the answer to the need for massive amounts of bandwidth across the country, across the world, and now even across the city. The need for this bandwidth has been, and continues to be, driven by the emergence of the Internet (and associated applications) as the single most significant development in the history of communications. This ever-increasing demand has changed the whole approach to facility, and even route, provisioning. Bandwidth increments (e.g., optical carrier [OC]–48) that would have been the entire cross-section on a given route only two or three years ago are now not even provisioning interval increments.

Optical cross-connects (OXCs or optical switches) have been recently recognized as an indispensable component of the evolving optical networks. Some vendors have rushed to claim that the optical version of OXCs (i.e., "transparent" OXCs as opposed to OXCs based on an optical/electrical conversion prior to switching) is the key to the vision of the all-optical networks (AONs). These claims have alleged that only the optical versions of the OXC fit this vision and that the optical/electrical OXCs are somehow inferior.

This article will provide a balanced investigation of OXCs and the advantages and disadvantages of each type. Particularly, we will explore differences as relate to transmission engineering requirements between all-optical OXCs and optical-to-electrical-to-optical (O–E–O) OXCs. As noted, there have been a lot of discussions, claims, and publicity about the "goodness" of an "all-optical" solution. This article is a demand for a recount on some of those claims.

We Had a Bottleneck; Now We Have Gridlock

Some of the carriers (AT&T, for example) are estimating that their backbones are increasing at a rate of 400% a year! While DWDM has given us the tool to deal with the bandwidth explosion, it has not given us a way to be able to control this massive amount of bandwidth. We were looking for a way to keep up with this unending demand for bandwidth, and we found it in DWDM. Trying to keep up with that growth, both the existing growth and the forward looking view of a really scary "hockey stick" growth curve, was the first problem. Now, we can take existing fiber (at least to a great extent—some of the older fiber may not support all of the capabilities of DWDM at all distances), add DWDM, and we have an instant increase in bandwidth of up to 100 times. So, that solves the bottleneck problem, at least for now.

What is left, however, may be an even greater problem. The questions are how to deal with all of this added bandwidth and how to deal with the rapid changes and rearrangements implied by a market growing this fast. In a market growing like this, the end customers are also in turmoil, trying to devise the best way to deal with growth from their viewpoints, thus causing many change orders to bandwidth providers.

In addition to the problems of the raw growth and the high amount of customer churn, the network is largely stuck with an architecture that is singularly unfitted to rapid changes and additions—i.e., synchronous optical network (SONET). To establish a new wavelength on SONET–derived facilities (SONET on DWDM or SONET directly on fiber), it is often necessary to make physical equipment additions and changes at many nodes—particularly where rings intersect. The additions and changes require significant engineering, equipment procuring, site visits, and carefully coordination of testing and turn-up activities.

As a result of all of this work, provisioning intervals stretch into many months and service costs continue to be very high in spite of decreasing costs of underlying infrastructure. These factors have all combined to lead us from a bandwidth bottleneck to a gridlock glut—we have a great deal of potential bandwidth, but it is very hard to effectively use it.

The great national and international carriers have built fiber/DWDM networks that promise and deliver bandwidth that was only dreamed of two or three years ago. Now the issue is learning that quality of service (QoS) involves more than electrical and optical standards. It also involves service flexibility, rapid provisioning and rearrangements, and the ability to support new "on-demand" services. These are the qualities that will support the new strategies of service providers in the era of Internet protocol (IP), the Internet, business-to-business (B2B), etc. They are also the parameters that will turn all of that bandwidth into useful and marketable services.

The answer that is developing to this gridlock glut is the OXC. This new (new in these sizes and with the capabilities now becoming available) device will (1) allow extremely rapid service provisioning and rearrangements; (2) facilitate mesh topologies that more directly support data traffic and that can save on equipment, facilities, and operations costs; (3) provide an extremely fast optical-level circuit (fiber/wavelength/route) restoration capability; and (4) support new services on a wavelength level based on rapid and remotely controlled switching.

What Is an OXC?

An OXC is a device that allows a given number of optical inputs to access a selection of optical outputs. These inputs and outputs may be wavelengths or fibers (with multiple wavelengths). "OXC" is a broad term denoting a class of optical (and opto-electronic, called O–E–O) devices that allow a flexible interconnection of lightwaves. These devices are variously called "optical switches," "optical routers," "optical cross-connects," and a number of combinations of these and proprietary names. In the broadest sense, OXCs replace physical patch panels and provide an optical "point of flexibility."

OXCs are relatively old devices (in terms of Internet time) in that they have been a long-time internal component of most DWDM terminals. In that application, they are very small, simple devices that are connected to detectors (that detect a change in a SONET signal or detect the loss of a light signal) that cause the OXC to switch between fiber paths for restoration or maintenance purposes. The devices and applications now being planned as control centers for our DWDM networks are all, more or less, derivatives of this simple function.

What Is the Difference between Transparent and Opaque OXCs?

Transparent OXC

A transparent OXC (sometimes called an optical or all-optical OXC) has no internal electronics in the lightwave path. It accepts a lightwave as input, reflects the lightwave (using one of a variety of technologies being employed by various vendors), and transmits the lightwave with only the amplitude being changed. Transparent OXCs are controlled by external electronics, but there are no electronic devices in the light path.

Figure 1 shows a particular wavelength (#3) coming in from a DWDM fiber (on the right of the drawing.) That wavelength is converted to a standard 1310 nm wavelength, is switched in the OXC by being reflected, and then is transmitted (on the left) to another DWDM system (channel #5) on another fiber.

Opaque OXC

O–E–O OXCs ("opaque" in the sense that the lightwave does not go through the switch) are the traditional way to perform this function. There are several systems shipping at this point with up to 512 x 512 ports. Many of the systems available are much smaller than this, however, with many limited to 32 x 32.

These switches largely use well-known and widely available application-specific integrated circuit (ASIC) very–large-scale integrated (VLSI) technology. The optical signal is terminated on a diode, where it is converted to an electrical signal. After conversion, the digital information can be monitored, switched, and used as a basis for intelligence in directing the output. It is converted back to an optical signal as the output of a laser.

Figure 2 illustrates an O–E–O OXC in a typical application. It shows a wavelength coming in on a DWDM system (channel #3) operating on a fiber on the right of the drawing. This DWDM wavelength is converted to a standard 1310 nm wavelength, introduced to the OXC, converted in the OXC to an electrical signal, switched in the OXC to an outgoing port, transmitted out as a 1310 nm wavelength, and ultimately coupled to another DWDM system, where it is transmitted out on channel #5 of that system on another fiber.

Comparison of Transparent and Opaque Switches

It should be noted that, although some of the press coverage would seem to suggest otherwise, transparent switches are not inherently better than opaque. Like most other technology choices, they each have their advantages and disadvantages.

FIGURE 1

Example of the Application of Transparent Switch—1310 nm Interfaces

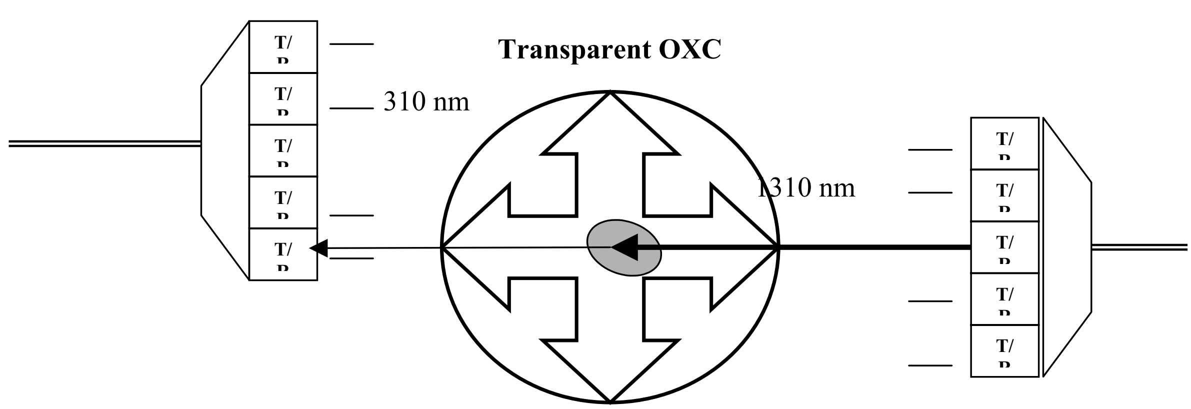

FIGURE 2

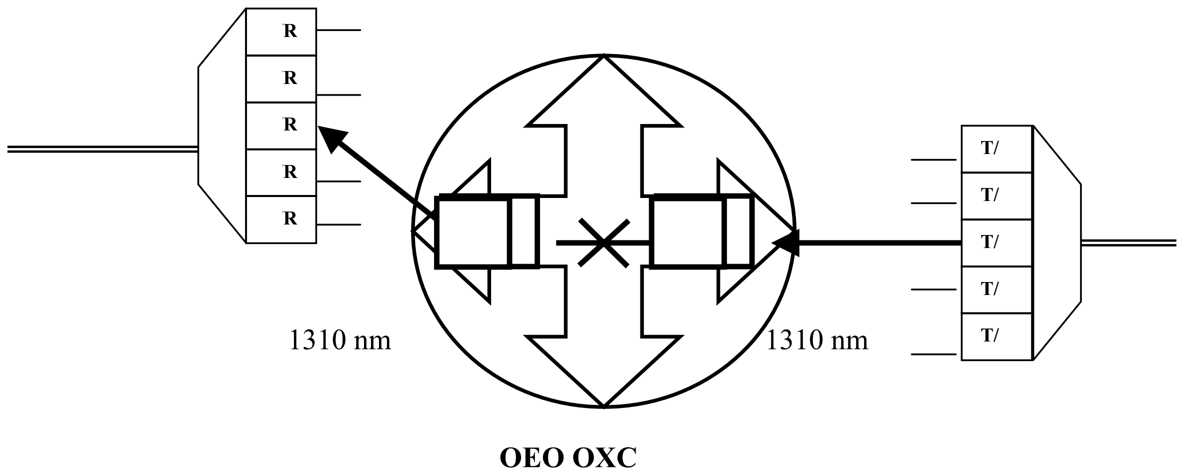
Example of an Opaque OXC in a Typical Environment



The advantages of the transparent switches are as follows:

- The simple interface and the elimination of the need to buy and deploy the light-to-electrical and electrical-to-light devices.
- The transparent switches are best suited to the vision of the nirvana of the "all-optical network."
- Transparent switches are speed and protocol agnostic, making upgrades easy. Opaque switches are especially bit-rate dependent. This makes upgrades of speed very difficult for opaque switches.
- Transparent switches can probably be built to a larger scale than opaque switches. More than 1,000 ports (in and out each) are clearly going to be shortly available, and many thousands of ports are likely. Opaque switches are going to be limited to 512 ports for at least a while.
- Transparent switches are extremely dumb devices, and thus simple and, at least potentially, cheap.

The disadvantages (at least at this time in the development cycles) are as follows:

- Using transparent devices introduces a loss item into the light-loss budget calculation. The transparent switches are not completely transparent. They reflect light by one means or another, and each reflection point is a loss point. In O–E–O systems, the switches are, in fact, regenerators, and they are improvements in the transmission path rather than detriments.
- There is as yet very little standardization among the makers of DWDM equipment as to the wavelengths that they use. In going through an O–E–O device, this makes little difference, as the right "color" is merely a question of selecting the right laser on the output side. In transparent devices, this is not the case. Light is only reflected through the device, so no change in wavelength can be achieved. The color "in" is the color "out," and that is the only one that can be used in that slot.
- Restoration presents another problem. If a lightwave is split (to establish a standby path), then its power is cut in half. With O–E–O, the split can be made in the electrical domain, and the loss can be easily overcome.
- Performance monitoring is also a problem with transparent systems. There is no real way to make the traditional digital error measurements (or corrections) that are possible in O–E–O systems.
- It is likely going to be 2001 before large-port-size versions of the transparent switches are available in any real commercial quantity. Opaque switches are shipping now.

Example of the Insertion Loss Problem with Transparent Switches

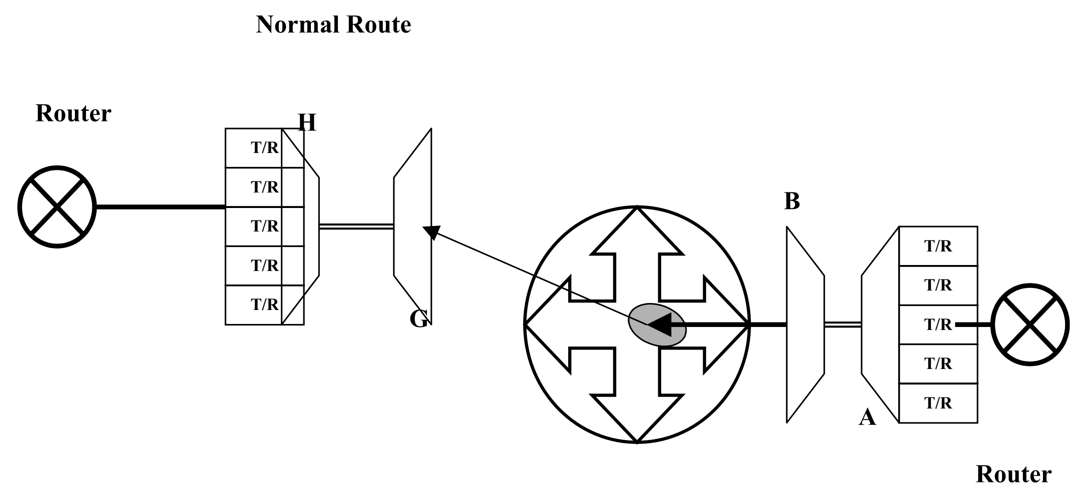
The issue of loss in the use of transparent switches is often misunderstood. The use of transparent switches in "all-optical" networks can easily be (mistakenly) thought of as a transmission advantage, and the press sometimes misleads us to think this is the case. In fact, transparent switches are *the source of optical signal loss* in the calculation of the optical path budget. They all use some kind of reflection to achieve the switching function, and several versions require substantial free space travel of the light beam. Both of these (reflection and free space travel) cause significant loss to the signal. Optical amplifiers can provide the remedy for this problem on a given circuit route. However, when transparent OXCs are introduced in the network, a new problem appears in that network segments may be connected together in a more or less random manner, making the end-to-end transmission design very difficult.

Opaque switches, on the other hand, convert the optical signal to an electrical signal. In the electrical domain, the signal is given the full "3R" (re-amplification, reshaping, and retiming) regeneration treatment, and then it is reproduced as an optical signal at a new, "cleaned-up," high level.

Figure 3 is a sketch illustrating a typical DWDM route with an OXC. This route takes a signal from point A to B on a

FIGURE 3

Normal Route for a DWDM System



DWDM system. At B, a DWDM terminal interconnects to an OXC and then to another DWDM system (G). This system goes to the DWDM terminal at H and finally to a router located also at H.

Figure 4 shows the situation when a fault has occurred between G and H. The normal path (A–B, G–H) for the light signal through the OXC has been disrupted. The OXC has switched the signal coming from A to a restoration path (C–D, E–F). It also shows this complete hypothesized restoration (A–B, C–D, E–F) path (assuming a fiber fault). The following chart (see *Figure 5*) shows the path-loss budget calculations for the two paths.

The significance of this loss difference depends on the receiver sensitivity and the transmitter output power. If the

Connector Loss (@ 1 db)	12 db	14 db
Splice Losses (@ 0.2 db – 1 per 5 km)	1.6 db	2.4 db
Margin for Repair Splices (@ 0.2 db – 2 per section)	0.4 db	0.6 db
Path Totals	**24.8 db**	**37.25 db**
Optical Switch Loss	7 db	7 db
Total Loss	**31.8 db**	**44.25 db**

output power is 0 db, and the sensitivity is –35 db (typical figures, however, some systems would have higher output power), then the normal path would be well within the limits of the receiver (–35 db). However, in the event of a switch for restoration, the alternative path would be out of limits for the receiver, even though the components of that path would individually be in limits. Obviously, the author has concocted this example to illustrate the point. However, the reader should note that all of the assumptions are absolutely real-life situations, and one would expect to encounter this problem in any use of transparent switches.

It should also be noted that if the transparent optical switch were not used (i.e., if an O–E–O switch were used instead), there would be no problem on the alternate path. In that case, the optical-switch loss will no longer apply, and the paths will not be additive for loss calculations. (In other words, the path A–B, C–D, E–F becomes two paths, A–B and C–D, E–F, each of which is within the allowable limits of the receivers. The C–D, E–F loss is 23.1 db, and the A–B loss is much less.)

Thus, there are two insertion loss problems: (1) the combination of routes, which have been individually engineered, and (2) the loss of the transparent optical switch itself. These problems can be overcome by very careful engineering of all conceivable interconnections and by the application of optical amplifiers. Both of these, however, are costly and detract from the main advantages of the all-optical approach—economics and simplicity.

While there are solutions for the transparent OXC problems indicated, the solutions might be worse than the problems. The real answer is that "all-optical" may not necessarily really mean that the OXCs are always fully optical. Both transparent and opaque OXCs have appropriate applications in our new networks. As in any technology choice, one needs to avoid the hype. Rather, potential users should carefully review the available alternatives as they apply their specific situations.

The author's latest "Lightwave" series of reports (www.igi-group.com) is the basis for this article. This article originally appeared in the April 9, 2001, issue of Telephony *as "Solving the Gridlock Glut."*

OSS Challenges for Multiple Broadband Service Integration

Karen Johnson
Chief Information Officer
e-Site, Inc.

Introduction

Technology exists today to support operation support system (OSS) flow-through provisioning. The majority of issues today are not centered around technology constraints, but rather involve business-interaction problems, such as the following:[1]

1. Labor-intensive processes and their associated time and costs
2. Error-prone hand-offs of information between operational entities
3. Delays in provisioning cycles
4. Low levels of service assurance
5. Lack of billing synchronization
6. Multiple proprietary solutions
7. Lack of visibility into partner systems and networks

Standardized flow-through, end-to-end interactions between various trading partners are just beginning to be implemented in broadband integration solutions today.

There are a multitude of broadband forecasts and projections published to date. *Figure 1* offers one such forecast as provided by the International Data Corporation (IDC) in the second quarter of 2000. As individual access provisioning processes among trading partners move to OSS standardization and technology improvements, the question is this: will this affect the rate of consumer adoption of one broadband access technology over another?

The current difficulties with broadband provisioning are highlited by a study conducted by Forrester Research. Participants were asked to identify the worst things about the current telecom purchasing processes. The results are shown in the *Figure 2*. Most, if not all, of these can be solved by the OSS integration of services.

Architecture Design

The architectural design of an OSS solution includes six distinct components, as *Table* 1 outlines.

As companies migrate an OSS solution from one access technology into multiple broadband access technologies, the level of complexity is increased because access technologies remain competitors. OSS standardization efforts are being addressed by each access technology individually.

Multi-Technology OSS Integration

The key to integration is to integrate business logic, not just functional capabilities. This requires consolidating provider-specific workflow and data transformations into a single consolidated software framework.

Legacy systems across technologies differ from, more than they parallel, each other. In addition, partially automated flows within each industry require more complex call-center support. Some industries use a standard version of middleware while others use a proprietary variant. Each provider product, regardless of broadband technology, requires the development of connectors and business logic to drive the connectors.

Application programming interface (API) suites within each industry are underway. However, they do not mimic other broadband technology API suites. The biggest challenge is in the analysis and modeling of data that must support a number of differing technology products used in one integrated solution.

OSS Issues for Multi-Industry Integration

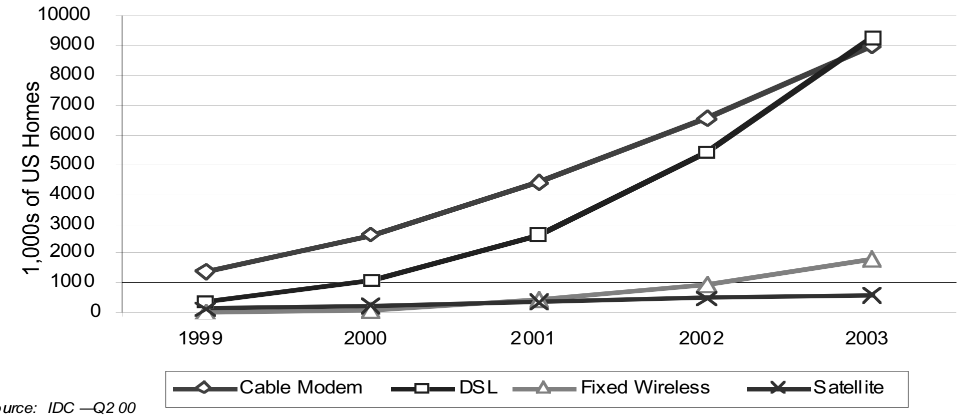
The challenge in creating connectors and business logic is getting cooperation with existing business logic and APIs that vary across industries.

The amount of work required for integration (APIs, data mapping, business-logic definitions, etc.) does not decrease when moving from one industry provider to another industry provider. Fault, configuration, accounting, performance, and security overlap, and the information requirements from one system to another differ. This is especially problematic when the same data is required in two industry-disparate systems.

The biggest issues for multi-technology integration is working through promised API functionality by isolating and

FIGURE 1

IDC's Broadband Deployment Projections



Source: IDC —Q2 00

testing not only the technology-specific data but also the provider-specific data.

The One with the Most Customers Wins

Network and service providers need to work together and across industries to provide customer-driven broadband-based solutions for services, products, and content.

Extending franchises, increasing customer acquisition while up-selling current customers, and creating new revenue streams succeed in any industry.

Next-Generation Broadband Users

Next-generation broadband users are diverse members looking for a broad range of services designed specifically to help them achieve their goals and provide a place where business can be easily transacted. These are the users who want high-speed Internet browsers and are generally quick to add on new services.

Build Community, Not Diversity

Competitors generally do not trust each other. And many broadband companies today are more comfortable going head-to-head rather than working side-by-side. Meanwhile, customers may have to wait several years to have interoperability issues resolved.

However, it is essential that these vendors and providers start working together for long-term viability. Collectively, industries can provide buyers and suppliers with content they cannot do without. Pure economic forces, then, should

encourage broadband companies to work with, rather than against, each other.

Summary

Successful broadband service providers will be able to do the following:

- Automate business processes
- Integrate back-end systems
- Enable on-line customer acquisition and support
- Extend their platforms into e-business partners and e-marketplaces
- Create more satisfied customers and less churn
- Increase sales, brand trust, and market share
- Adapt quickly to additional revenue sources
- Integrate systems for network and application provisioning
- Adhere to technology standards
- Build community, not diversity
- Build integration architecture that adapts to the evolution of products both within and outside the core technology

DWDM Passive Components

Gerd Keiser
President
PhotonicsComm Solutions, Inc.

This paper discusses the passive components that are the enabling technologies for dense wavelength division multiplexing (DWDM). It shows why people are using wavelength multiplexing, and it discusses what international standards groups such as the International Telecommunication Union (ITU) are doing to specify wavelength spacings. Four fundamental DWDM technologies are compared: dielectric thin-film filters, fiber-based Bragg gratings, arrayed waveguide gratings, and bulk diffraction gratings. The discussion covers operating principles, advantages, limitations, and performance characteristics for each of these technologies.

Transmission Windows

The curve in *Figure 1* shows typical attenuation as a function of wavelength for a silica fiber. The curve has a downward trend because of Rayleigh scattering. It also has a large attenuation spike at around 1400 nanometers (nm) because of absorption of the light by water molecules in the glass. Current material processing methods can now eliminate this spike and create a continuous curve, but this paper will assume that the spike is there, as most installed fibers tend to have this characteristic.

The two transmission bands used by telecommunication systems are the so-called second and third windows. Because optical sources have very narrow output spectral widths, many optical sources can fit within these two windows, allowing the simultaneous transmission of many independent information streams at different wavelengths. The spacing between the wavelength channels is specified by Recommendation G.652 from the ITU–Telecommunication Standardization Sector (ITU–T). The standard spacing is 100 gigahertz (GHz), which is equivalent to 0.8 nm at a 1550-nm wavelength. The G.652 document also specifies optional spacings of 25, 50, and 200 GHz.

ITU-T Wavelength Grid for Wavelength Division Multiplexing

Figure 2 shows a typical wavelength grid for 100-GHz channel spacings for 32 channels. This is based on the ITU–T reference frequency of 193.100 terahertz (THz), which is 1552.52 nm in the wavelength domain.

Dielectric Thin-Film Filter

The first DWDM technology discussed here is the use of dielectric thin-film filters (see *Figure 3*). These filters consist of a stack of dielectric thin films separated by cavities. The multiple reflective dielectric thin-film layers form mirrors that surround the cavities, thereby creating a thin-film resonant cavity filter or a Fabry-Perot interferometer. The device is made to pass a particular wavelength straight through and to reflect all others. The length of the cavity determines which wavelength passes through the filter.

As the number of cavities increases, the passband of the filter sharpens up, creating a flat top for the filter, a desirable characteristic. Some advantages of a dielectric thin-film filter are its flat passbands with sharp frequency rolloffs, its low insertion loss (less than three decibels [dB]), and its high reflection loss (more than 50 dB). One of its limitations is that its use for closely spaced channels requires many very uniform thin-film layers for a number of cavities. Also, one filter is needed for each wavelength. Because of these limitations, dielectric thin-film filters are useful for a small number of wavelength channels. Standard commercial devices are available for up to 20 channels with 100-GHz spacings, and some vendors are offering products with smaller channel spacings.

Bragg Grating Principle

A second DWDM technology is based on the Bragg grating principle. These devices are used extensively for functions such as dispersion compensation, stabilizing laser diodes, and add/drop multiplexing in optical systems. One embodiment is to create a Bragg grating in the core of an optical fiber. In such a fiber-based Bragg filter there is a periodic variation in the refractive index along the direction of light propagation. This variation is shown in *Figure 4*, where n_1 is the refractive index of the core of the fiber, n_2 is the index of the cladding, lower-case lambda (l) is the wavelength, and upper-case lambda (L) is the period of the grating. If an incident optical wave at l_0 encounters a periodic variation in refractive index along the direction of propagation, l_0 will be reflected back if the following condition is met: $l_0 = 2n_{eff}L$, where n effective (n_{eff}) is the average weighting of the two indices of refraction, n_1 and n_2. When a specific wavelength l_0 meets this condition, that wavelength will get reflected and all others will pass through.

Fiber-Based Bragg Grating Formation

A fiber-based Bragg grating is typically made from germanium (Ge)-doped silicon fiber, as this material is sensitive to ultraviolet light. One method for forming a Bragg grating in

FIGURE 1

11	1549.31	27	1536.61
12	1548.51	28	1535.82
13	1547.72	29	1535.04
14	1546.92	30	1534.25
15	1546.12	31	1533.47
16	1545.32	32	1532.68

a fiber is shown in *Figure 5*. Two ultraviolet beams at 244 nm are used to establish an interference pattern in the fiber core, which results in a permanent photo imprint of an index variation. The space between these index variations is L (the period of the grating). This fiber by itself is normally temperature sensitive, which will cause the Bragg wavelength to shift with temperature changes. However, special packing techniques can be implemented to compensate for this thermal drift, thus making Bragg gratings athermal devices.

Simple Demux Function

A simple example of how to apply a Bragg grating as a drop element is shown by the demultiplexing (demuxing) function in *Figure 6*. One key element of this process is an optical circulator, which performs the following function: Light that enters port one exits port two, light that enters port two exits port three, and light that enters port three exits from port one. Suppose the Bragg grating is designed to reflect l_2. After the wavelengths l_1 through l_4 enter port one and exit from port two, l_2 gets reflected by the grating, goes back into port two of the circulator, and exits from

FIGURE 3

Dielectric Thin-Film Filter

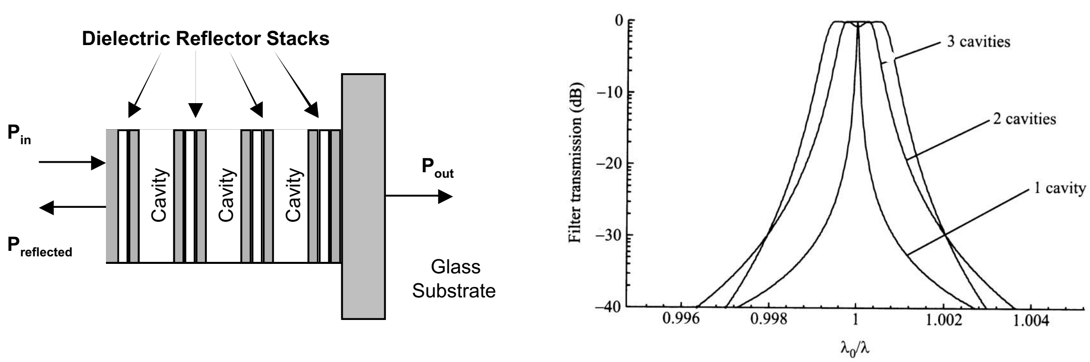

FIGURE 4

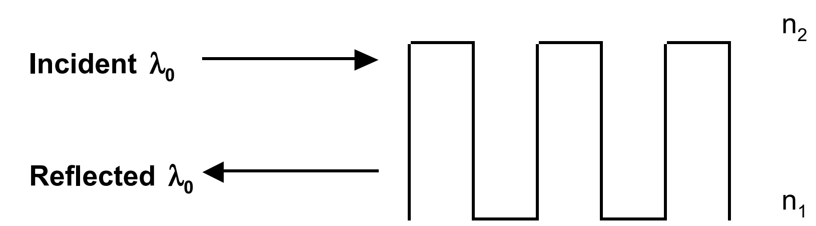
Bragg Grating Principle



port three. With this procedure that wavelength is dropped and the others pass straight through both the circulator and the grating.

Extended Add/Drop Multiplexing

More complex structures can be made using additional circulators and different gratings in series (see *Figure 7*). These gratings may be made to reflect a fixed wavelength, or they can be tunable to have greater implementation versatility. In this example, there are two three-port circulators and three gratings. The gratings are set to reflect l_1, l_2, and l_3. If a series of wavelengths l_1 through l_N enters port one of the left-hand circulator, l_4 through l_N go straight through both circulators, entering at port one and exiting from port two in each device. The other three wavelengths are reflected by the gratings after the first circulator, re-enter its port two, and exit from port three. These wavelengths then can be demuxed into individual channels and processed. To add these wavelengths back into the fiber-optic stream, they can be sent to a multiplexer (mux). In this case, they would enter port three of the second circulator, exit port one, head toward the first circulator, get reflected by the three gratings, re-enter port one of the second circulator, and exit port two, where they join the other wavelengths.

Fiber-Based Grating Characteristics

Bragg gratings allow wavelength channel spacings as narrow as 25 GHz. By using special packaging techniques, Bragg gratings can be made to have a very low thermal drift, down to less than half a picometer (pm) per degree centigrade, and they exhibit very low interchannel crosstalk. One filter is needed for each wavelength, and normally the operation is sequential, with wavelengths being reflected by one filter after another. Therefore the losses are not uniform from channel to channel, as each wavelength goes through a different number of gratings, each of which adds loss to that channel. This may be acceptable for a small number of channels, but the loss differentials between the first and last reflected wavelengths in a series of Bragg gratings is a limitation for large channel counts.

FIGURE 5

Fiber-Based Bragg Grating Formation

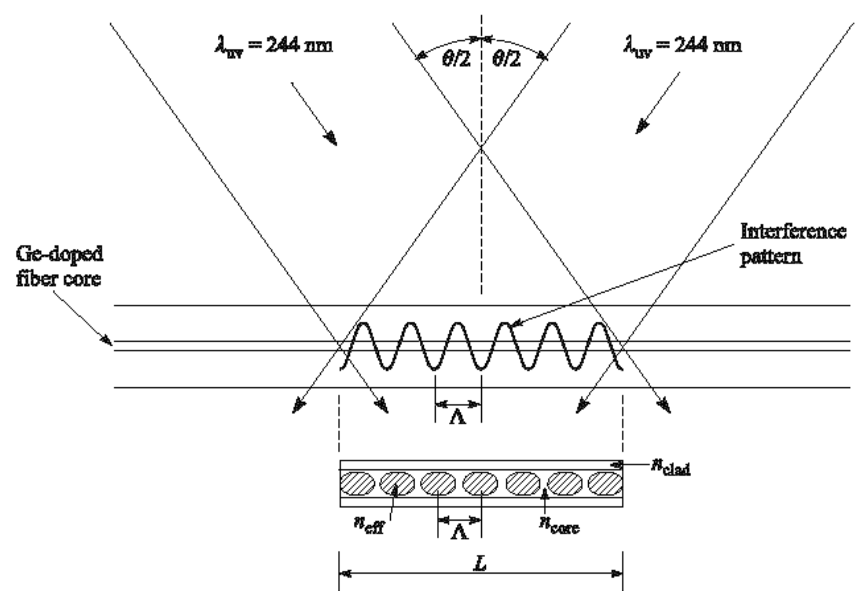


FIGURE 6

Simple Demux Function

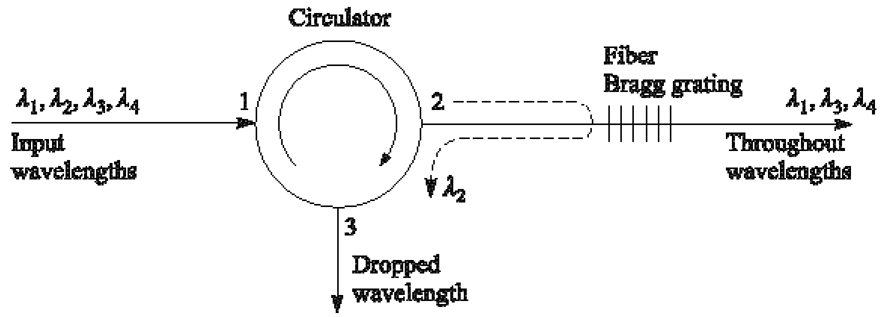

FIGURE 7

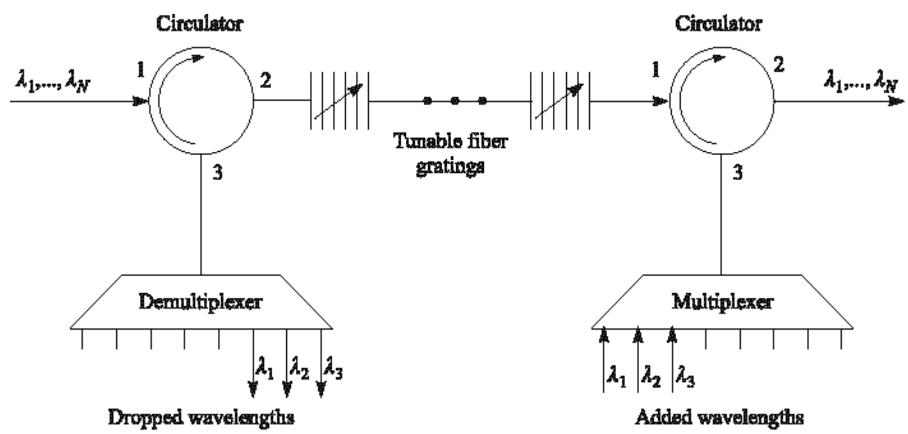
Extended Add/Drop Multiplexing



Arrayed Waveguide Grating

Arrayed waveguide gratings (AWG) are a third DWDM device category. These gratings use input and output slab waveguides to focus light in planar star couplers and a series of waveguides with different path lengths called a grating array waveguide. If different wavelengths come in on separate fibers, the path length differences of the grating array waveguides can be chosen such that all input wavelengths exit from one port of the device. The operation is also reciprocal, so that if all the wavelengths come in on one fiber, the device will separate them into individual output channels.

AWG Characteristics

AWG technology makes it easy to achieve very narrow channel spacing of 25 GHz. Devices with 16, 32, and 40 channels are available commercially, and they are easily fabricated on silica wafers. Their compact footprint eases system integration. Originally these devices required a thermoelectric cooler to prevent wavelength drift, but newer packaging designs make the devices athermal so they do not need any special dynamic temperature-stabilizing mechanisms.

Bulk Diffraction Gratings

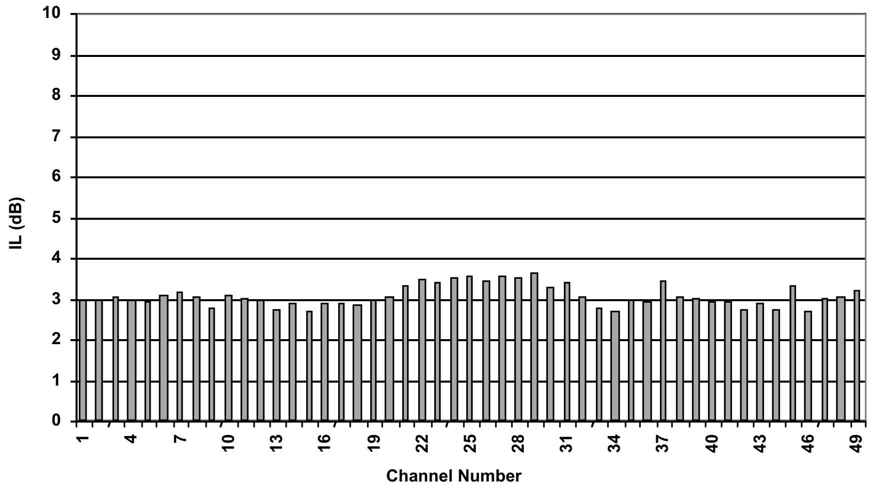
A fourth DWDM technology is based on bulk diffraction gratings. These gratings are fine-ruled or etched parallel lines on some type of reflective surface. With these gratings, light will bounce off the grating at an angle. The angle at which the light leaves the grating depends on its wavelength, so the reflected light fans out in a spectrum. For DWDM applications, the lines are spaced equally, and each individual wavelength will be reflected at a slightly different angle. There can be a reception fiber at each of the positions where the reflected light gets focused. Individual wavelengths will thus be directed to separate fibers.

Characteristics of Bulk Diffraction Gratings

With bulk diffraction gratings, separating and combining wavelengths is a parallel process, as opposed to the serial process used with the fiber-based Bragg gratings. Adjacent-channel crosstalk is very low, usually less than 30 dB. Insertion loss is also low (less than three dB) and is uniform to within one dB over a large number of channels. *Figure 8* shows ruled-grating insertion loss over 50 channels. The variation between the highest and lowest channels is less than one dB, even for high channel counts, such as 50 channels. A

FIGURE 8

Ruled-Grating Insertion Loss



passband of 30 GHz at one-dB ripple is standard. As is the case with other wavelength division multiplexer (WDM) schemes, packaging designs can make the device athermal so that no active temperature control is needed.

Ruled-Grating DWDM Module

Figure 9 shows how this device works. In this schematic, there are several different input fibers. As the light from a fiber spreads out in a cone, there are some simple focusing elements that collimate the light. The lenses are fairly standard components that are readily available. After it is collimated, the light is reflected off the bulk grating. Each wavelength is reflected at a slightly different angle, so that when the light travels back to the array of fibers on the left side of the schematic the optical elements focus each wavelength onto a different output fiber. The device works reciprocally; that is, if different wavelengths come into the device on the individual input fibers, all of the wavelengths will be focused back into one fiber after traveling through the device.

Comparison Summary

Each WDM technology has its own advantages and limitations. *Figure 10* summarizes and compares the four DWDM technologies discussed in this paper. For example, the chart shows that it is difficult for thin-film filters and Bragg grating to handle narrow wavelength spacings. In addi-

FIGURE 9

Ruled-Grating DWDM Module

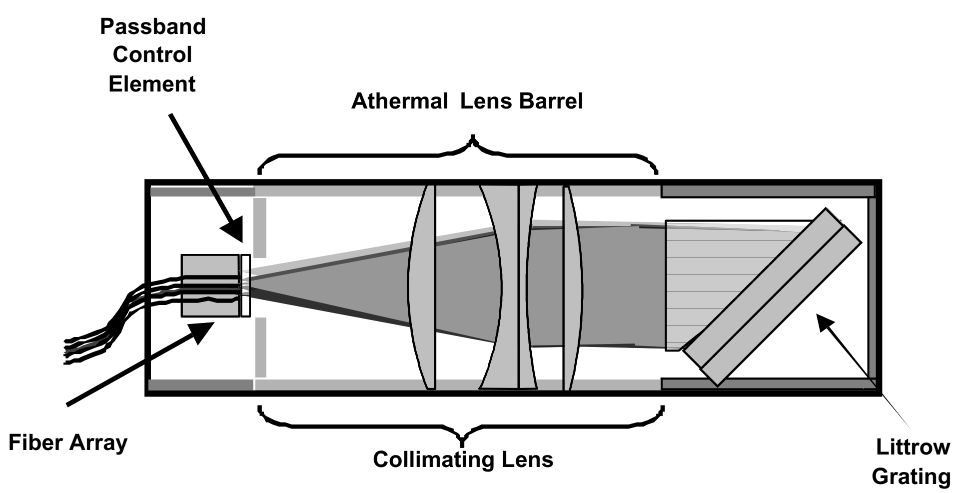


FIGURE 10

Comparison Summary

Parameter	Thin-Film Filter	Fiber Bragg Grating	Arrayed Waveguide Grating (AWG)	Bulk Diffraction Grating
Channel Spacing Accuracy	Good but difficult for < 100 GHz	Good down to at least 50 GHz	No problem down to 25 GHz	No problem down to 25 GHz
Fiber-to-Fiber Loss	Very good; not uniform because of sequential operation	Very good; not uniform because of sequential operation	Uniform; typically < 3 dB overall	Uniform; typically < 3 dB overall
Crosstalk Level	Very good for spacings > 100 GHz	Very good; 30 to 35 dB	Very good; 30 to 35 dB	Very good; 30 to 35 dB
Absolute Wavelength	Each channel is adjusted separately	Each channel is adjusted separately	Good but may need temperature control	Very good; athermal device
Cost per Channel	High	High	Low	Low
Channel Count	Good for < 20 channels at 100 GHz	Good for < 20 channels at 25 GHz	Good for more than 16 channels	Good for more than 16 channels

tion, they work well for a small number of channels, whereas AWG and bulk diffraction gratings are more advantageous for narrow-wavelength spacing and for a large number of channels.

Comparison of Metro SONET and DWDM

Andrew Knott
Vice President, Marketing
White Rock Networks

SONET and DWDM in the Metro

This paper will compare the metro markets for synchronous optical networks (SONET) and dense wavelength division multiplexing (DWDM). Most vendors seem to take the *Field of Dreams* view of the market: If the vendor builds it, carriers will come. But carriers will come only if it is to their advantage. The success of metro SONET and DWDM will depend on network evolution and carrier spending—not just on the technology.

Background

White Rock Networks, headquartered in Dallas, was founded just over a year ago to provide modular, scalable, optical networking products for the metro market. It is funded by bench capital backed by a start-up, has raised more than $120 million so far, and has more than 200 employees. Its target customers are metro local-exchange carriers (MLEC). Paul Johnson at Robertson Stephens has joked that the *m* in MLEC stands for "monied." The first shipments to these "monied" LECs was to be in August or September of this year, which is important because new vendors in this market are more likely to succeed if they can turn ideas into implementation in a short time to match advances in networks and component technology.

The Carrier Dilemma

In the United States, *a huge growth in bandwidth is projected over the next three to four years* (see *Figure 1*). Similar growth is projected worldwide. There will also be healthy growth in revenue. But the real problem in today's market is that carrier costs are rising faster than revenue. That is one of the reasons why a large number of carriers are now concentrating heavily on providing services where they can actually make money and on getting the best value out of their existing networks. Solutions that provide maximum profits with immediate return on investment (ROI) are crucial.

White Rock's Laws of Carrier Motion

The following laws of carrier motion, in the spirit of Newton's Laws of Motion, condense White Rock's view of the market.

First Law of Carrier Motion

The First Law of Carrier Motion is that every successful vendor-carrier relationship tends to remain successful unless an external force is applied. That external force could be a competitor with a product that does much the same thing for less money, or it could be the vendor trying to do something that the customer does not want.

Second Law of Carrier Motion

The Second Law of Carrier Motion is that force is equal to money times acceleration (F = m*a), where force is the amount of force that a vendor uses to convince carriers to adopt a new method of operation; money is, in most cases, revenue; and acceleration is the rate at which that money will move from the vendor to his competitors. When a vendor shows a new technology to a large carrier, the response the vendor dreads most is that the technology is interesting and the carrier is studying it. "Studying" in carrier-speak means "do not expect to see revenue from this product in your lifetime."

Third Law of Carrier Motion

The Third Law of Carrier Motion is that for every disruptive vendor push, there is an equal and opposite carrier push. If a vendor attempts to do something that a carrier is not ready for, the carrier will tend to push back—and push to other vendors.

The Laws of Carrier Motion Applied

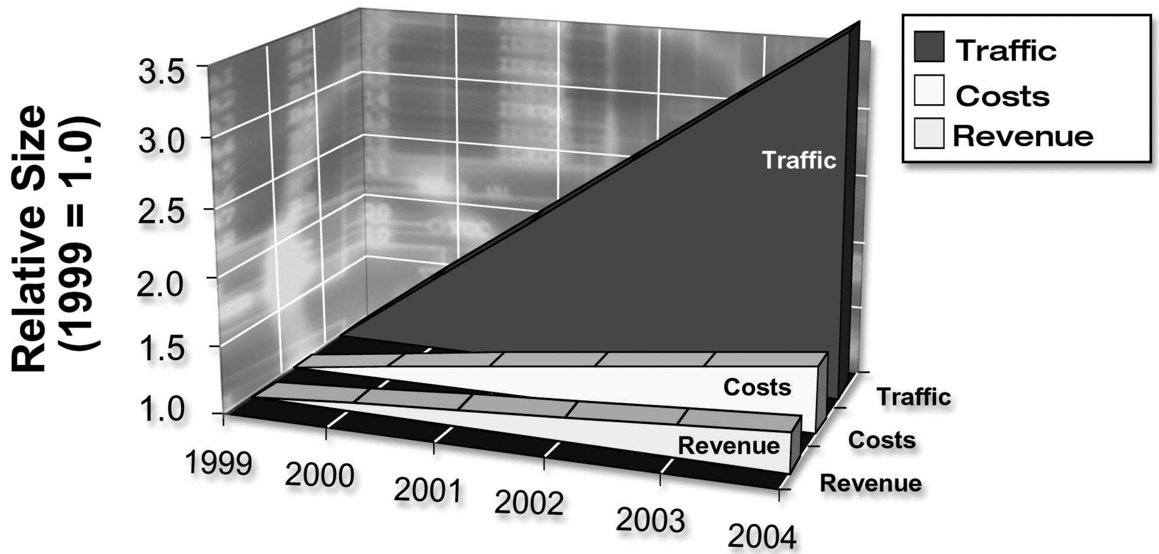
The laws of carrier motion can be applied much the way a high school physics teacher might give students a set of rules and then see how they apply to the real world.

When Vendors Push, Carriers Push Back

A good example of the Third Law—when vendors push, carriers push back—is the way radical technology changes tend to force disruptive operational cost changes that can outweigh the short-term cost benefits of the new technology. This is one reason why a lot of new technology does not get absorbed into large carriers, or gets absorbed only through fairly slow adoption cycles. For example, two to three years ago, every industry report predicted that asynchronous transfer mode (ATM) over SONET would be the technology that was used in the

FIGURE 1

The Carrier Dilemma



network, and that Internet protocol (IP) and other technologies would run over ATM over SONET. But currently, there appear to be no successful ATM over SONET products.

When Carriers Pull, Responsive Vendors Stay Synchronized

Things really happen in the network when carriers pull and responsive vendors stay in synchronized motion with their customers, following the first law. Staying synchronized is a challenge for the vendor, however, because carriers can normally predict what their networks will look like in the next year, but not in three or four years. That can be a real problem if the vendor's product development cycle is three to four years.

Force Equals Money Times Acceleration

New products that allow immediate cost reductions without forcing radical changes in existing network architecture tend to break in quickly. In other words, most products that involve network evolution rather than revolution succeed extremely well (the Second Law). Cerent's 454 product, otherwise known as the Cisco 15454, is a good example of this in the transmission world. Prior to Cerent's introduction, no new SONET vendor, other than the original five, had produced revenues much over $30 million a year.

Metro Market Size and GrowthæLaws of Motion in Action

The metro market reflects the deployment of SONET products that evolve networks, rather than disrupt networks (see *Figure* 2). A chart from Ryan Hankin Kent such as that in *Figure 2*, showed the last stitch of SONET being sold in North America next year. However, the numbers in *Figure 2* show that SONET remains the largest market in North America and has the highest projected dollar growth. Also, the DWDM market is growing and will represent about 30 percent of the overall metro market by 2004, but it will not completely overwhelm the network. SONET and DWDM will coexist, because carrier networks will force them to.

Metro Market Environment

Diverse Application Space

The metro market environment is very different from what most vendors would like it to be. It is a diverse application space that requires multiservice capabilities, while most vendors would find it easier to design products for customers that look the same. Site-by-site selectability is also needed, because a small competitive local-exchange carrier (CLEC) in a single city is very different from WorldCom or Southwestern Bell. And the metro market requirements in Louisville, Kentucky, are very different from those in San Francisco. While there is a requirement for multiservice delivery, there is a bigger requirement to be able to customize that delivery cost-effectively. Carriers love cheap products. It is also necessary to be able to fit the application to the kind of building that is being entered.

Technology Changes Quickly, but Carriers Do Not

Metro technology changes extremely rapidly. Test component vendors, replace their component technologies every nine to 12 months. So one way for a vendor to stay ahead is to continually refresh and build next-generation technology into its products.

But carriers want the latest technologies only to the extent that they can reduce prices, allowing them to generate fast profits while using their existing networks. They want the benefits of the new technology, but they cannot change architectures in their network every nine to twelve months. Carriers adopt new architectures slowly, but they want immediate cost benefits over present mode of operation (PMO).

FIGURE 2

Metro Market Size and Growth—Laws of Motion in Action

	2000	2001	2002	2003	2004
□ Metro DWDM (rhk)	$401	$549	$717	$973	$1289
■ Metro SONET (rhk)	$5074	$2882	$2441	$3195	$3768

Fiber Deployment Is NOT Homogeneous

Fiber deployment is anything but homogeneous in the United States. About 10 percent of the buildings in the United States are served directly by fiber. The other 90 percent are served by copper or wireless. A typical large CLEC, interexchange carrier (IXC), or incumbent local-exchange carrier (ILEC) has either *no* fiber-to-the-building (FTTB) or an *excess* of FTTB, with multiple strands not being used.

Metro SONET and DWDM Compared

SONET

SONET has the great advantage of having been around for 10 years or so. It is a highly reliable transport for high-bandwidth services. And SONET has been able to grow with the growth of bandwidth in the United States. As recently as three years ago, the default SONET speed used in a metro environment was optical carrier (OC)–3. This year it is OC–48, and next year 30 to 40 percent of deployments will use an OC–192 line rate.

SONET is also ubiquitous. It has well-defined operations that are understood by the vast majority of carriers, and they have operational practices to control it. It is very good at grooming and performance monitoring (PM) at both the transport level and the end-to-end service delivery level. And it enables efficient and extremely non-complex transport of digital signal (DS)–3, OC-n, and data services.

The introduction of low-cost OC–48 add/drop multiplexers (ADM) like the Cerent 454, which came with local area network (LAN) service delivery capabilities, vastly increased the viability of SONET–based service delivery. Next year, there will be volume deployment of low-cost OC–192 ADMs that are metro-capable. There may be a 40 to 50 percent fall in the price of short-haul OC–192 SONET products over the course of the next year. That would be the same factor that pushed OC–48 into the metro market. And the introduction of Gigabit Ethernet (GbE) interfaces onto those products will stretch the life of SONET in the metro.

So SONET addresses the bulk of today's metro market needs and the applications that the majority of "monied" LECs deploy today. The most notable exceptions are sporadic fiber relief and storage area networks (SAN).

DWDM

DWDM can be broken down into two categories: metro fiber relief and wavelength services.

Metro Fiber Relief

Three aspects of DWDM provide metro fiber relief. First, there are DWDM solutions with very low cost, allowing for immediate return on investment (ROI). Second, these solutions are simple and easily understood. And third, it is relatively straightforward to design simple passive DWDM networks, eliminating power and management complexities. A proposed standard has been filed by Lucent with the International Telecommunications Union (ITU) for coarse wavelength division multiplexing (CWDM). With existing DWDM technologies, it is possible to multiply vastly the amount of service that can be deployed in a network without really having to learn too much.

Wavelength Services

Wavelength services are still awaiting prime-time feasibility outside of greenfield carriers. There is a fundamental need for lower component costs and SONET–like management processes in this arena. Also, these products typically provide no direct support for DS–3, which is still viewed as the bread-and-butter service solution by most large carriers. For example, the latest reports show that DS–3 service at BellSouth grew by 60 percent year-over-year.

Also, wavelength services waste fiber potential. The cost of wavelength services simply cannot be justified today for individual service delivery below OC–48, and few customers want individual services at OC–48 and above. A better option, therefore, is a low-cost time division multiplex (TDM) aggregator in front of the DWDM terminal, but only where necessary. That allows multilevel grooming capabilities and PM visibility, and it allows maximum use of fiber potential for the wavelengths that have been deployed.

SONET and DWDM Provide Complementary Benefits
SONET and DWDM provide complementary benefits. SONET provides grooming capabilities and project management at the transport and end-to-end services levels, and its management capabilities are well defined and understood. It also offers low-cost, direct support of DS–3, OC–n, and GbE.

DWDM can be used in a spot fashion for fiber relief, or for direct support of services that are not SONET–compatible, such as fiber channel or services that operate above OC–48 line rates. These capabilities are part of existing carrier networks today, and any technology that is introduced in the future will have to continue to provide these services.

Why Not Just Integrate SONET into Next-Generation DWDM Platforms?

Cost
Integrating SONET into next-generation DWDM platforms is an appealing concept when trying to set up a company, but the biggest reason not to do it is cost. Only a small proportion of locations in an access network require both SONET and DWDM capabilities. And if SONET and DWDM are integrated, carriers will pay a tax for embedded features whether they are using them or not. Also, interoperation will be required between devices that do both DWDM and SONET and devices that do only DWDM or only SONET. Few carriers will voluntarily support two different types of TDM (SONET) multiplexing (integrated and standalone) in a single customer access ring in a single city. "Over-integration" results in a much slower time to market and a sub-optimal cost performance. It is a vendor "push" against carriers' love for low cost.

Complexity
The other reason not to integrate SONET and DWDM is complexity. Carriers have tamed the issues raised by deploying DWDM or SONET alone, but they have not yet tamed the issues raised by deploying both of them on the same product at the same time, including the impacts on management, employees, training, and operations.

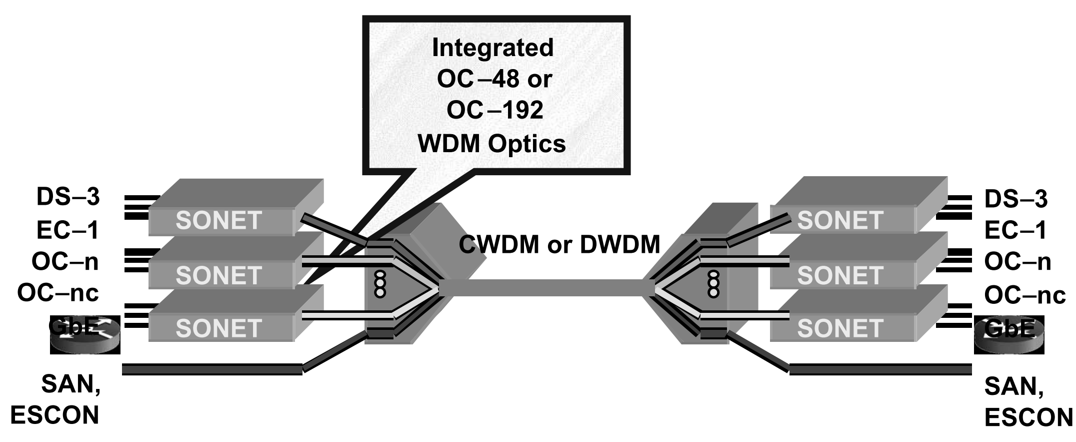
Metro SONET and DWDM—A "Dis-Integrated" Solution

A cost-feasible solution that addresses the bulk of today's metro market needs is to deploy SONET and DWDM together in a dis-integrated fashion (see *Figure 3*). In this solution, DWDM or CWDM provides additional wavelengths on a spot basis where carriers start to run out of fiber. SONET is used for the majority of the multiplexing techniques and supports the majority of the customer interfaces. SONET plus CWDM provides very low equipment cost and up to eight lambdas (l) per fiber. SONET plus DWDM provides low equipment cost and better fiber usage.

White Rock Networks offers a building-block family of metro products. Every product is pure play, so no single product has DWDM and SONET in the same platform. Customers can clip products together like Lego blocks to build up exactly what they want to use in a metro environment. The architecture allows products to be built with a 12- to 15-month development cycle, so they can be synchronized with the planning cycles of customers and with the development cycles of suppliers (component manufacturers). The products can thus piggyback on rapid enhancements in optics and optic electronics technology.

White Rock Networks applies the Dell model to the transmission space: technology is continually refreshed to

FIGURE 3
Metro SONET and DWDM—A "Dis-Integrated" Solution



bring best price points and functionality to customers. However, selling carriers a whole load of discrete boxes, even if they are cheap and small, could make carriers' management problems worse. So all the products come with control-playing technology, so as carriers clip them together, they form a single network element. White Rock Networks creates evolutionary optical networks with revolutionary technologies. The first product, announced less than three months ago, is a SONET ADM that is one-twentieth the size of the most common SONET ADM shipped today.

Summary

DWDM can offer significant benefits in fiber consolidation and support for services with very high bit rates, greater than OC–48. SONET, however, is ideally suited for integrated grooming, delivery of individual services up to the OC–48 per customer line rate, and deterministic service protection. So far, large carriers have been slow to standardize "all-optical" solutions. It is the combination of SONET and DWDM in a discrete fashion that will remain the large-carrier access model for the foreseeable future.

Generalized Objected-Oriented Simulation Frame Work for Multimedia-on-Demand Services

Abstract

In today's information age, a growing need is felt for multimedia-on-demand services to provide a variety of facilities such as movie-on-demand, interactive network games, remote education, catalogue browsing, multimedia libraries, home shopping, etc. Currently these facilities are not available widely on a large scale. In this paper, we present a simulation of a generic system to support multimedia-on-demand services over an asynchronous transfer mode (ATM) network. The simulation has been performed using an object-oriented simulation (OOS) approach. Discrete event system specification (DEVS) methodology has been used in the design and implementation of the simulation. This simulation approach also helped in the development of a modular, reusable, and easily extendable model of a multimedia-on-demand system. Also, this approach is shown to be very useful in adapting the basic model to simulate any of the aforementioned multimedia-on-demand services. To illustrate this, we have simulated a movie-on-demand service using our generic multimedia-on-demand simulation model. We have demonstrated the real-time nature, scalability, and cost-effectiveness of a movie-on-demand system based upon our generic multimedia-on-demand system. This model will be useful for studying the performance of services such as movie-on-demand, interactive network game, and multimedia libraries.

1. Introduction

The advent of fast networks, large storage capacity, and high computing power has not only served to make multimedia-on-demand services feasible but has also triggered a strong interest in the development of applications in this area. Basically, multimedia-on-demand services refer to the services that provide user-controlled viewing of multimedia (audio, video, text, graphics, animation, etc.) information. These services include facilities such as movie-on-demand, interactive network games, remote education, catalogue browsing, multimedia libraries, home shopping, etc. Several systems have been proposed that provide a subset of the aforementioned facilities [6,7]. But most of these systems are not very widely available on a commercial basis.

A multimedia-on-demand system has to be designed keeping in mind its feasibility (i.e., whether the current state of technology can support the designed system) and economic viability and performance (i.e., whether the system can meet the required constraints). The existence of high-speed networks such as broadband integrated services digital networks (B–ISDNs), which use ATM, and rapid advances in storage and very–large-scale integrated (VLSI) technology have made multimedia-on-demand systems feasible. The cost and the performance of such a system are heavily influenced by the storage scheme used to store the multimedia data [7,5] type of network and the quality of display. Therefore, it is important that these factors be carefully analyzed before building the system. Three widely accepted techniques that are used in design evaluation to ensure economic viability and performance are prototyping, analytical studies, and simulation.

Building a prototype of a multimedia-on-demand system is expensive because it requires specialized software and hardware. Moreover, complete evaluation of all of the services will not be possible with a small prototype. In general, analytical studies are best for evaluating the performance of a system, but they provide mostly the bounds (upper or lower) on the performance. The main complexity in analytical study comes from 1) the average system performance analysis, 2) sensitivity analysis of various inputs on the system performance, and 3) the interactive nature of an application. Therefore, simulation is the best method to analyze the average system performance and study the sensitivity of various inputs on the performance of the multimedia-on-demand system.

In this paper, we have presented an object-oriented model [1] for a generic multimedia-on-demand system using the C++ programming language. Design details of this system can be found in [5]. Since we are concerned with time-related behavior of the system, a discrete event-simulation approach has been used. To formally present the model and the simulation technique of our system, Zeigler's DEVS methodology [2,3,4] has been adopted. This methodology helps in the hierarchical and modular development of a simulation model of complex systems. The modular nature of our model helps in simulating different storage methods, network parameters, and variable quality displays with minimal changes. To illustrate the generality of our multimedia-on-demand system model, we have simulated a movie-on-demand system and also have compared the performance of the movie-on-demand system for different storage methods and network parameters.

This paper is organized as follows. Section 2 explains the DEVS formalism. Section 3 explains the system architecture in detail. The simulation model is discussed in Section 4. Simulation details are given in Section 5. The simulation studies performed and the results obtained are discussed in Section 6. Section 7 concludes the paper.

2. DEVS Formalism

DEVS is a set-theoretic formalism [2,3] that supports hierarchical and modular specifications of discrete event models. Semantics of this formalism is highly compatible with object-oriented specification of a simulation model. Having set up a simulation model in DEVS, its implementation using an object-oriented programming language (such as C++, MODSIM, etc.) is straightforward. The object-oriented design also supports the distributed implementation of the simulation models. DEVS provides a method to represent a basic model as an atomic unit. Using these atomic units, larger models can be built. A method to lump and/or prune the models has also been proposed by Ziegler [4], which helps in the simplification of simulation models.

2.1 *Atomic Models in DEVS Formalism*

The atomic model, is described as follows:

$M = < X, S, Y, \delta_{int}, \delta_{ext'}\ \lambda, ta >$ where:
X: Input event set
Y: Output event set
S: Sequential states set
δ_{int}: $S \rightarrow S$, Internal transition function
δ_{ext}: $QxS \rightarrow S$, External transition function
λ: Output function
ta: $S \rightarrow R$, Time advance function
$Q = \{(s,e) \mid s \in S, 0 \leq e \leq, ta(s)\}$: Total state of M

In this model, input event set (X) is a collection of all the inputs that influence this atomic model. Information about the input event set is important in order to decide the internal and external transitions δ_{int} and δ_{ext}. The output event set (Y) decides the influence of this model on other models (atomic or coupled). The sequential state set (S) describes the internal states of the atomic model that can be reached by a specified input event from a specified state. Depending upon the current state of the atomic model and the transition rules δ_{int} and δ_{ext}, an output is generated. On an internal event, the output is produced by the output function (k) depending upon the current state of the atomic model. The time advance function (ta) describes the time in which an external event is scheduled to occur. If an external event arrives within ta(s), where s is the current state, then δ_{ext} decides the transition, otherwise δ_{int} decides the transition. The total state (Q) of an atomic model M represents the current state (s) of that component and the time elapsed (e) in that state. A detailed description of the specification of atomic model could be found in [4].

An atomic model is used to define every indivisible component of a simulation model. Using atomic models, other models called molecular models are developed, which have a specified behavior after their composition is defined. Molecular models can also be classified as coupled models. A formal method to represent coupled models in DEVS is given next.

2.2 *Coupled Models in DEVS Formalism*

Several atomic models can be coupled to form a coupled model. This model can be used as a component in a larger coupled model. Thus, complex models can be constructed in a hierarchical fashion. A coupled model so generated has the advantage of information hiding (known as encapsulation in object-oriented methodology). This feature of coupled models lends itself to be considered as an object. A coupled model (CM) is defined as the following:

$CM = < D, (M_I), (I_{ij}), (Z_{ij}), SELECT >$, where:
D: Component names set for each component i in D
M_i: DEVS model for component i in D
I_i: Set of influences of i for each element in I_i
Z_{ij}: Output transition function for transition from from component i to j
SELECT: Subsets of D $\rightarrow$ D, tie-breaking selector

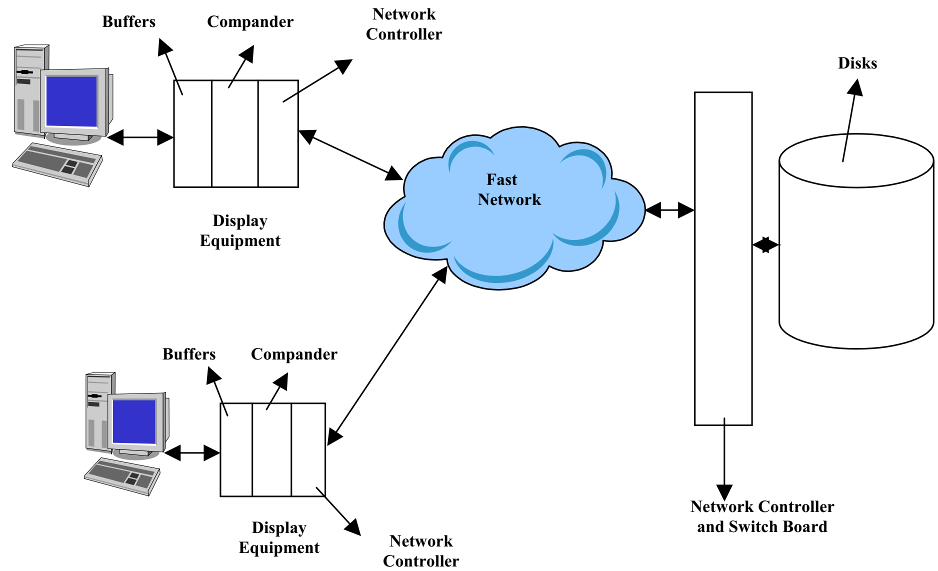
In the previous definition of a coupled model, D is a set of the components upon which this model is constructed. These components could be an atomic model or another coupled model. M_i is a DEVS model for each component that is a part of the coupled model. This information is necessary to allow the internal or external events to be processed by an appropriate component.

3. Architecture of Multimedia-on-Demand Systems

Our multimedia-on-demand system is comprised of three major components (see *Figure 1*), namely the storage server, display equipment, and a fast interconnection network. *Figure 1* explains the organization of the complete system. A brief description of the major components of the system and their responsibilities is given next.

FIGURE 1

Components of a Multimedia-on-Demand System



3.1 Storage Server

The storage server is responsible for controlling access to the multimedia data stored in its disks and for transmitting the requested information to the users. The storage server comprises a fast computer, a large number of disks, a broadband switch (e.g., ATM switch), and an efficient network controller. The storage server accepts requests from the users and finds out the appropriate switch (which gets data from one of the disks in the disk array) that can satisfy the request. Then it transmits the incoming information from that switch to the user. The storage server can multicast the same data to a large number of users from the same switch if they happen to have requested the same information at the same time.

3.2 Display Equipment

Display equipment, in our system, is an intelligent display unit capable of sending/receiving signals and multimedia data to/from the server. The display unit can perform real-time uncompression of media information. Thus, a compander, RAM, a network interface, and a high-resolution display constitute display equipment. Each display-equipment unit also has a remote control and/or a joystick for interactive viewing.

3.3 Fast Network

The interconnection network is assumed to have a high bandwidth, guaranteed sequential delivery of packets, and bounded delay in packet-delivery B–ISDN networks using ATM are best suited for providing multimedia-on-demand services. Detailed information on B–ISDN and ATM can be found in [8,9].

4. Simulation Model

We have developed a simulation model of our multimedia-on-demand system using DEVS methodology. The simulation model, shown in *Figure 2*, is a hierarchical coupled model and is object-oriented in nature. The major components of our models are a storage server, display equipment, a global clock, a coordinator, a simulation engine, and a statistics collector. Among these components, the storage server and the display equipment are coupled models, and the rest of them are atomic models. Coupling of these components has been performed according to the discussion in Section 2.2. Due to space limitation, only the details of coupled models have been given. The atomic models can be constructed easily by the description of the component and the methodology given in Section 3.1 [5].

The model of the overall system can be represented using DEVS methodology as follows:

Multimedia-on-Demand System = <

(storage server, display equipment, global clock, coordinator, network, simulation engine, statistics collector),

{{M_{network}}, {CM_{server}} ($CM_{\text{display equipment}}$), ($M_{\text{clock}}$}, {$M_{\text{coordinator}}$} ($M_{\text{simulation engine}}$), ($M_{\text{statistics}}$)),

$Z_{\text{network to server}}$ = Send user request (e.g. some remote control button pressed or joystick moved etc.),
$Z_{\text{network to display equipment}}$ = Send multimedia unit or control signal,
$Z_{\text{server to statistics}}$ = Update statistics,
$Z_{\text{server to network}}$ = Send user request,
$Z_{\text{display equipment to network}}$ = Send user request,
$Z_{\text{display equipment to statistics}}$ = Update statistics,
$Z_{\text{clock to server}}$ = Provide current time,
$Z_{\text{clock to display equipment}}$ = Provide current time,
$Z_{\text{clock to coordinator}}$ = Provide current time,
$Z_{\text{coordinator to server}}$ = Request to begin processing,
$Z_{\text{coordinator to display equipment}}$ = Request to begin processing,
$Z_{\text{coordinator to simulation engine}}$ = Inform when simulation ends,
$Z_{\text{simulation engine to coordinator}}$ = Request start of simulation,
(The rest of the interactions are null, hence they are not given.)}.

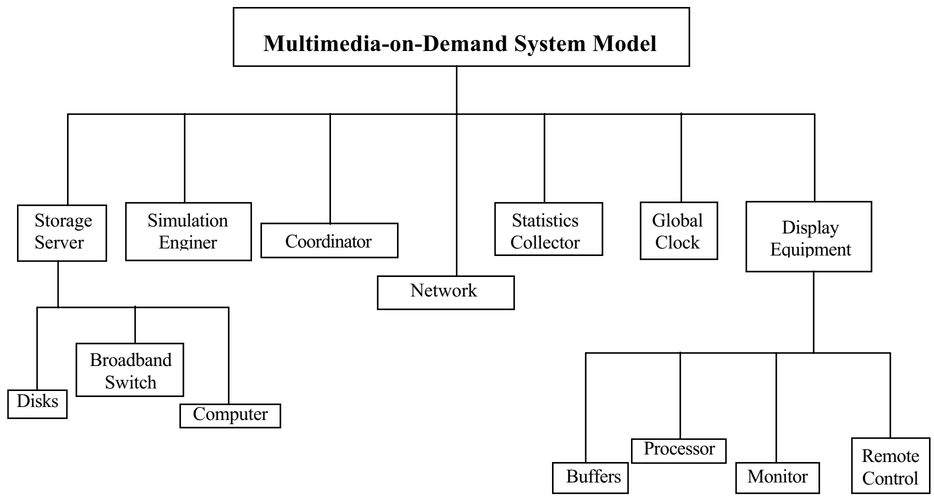
Select >

Where Select resolves a tie by priority.

As can be seen from the formalism of the model, the emphasis is only on the interaction of the various components with each other. The internal details of the components are hidden,

FIGURE 2

Model of the Multimedia-on-Demand System



which helps in making the system general (i.e., even if the internals of any component are changed, the model will be unaffected as long as the interactions among the various components are not changed). This feature of the model made it possible to simulate and study the performance of a multimedia-on-demand system for different storage methods and network parameters. A brief description of the components of our simulation model is given in the following sections.

4.1 Model of Storage Server

The storage server comprises an array of disks, a broadband switch, a network controller, and a computer. The server receives inputs from the simulation coordinator and the display equipment and sends the requested data to the display equipment. The server's interaction with the display equipment takes places via the network controller. Since a multimedia-on-demand system is highly interactive, a computer is required to process all the user requests. The server generates statistics about the search and access time for the desired data.

Several constrained allocation schemes have been proposed [5,7] for the storage of multimedia data. Depending on the type of on-demand application, an appropriate layout scheme has to be chosen. In our model for disk (discussed in Section 4.1.1), the model of our storage server can be represented using DEVS methodology as follows:

Storage server = <{array of disks, network controller, broadband switches, computer},

{{M_{disks}}, {$M_{network\ controller}$}, {$M_{broadbases\_switch}$}, {$M_{computer}$ },

$Z_{disk\ to\ broadband\ switches}$ = In every update cycle the data is made available at the corresponding broadband switch buffer,
$Z_{broadband\ switches\ to\ network\ controller}$ = Transmit data to the respective display equipment,
$Z_{network\ controller\ to\ computer}$ = Send user requests to computer for processing,
(The rest of the interactions are null, hence they are not given.)},

Select >

…where Select first accepts the requests coming from the display equipment before the server performs any other operation and $M_{<unit\ name>}$ represents the atomic model for that unit. A brief discussion on the aforementioned atomic units is given next.

4.1.1 Array of Disks

An array of disks is used to store the multimedia data. The layout of this data is discussed in [5]. The disks are responsible for updating their current head position at appropriate intervals of time (decided by the disk retrieval rate) and sending the currently accessed multimedia unit to the server on request. The parameters guiding disk operations in our simulation are disk retrieval rate and disk seek/latency times.

4.1.2 Broadband Switches

In our model, the broadband switches are assumed to be high-speed switches with negligible switching delays. A small number of buffers are attached to each switch to take care of processing delays. The retrieved multimedia units are placed in the buffers by the disks. The switches are responsible for transmitting the multimedia units from their buffers to the appropriate display equipments.

4.1.3 Computer

An intelligent processor is required to maintain the status of each display equipment unit, to handle the interaction between the server and the display equipment, and to locate an appropriate disk for satisfying a user request. For our simulation model, we have assumed that processing time is negligible. This does not cause any inaccuracy in our simulation model because the processing time for any of the aforementioned tasks is at least an order of magnitude smaller than the disk retrieval time, communication delays, etc.

4.1.4 Network Controller

The network controller provides an interface between the storage server and the interconnection network. The computer transmits multimedia data/control signals to and receives control signals from the display equipment via the network controller over the interconnection network.

4.2 Fast Network

The interconnection network provides a communication path between the server and the display equipment. The interconnection model has been designed such that it can incorporate different values for network parameters. Using our model, we can simulate several networks, such as transmission control protocol (TCP)/IP, ISDN, and B–ISDN. In our simulation model, the interconnection network causes a bounded delay in each transmission. The network delay has a significant influence on the buffer requirement of the display equipment. As the network delay increases, the network can also lose packets with a certain probability.

4.3 Model of Display Equipment

The display equipment of a network controller includes a set of buffers, a compander, a monitor, a processor, and a remote control. The display equipment receives input from the coordinator, the server, and the remote control. A processor processes the input coming from the remote control. The input from the server is received via the network controller. The display equipment is responsible for transmitting all user interaction requests to the server. It also collects and transmits statistics about display starvation, start-up delays, buffer overflows, etc. to the statistics collector. To simplify the model, the compander has been lumped with the monitor. Using DEVS formalism, the display equipment model can be expressed as the following:

Display equipment = <
{network controller, buffers, monitor, remote control, processor},
{{$M_{\text{network controller}}$}, {$M_{\text{buffers}}$}, {$M_{\text{monitor}}$}, {$M_{\text{remote control}}$}, {$M_{\text{processor}}$}},

{$Z_{\text{network controller to buffers}}$ = Put an available multimedia unit in the buffer,
$Z_{\text{buffer to monitor}}$ = Transmit a multimedia unit whenever monitor requests,
$Z_{\text{remote control to processor}}$ = Send the user request to the processor.
$Z_{\text{processor to network controller}}$ = Send the user request to the network to be transmitted to the server,

(The rest of the interaction are null, hence they are not given.)},

Select >

…where Select resolves a conflict (if there is one) between an outgoing remote control signal and an incoming server data/signal. A conflict may arise if the two signals arrive at the same time. $M_{\text{<unit name>}}$ represents the atomic model for that unit. The atomic units, which have not been discussed in the context of the server, are described next.

4.3.1 Buffers

Every display-equipment unit has a number of buffers that store the data to be displayed. This is needed to maintain a jitter-free display. Since the number of buffers is limited, it is possible that an overflow may take place and that some data may be lost. The optimal number of buffers required depends on the type of multimedia-on-demand service. One of the studies performed in our simulation model is to determine the optimal number of buffers for a jitter-free display.

4.3.2 Monitor

The monitor performs the functions of decoding multimedia units and displaying them. The time taken for decoding depends on the coding technique used. As soon as the monitor finishes decoding a multimedia unit, it examines the buffers to get the next multimedia unit. If the buffers are empty, then the monitor records it as a jitter.

4.3.3 Remote Control

The remote control provides the interactive nature to the multimedia-on-demand system. The actual, physical form of a remote control may vary depending upon the kind of on-demand service (e.g., it may be a conventional remote control in movie-on-demand systems, a joystick in an interactive network game, etc.), but conceptually it has the same meaning in all services. The remote control transmits user signals to the display equipment's processor, which in turn transmits it to the server. In our simulation model, the remote control generates signals randomly to emulate user actions.

4.3.4 Processor

The processor provides an interface between the remote control and the server. It coordinates the display at the monitor with the remote-control actions (e.g., when a "Pause" button is pressed in a movie-on-demand system, the processor freezes the display on the monitor and at the same time informs the server of its action.) In our model, the processing delays are assumed to be negligible.

4.3.5 Network Controller

The network controller provides an interface between the display equipment and the interconnection network. The processor receives multimedia data/control signals and transmits control signals via the network controller over the interconnection network.

4.4 Global Clock

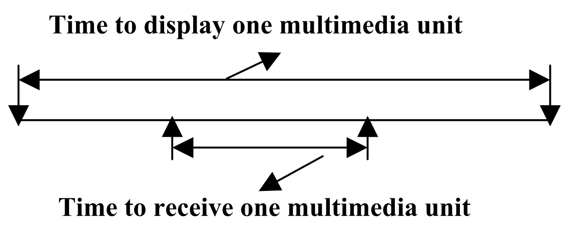
We have used a global clock in our simulation, which controls the local time management of all of the elements of our simulation model. The clock tick for this clock is set to the highest common factor of the time units used in the components of our model. This clock tick ensures that any event in our system will occur only at multiples of the global clock tick. The actual value of this clock tick depends upon the type of the on-demand application as well as on the parameters of the atomic units. For example, in *Figure 3* the relationship among the time unit associated with disks, monitor, and the global clock has been shown. It can be seen that although the time units for disks, monitor, and the global clock are all different, they are still synchronized.

4.5 Coordinator

In our simulation model, the coordinator is an atomic model that is responsible for coordinating the message exchange between the server and the display equipment. The coordinator initiates the global clock tick and updates it during the simulation. But it does not update any of the local clocks (the local clocks are updated by their "owner" units). The main function of the coordinator is to initiate the system operation and manage the flow of control between the server and the display equipment. To simulate concurrent events on a sequential machine, the coordinator allows all of the components to generate an event at every global clock tick. If a conflict occurs because of multiple events being generated at the same time, the appropriate tie-breaker (referred to as Select in DEVS terminology) is used to resolve the conflict. Coordinator also instructs all of the components of our simulation model to collect and transmit statistics to the statistics collection module. When the simulation time is over, the coordinator dies after returning control to the simulation engine

FIGURE 3

An Example of Clock Synchronization



4.6 Simulation Engine

The simulation engine has the responsibility of interpreting the simulation data and of presenting it to the user in accordance with the goals of the simulation exercise. This is a very critical module, and any error in interpreting the data can lead to unrealistic results about the system. If the error is not very obvious, the performance of the simulated system may get erroneously evaluated. In our simulation model, the simulation engine accepts all of the user-defined parameters and requests the coordinator to begin the operation of the system. At the end of the simulation, when the control is returned to the simulation engine, it queries the statistics collection module for the simulation statistics and performs any necessary translations before presenting it to the user.

4.7 Statistics Collector

Statistics collection is vital to any simulation, as the primary purpose of performing a simulation is to collect meaningful statistics about the system's behavior. Thus, the statistics collector module is very important and needs to be designed carefully so that the desired information about the system under study is collected. In our simulation, the statistics collector is basically a data container for statistics pertaining to each module. It is passive in the sense that the responsibility of updating the statistics lays with the respective modules and not with the statistics collector. Also, it does not generate any events of its own and does not have a local clock. The statistics collector module is initialized with the proper values before the simulation is actually started by the simulation engine.

The complete organization of our simulation model is given in *Figure 4*.

5. Simulation Detail

Using our generic multimedia-on-demand simulation model, we have simulated a movie-on-demand (MOD) system. A brief discussion on a MOD system is given next.

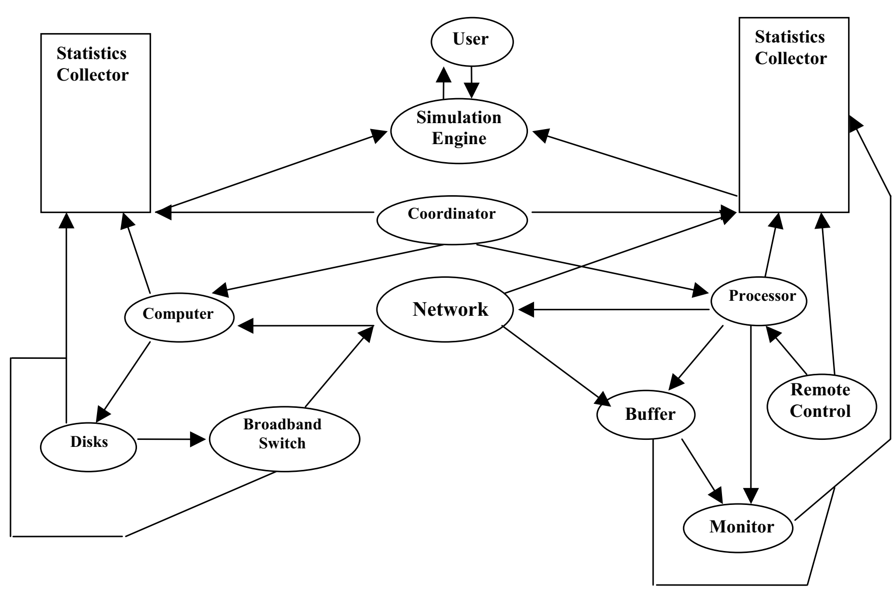
5.1 MOD System

The aim of a MOD system is to provide facilities similar to a video cassette player (VCP) while serving as a video rental store. Essentially, MOD can be thought of as an electronic video rental system. The primary advantage of MOD is that it delivers customer-selected movies at a customer-specified schedule. Thus, unlike a conventional VCP, the customer does not have to go to a video rental store. Also, a movie can be selected at the customer's will (unlike in pay-per-view [PPV] services). The MOD service is targeted toward residential customers seeking video information for educational or entertainment purposes.

Market surveys indicate that there is a great demand for MOD services. Although several systems have been proposed in the recent past [6,7], none of the systems provide all of the facilities of a VCP and, moreover, cannot support a large number of users at a reasonable cost. We have proposed

FIGURE 4

Interaction of All the Components in the Simulation Model



an MOD system that is cost-effective and can support a large number of users while providing all the features of a VCP in [8]. In our MOD system, the server stores a number of movies in an array of disks. Further, multiple disks are used for each movie. Since relatively inexpensive disks are used to store a movie, the use of multiple disks does not increase the overall cost of the system appreciably. The disks are divided into normal and special disks depending on their usage. When display equipment is in rewind or fast-forward mode, it is transmitting data from one of the special disks. When it is in normal mode, it is transmitting data from the normal disks. In our design of the MOD system, the use of multiple disks serves to enhance performance in terms of reducing certain delays (e.g., the delay after which a user starts viewing the requested movie, delay in activating the remote-control features, etc.) in the system. In our scheme, increasing the number of disks can reduce these delays. This is supported by the simulation studies presented in this paper. Also, our scheme is scalable with respect to the number of users in the system, i.e., the performance of the system is not affected as the number of users in the system is increased. The details of our scheme can be found in [5].

In this paper, we present simulation studies of our MOD system. Two different data layout schemes are examined for our MOD system, and their effect on various system performance parameters is compared.

5.2 Parameters Used in the Simulation of a MOD System

In our simulation, we have considered National Television Standards Committee (NTSC) quality video for all movies. The display rate is assumed to be the same for all of the display equipments. The display rate used in our simulation is 1.5 Mbps. All of the movies served by the server are 100 minutes long. Multiple disks with a data retrieval rate of 100 Mbps are used to store the movies. The data unit size of a movie has been kept at 0.05 Mbits (with a 30-frames-per-second display rate, this is the size of a frame of a movie). In our simulation, the display equipment can generate random requests for the *fast forwarding or rewinding with display, fast forwarding or rewinding without display, Pause*, and *Start (Play)*.

Since network delays are assumed to be bounded, their effect on system performance is studied by varying the lower and upper bounds on the network delay. The number of customers in the system is also kept variable.

5.3 Simulation Strategy

In this section, the simulation dynamics are discussed in detail. *Figure 5* gives the complete flow of control of simulation of MOD. Since our simulation is time driven, it is essential to relate the events precisely with the time. In our simulation, all events are time stamped and the delays experienced by an event are also kept with the event. This method ensures that an event is never processed before it reaches the destination. To allow concurrent events, each event generated is stamped with its birth time (decided by the statistical method chosen to generate events; in our simulation, we have generated all events randomly), and its arrival time at every module is also recorded. This allows more than one event to have the same time stamp. In our simulation, at any tick of global clock, all modules are visited in hierarchical order. If the global clock tick matches with the clock tick of the module being visited, an event can be generated. Otherwise, the module does not do anything and passes on the control. As shown in *Figure 5*, the MOD system starts by updating the clock, and then it updates the disks, i.e., accesses a multimedia unit (if available) and feeds it to the broadband switch for transmission. Then the server is asked to check if there are any unattended requests pending to be considered at the current clock tick. If there are some pending requests, the server services them first. Then it checks whether some of the display equipments need a multimedia unit. If so, the respective broadband switch is instructed to send the multimedia unit to that display device. The multimedia unit transmitted carries the time when it was transmitted and the delays experienced, if any. This ensures that, when control is passed to the display equipment, it does not process a media unit, which is physically there but logically should not have reached. Now the display equipment is allowed to process the pending server replies for its requests generated in past. The display equipments also display a multimedia unit at this time (provided there is one available and the display is not stopped because of some remote-control action). Next, the display equipments are requested to generate any requests for the server. If a request is generated, it is transmitted to the server for its consideration at a later time. This completes one simulation cycle. If the simulation time is not yet over, the clock is updated and the next simulation cycle begins. During a simulation cycle, the modules also update the statistics collector. At the end of the simulation, the maximum, minimum, and average values of the collected statistical data are displayed to the user. The analysis of this data is left to the user.

6. Simulation Results

As explained in Section 5.2, the simulation studies are performed for MOD services over an ATM network. The simulation model can be used to compare different layout schemes and network parameters with respect to the following performance measures: 1) average delay in starting a requested movie (referred to as the startup delay), 2) average delay in a remote-control feature (Pause/FF/REV) to become active, 3) average delay in resuming normal display after the remote-control feature has been inactivated, 4) buffers required at the display equipments, 5) average number of jitters experienced in the display, 6) maximum number of display equipments that can be supported by the MOD system, and 7) optimal number of normal and special disks required per movie.

In the simulation studies presented in this paper, we have compared contiguous and constrained (developed in [8]) allocation schemes for our MOD system with respect to the buffers required at the display equipments. The start-up delay and the average delay in the activation of a remote-control feature for the constrained allocation scheme are also discussed.

6.1 Buffers Required at the Display Equipments

The buffer requirements at the display equipments depend heavily on the data layout scheme employed and the network delay. A comparison of the constrained and contiguous data layout schemes with respect to buffer requirement is presented in *Table 1*. Each cell of the table shows two values for the buffer requirement for a particular network delay and the amount of movie passed. In

FIGURE 5

Flow Control in the Simulation Model of the MOD System

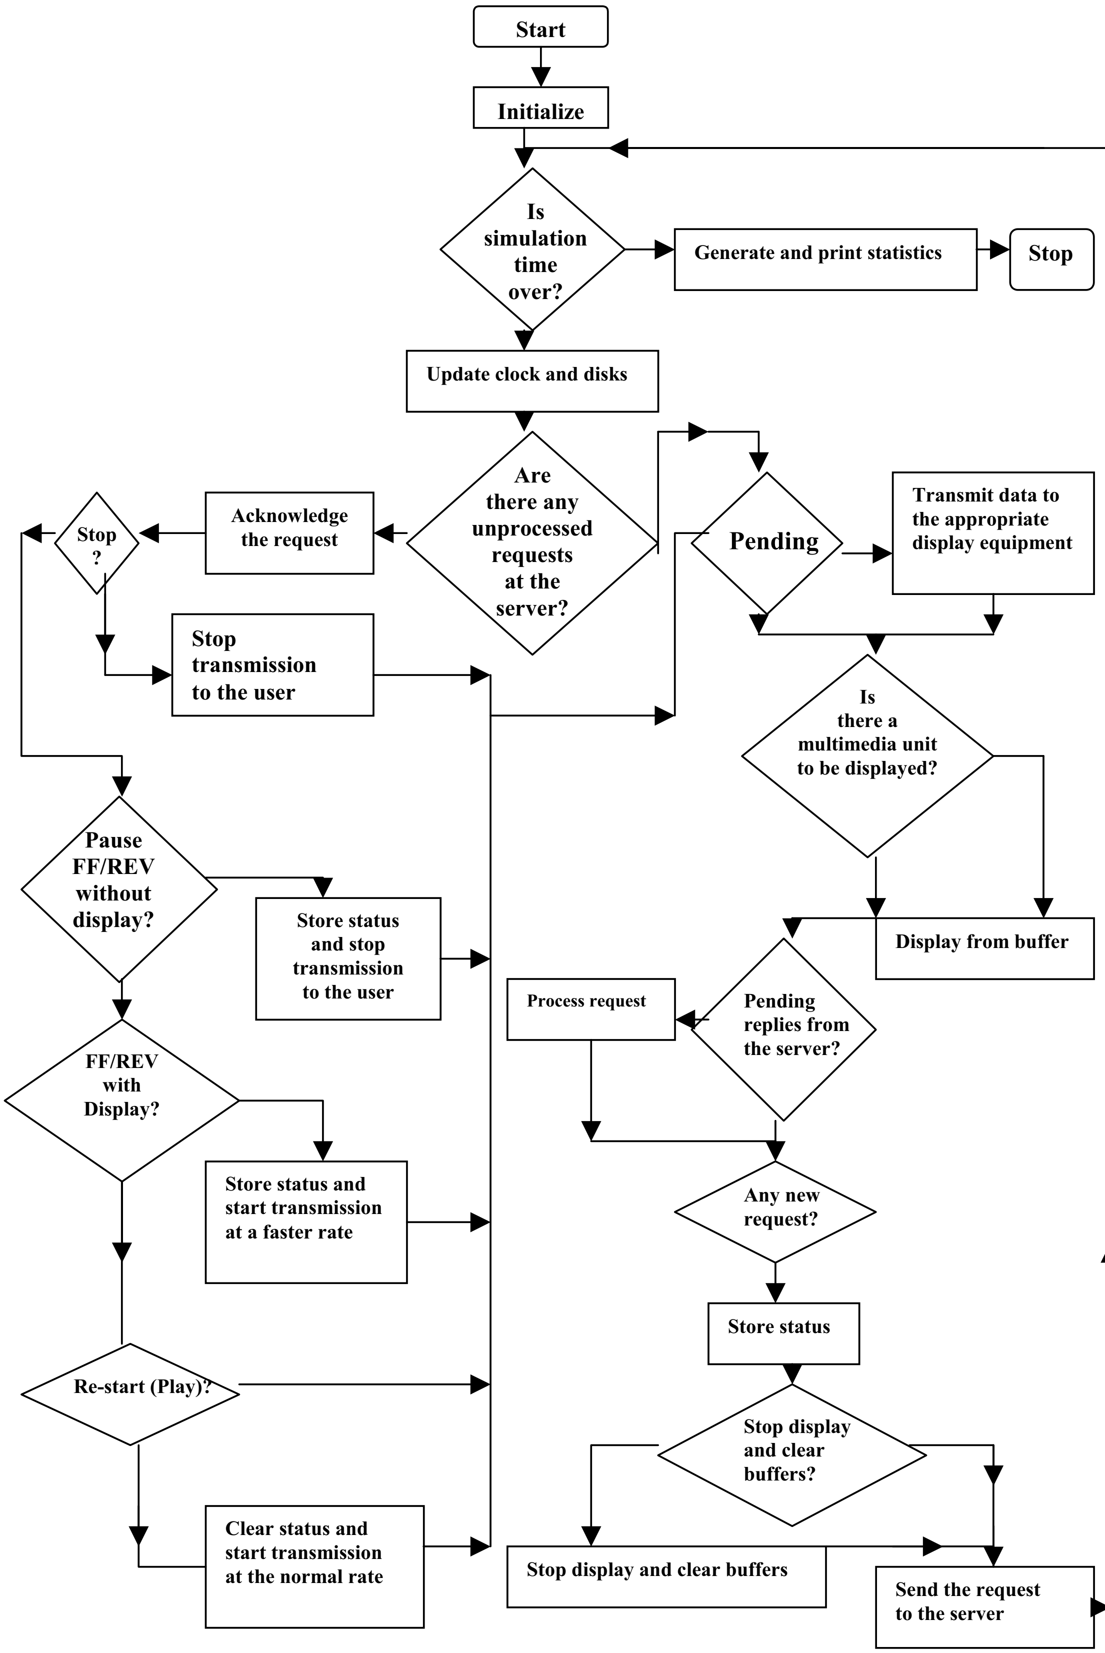


TABLE 1

Comparison of Buffer Requirement in Contiguous and Constrained Allocation Schemes

Network Delay	*Movie Time*				
	1 Min.	*2 Min.*	*3 Min.*	*4 Min.*	*5 Min.*
0.02 Sec	0 2,122	0 4,783	0 7,295	0 9,412	0 12,014
0.04 Sec.	0 4,752	0 9,612	0 14,531	0 18,952	0 23,760
0.06 Sec	0 7,231	0 13,784	0 –	0 –	1 –
0.08 Sec	0 9,412	0 18,983	0 –	0 –	1 –
0.20 Sec	0 –	0 –	0 –	1 –	1 –

each cell, the upper value is the buffer requirement for constrained allocation and the lower value is for contiguous allocation. In *Table 1*, a dash is used in place of the actual number when the number of buffers become greater than 24,000. As we can see from *Table 1*, the number of buffers required for the contiguous allocation scheme is much larger than the buffers required for constrained allocation. Also, the buffer requirement for contiguous allocation increases rapidly as the movie progresses. An increase in network delay also increases the buffer requirement. From *Table 1*, we can see that the buffer requirement for contiguous allocation, with the display of just five minutes of the movie becomes 23,760, whereas for contiguous allocation, the number of buffers required increases only to 1. Since increasing buffers increases the cost of the system, the contiguous allocation scheme is not economically feasible for any full-length movie.

Table 2 shows the variation in buffer requirement for a constrained allocation scheme with an increase in the network delay. A movie of 100 minutes in length is considered. The buffer requirement increases with an increase in the network delay.

6.2 Start-Up Delay

Figure 6 shows the start-up delay for a constrained allocation scheme. The number of users is kept constant at 100, and the number of normal disks used per movie is increased from one to five. The start-up delay is calculated for a 100-minute long movie. It can be observed from this figure that as the number of disks increases, the start-up delay decreases. The decrease in start-up delay is significant when the number of disks is increased from one to two, but it becomes more gradual as the number of disks is increased. The reason for this is that according to our design, the start-up delay is inversely proportional to the number of disks. Thus, when the number of disks is increased from one to two, the start-up delay is effectively halved [5]. By considering a cost curve with this figure, the optimal number of disks required for a desired start-up delay can be found.

6.3 Delay in a Remote Control Feature (Pause/FF/REV) to Become Active

A delay is experienced before a selected remote-control feature (Pause/FF/REV) becomes active because, for some of the remote-control features (features with display), the provision of multimedia units to the display equipment from a special disk is required [5]. This involves locating an appro-

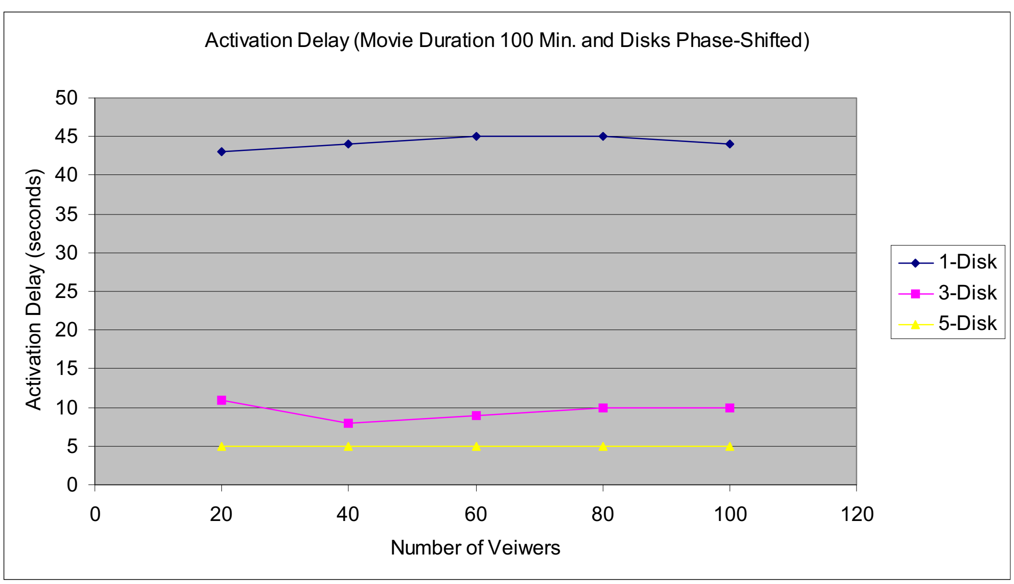
priate special disk and finding the desired multimedia unit. This activation delay is inversely proportional to the number of special disks. *Figure 7* illustrates the activation delay for a constrained layout scheme. The inverse relationship between the activation delay and the number of special disks is also illustrated in this figure by varying the number of special disks from one to five.

7. Conclusions

In this paper, an object-oriented generalized simulation model is developed for multimedia-on-demand systems. This generalized model can be easily extended to simulate various services such as movie-on-demand, interactive network games, remote browsing, multimedia library access,

FIGURE 7



and remote education. Different algorithms for implementing these services can be compared using the simulation model. One of these studies is conducted in this paper, where two disk layout schemes (continuous and constrained) are compared. The comparison is based on buffer requirements for each approach. It can be observed that constrained allocation provides better results than continuous allocation. In addition, the delays for constrained allocation are also reported.

Exploring the Role of Ethernet-Based Technologies in the Metro/Access Network

Ron Landi
Senior Engineer, Network Architecture and Advanced Technology
WorldCom

1. Introduction

This paper explores the role of Ethernet-based technologies in the access and metropolitan networks. There are many changes occurring in the carrier access and metro space making Ethernet-based solutions an appealing and potentially viable alternative to traditional networking technologies. It is important for carriers to understand how access is changing: the transition from narrowband to broadband applications, the increasing move from traditional voice to data and media-centric applications, and the emergence of new technologies focusing on the access and metro environments. There are many new applications and communications services enabled by these changes. Examples are e-commerce, Web hosting, bundled voice and data, mobile data, content/media management, bandwidth-on-demand capabilities, and cell- or packet-based voice applications (e.g., voice over Internet protocol [VoIP]). Many telecom industry forecasts and predictions suggest that Internet (IP) and data traffic will continue to grow significantly over the near- and mid-term periods—with data becoming the dominant type of traffic carried over the carrier networks. Newly emerging legacy-free carriers are already building high-speed optical networks using Internet protocol (IP)–based protocols, while existing carriers are exploring these technologies and beginning to transition their legacy networks. This paper explores the fundamental differences and drivers impacting the network architecture, technology, and costs of Ethernet-based networks as compared to traditional networks.

2. Traditional Verses Ethernet-Based Networks

2.1. Traditional Networks

Today's carriers primarily leverage time division multiplexing (TDM) and asynchronous transfer mode (ATM) technologies to transport voice and data across customer sites in the access and metro networks. The following are some network considerations of these traditional networks:

- They place costs in the International Organization for Standardization (ISO)/Open Systems Interconnection (OSI) network model layers 1 (physical) and 2 (data-link) for service control and network intelligence
- These networks provide carrier-level quality of service (QoS)
- They provide the highest levels of network reliability (i.e., five nines)
- These networks scale as the customer base grows
- These networks have proven network performance, security, and control capabilities

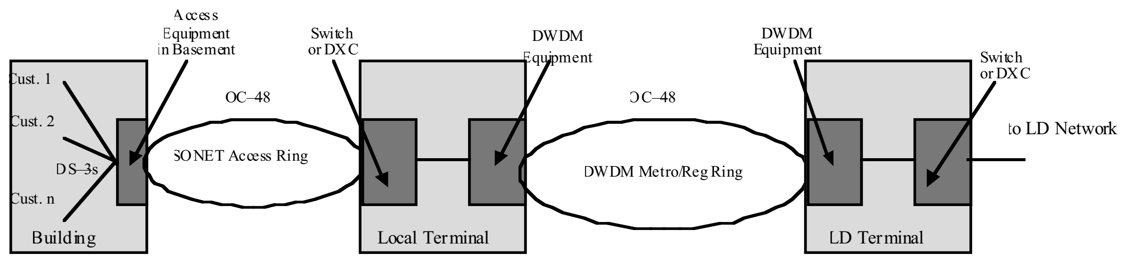
Figure 1 provides a general view of the traditional network. The building houses multiple customers who are served by the carrier. Connecting the building to the carrier network is an access ring—this could be a synchronous optical network (SONET) ring or an asynchronous transfer mode (ATM) data ring. The access ring terminates into the building via access equipment that may be located in the building basement or service-provider point of presence (POP). The access equipment terminates an optical signal, converts to electrical signals, and demultiplexes the channels into digital signal (DS)–3s. The DS–3s are provided, via in building wiring, to each of the customer locations in the building. The DS–3s may be channelized time division multiplexing (TDM) or concatenated ATM transport circuits terminating to customer equipment. The local terminal is an aggregation point in the carrier metro network. Multiple buildings and access rings will terminate into this location. The local terminal aggregates, multiplexes, and switches traffic; in addition, it transits traffic to the long-distance (LD) terminal via wavelengths across the metro/regional ring. The LD terminal provides additional aggregation, multiplexing, and switching functions, in addition to handing off traffic to the long-distance/backbone network.

2.2. Ethernet-Based Networks

During the past one to two years, legacy-free carriers have been entering the access/metro market space. These legacy-

FIGURE 1

Today's Metro TDM/ATM Networks



free carriers are deploying Ethernet-based technologies to transport traffic across customer sites in the access and metro networks. These carriers and some large enterprise companies are expanding their local-area networks (LANs) into the access and metropolitan networks. Ethernet is a physical-layer LAN technology and the de facto protocol for IP traffic—speed, cost, and ease of implementation have driven its popularity as a LAN technology in the enterprise market, and it is beginning to take hold in metropolitan-area networks (MANs). The Institute of Electrical and Electronics Engineers (IEEE) LAN standard has been around since 1980, and it is one of the IEEE 802 LAN standards impacting layers 1 and 2 of the ISO/OSI network model. *Figure 2* shows a portion of the ISO/OSI model stack and where Ethernet resides. The following are some network considerations:

- Ethernet takes costs out of the ISO/OSI network model layer 2 (data-link) and relies on layers 3 (network) and above (transport, session) for control and intelligence.
- Shared Ethernet lacks carrier-level QoS and provides "best efforts" and tiered services.
- Ethernet makes "plug and play" of networking equipment a reality but addresses only IP data.
- More than 90 percent of data originates on Ethernet framing.
- Ethernet is expected to grow at approximately the IP growth rate, forecasted at 50 to 100 percent per annum, but Ethernet growth will be limited by access to and availability of fiber in the access and metropolitan networks.
- Ethernet networks have some cost advantages, such as local-exchange carrier (LEC) bypass by moving customers on-net, lower-cost equipment and ports, and potentially lower operating costs to support a less complex network.
- Ethernet has potential for greater efficiencies in networks carrying IP traffic.

Figure 3 provides a general view of the Ethernet-based network. The building houses multiple customers who are served by the carrier. Connecting the building to the carrier network is a dark fiber access ring. The access ring terminates into the building via a Layer-2/3 Ethernet switch that may be located in the building basement or service-provider POP. The Ethernet switch terminates Gigabit Ethernet (GbE) signals transported over fiber. The Layer-2/3 Ethernet switch demultiplexes the GbE signal into 100 Mbps signals, providing 100 Mbps Ethernet connections to the customer routers. The local terminal is an aggregation point in the carrier metro network. Multiple buildings and access rings will terminate into this location. The local terminal aggregates, multiplexes, and switches traffic via another larger Ethernet switch. In addition, it transits traffic to the LD terminal via GbE over fiber across the metro/regional ring. The LD terminal provides additional aggregation, multiplexing, and switching functions in addition to handing off traffic to the long-distance/backbone network.

Ethernet is being deployed today to provide Internet access and point-to-point LAN connections. In the future, it will support multipoint transport between multiple sites. Ethernet alternatives today include the following:

- 10BaseT/100BaseT for enterprise networks. These networks leverage established and widely used LAN tech-

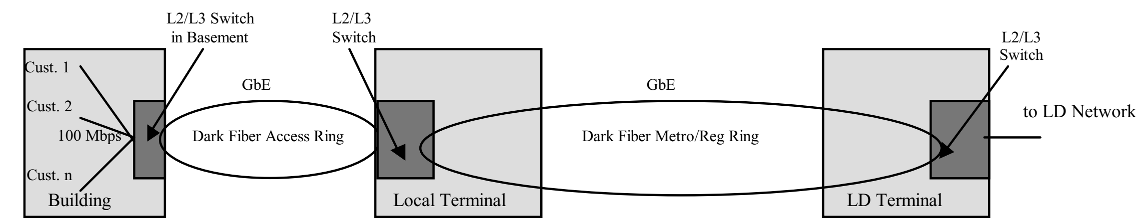
FIGURE 3

Ethernet Networks



nologies. They offer potentially cheaper point-to-point access and aggregation in the access/metro network.

- Gigabit Ethernet: Ethernet carried over optics, such as SONET or dark fiber rings. These networks are designed for interoffice links and high-speed LANs, extending the LAN into the MAN.

Ethernet alternatives in the future include the following:

- 10 Gigabit Ethernet: Ethernet over SONET Lite. 10 Gigabit Ethernet is an evolving solution for metro and core (or backbone) transport. The standards are being developed at this time, with the first switch ports due out by the vendors in 2002. This Ethernet solution should provide scalable IP over Ethernet over SONET transport, enable improvements in transport of IP data traffic, and enable improved efficiencies in the regional and core networks through flow-control capabilities.

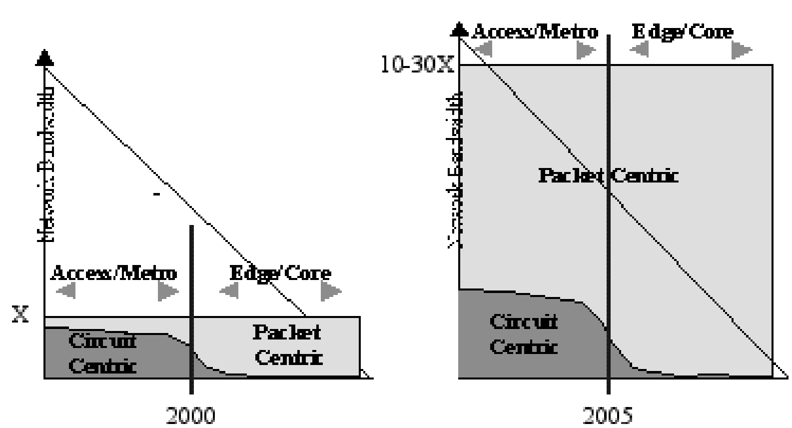
3. Ethernet/GbE Market Size and Potential

The U.S. market for Ethernet-based services is potentially very large. The total U.S. interconnect market size in 2000 was estimated at about $38 billion—this includes all LAN private lines, frame relay, and ATM. The total U.S. interconnect market size is forecasted to grow to more than $100 billion by 2005. In 2005, a reasonable portion of this interconnect will be via Ethernet-based transport—the market addressable via Ethernet is estimated at more than $20 billion in 2005. The build-out and availability of fiber in the access and metro networks is a key factor limiting this estimate. Gigabit Ethernet services, including Internet service provider (ISP) access and the U.S. interconnect market, is estimated at more than $2 billion in 2000 and is projected to grow to $10 billion by 2005. Packet solutions, such as Ethernet, will enable growth in the access and metropolitan networks. As depicted in *Figure 4*, in 2000, circuit-centric technologies dominate the access network and packet-centric technologies dominate the edge/core networks. In 2005, as applications and new services drive up the demand for bandwidth across the network, it is anticipated that packet-centric technologies will be dominant across the network—in the access, metro, edge, and core networks.

4. Players in the Ethernet/GbE Space

There are a number of emerging service providers that are focusing on Ethernet-based networking, specifically in access and metro city networks. Existing network infrastructure and voice-centric equipment do not encumber these legacy-free carriers. They are leasing facilities and dark fiber, deploying Ethernet equipment, and targeting

FIGURE 4



specific local markets offering data services. These new legacy-free carriers have the following characteristics:

- They are small networks serving hundreds of customers.
- Most are leasing dark fibers in MANs.
- Most are outsourcing the long-haul transport via traditional (SONET) solutions.
- They are offering data services, such as high-speed Internet access, point-to-point dedicated, and best-effort shared services.
- Gigabit Ethernet does not scale presently—limiting metro network capacity and making monitoring/supporting these new data networks difficult for the legacy free carriers.
- Significant growth will be enabled by 10 Gigabit Ethernet and network (ISO/OSI model layer 3) improvements. This will extend the carrier Ethernet-based network to the regional and core networks—in the future.

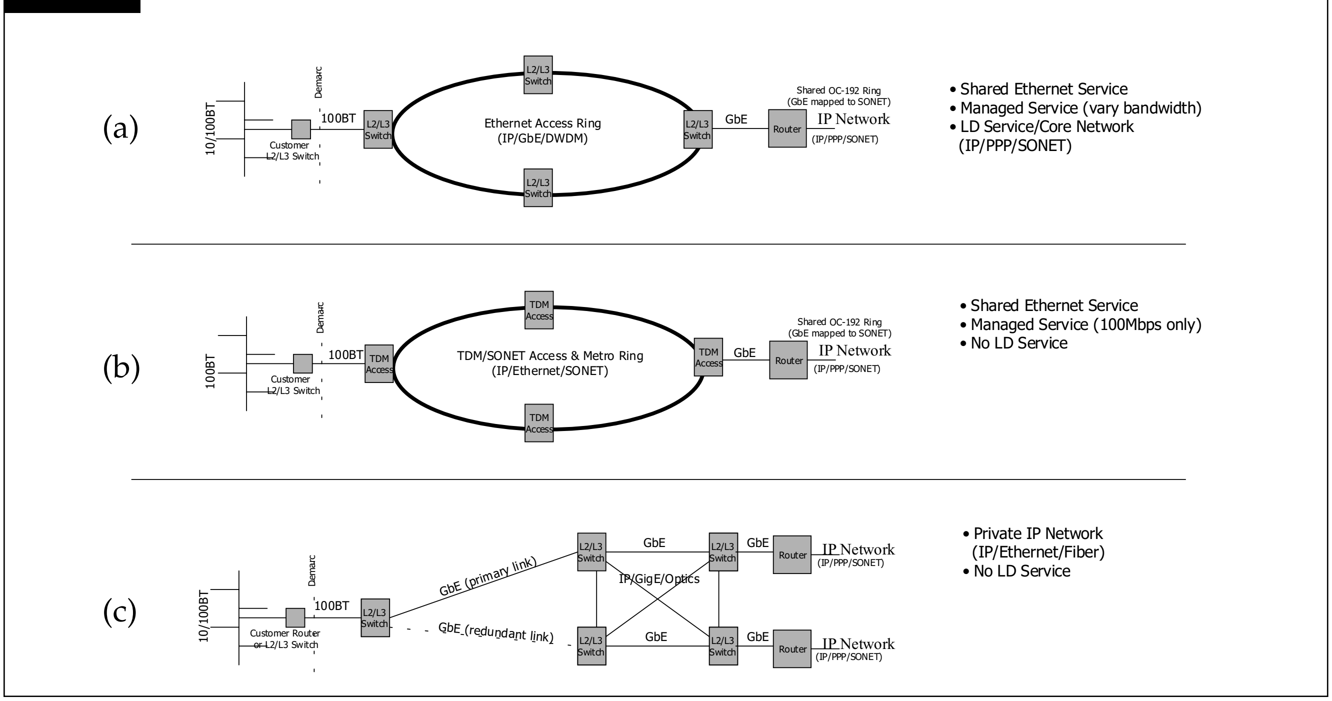
Figures 5a through *5c* depict the basic network deployments of these new legacy-free carriers. *Figure 5a* shows a topology that supports a shared Ethernet service. This network interconnects Ethernet Layer-2/3 switches that provide 100BaseT Ethernet interfaces to the customer routers. These switches can do traffic policing, rate limiting, and shaping, allowing the service provider to provide a managed service with varying bandwidth. The customer is provisioned a physical port interface and could be sold committed and burstable bandwidth. The Ethernet frames are aggregated at the edge and transported as GbE over dark fiber or optical (e.g., dense wavelength division multiplexing [DWDM]) rings to a router that connects to private and public Internet networks. *Figure 5b* also shows a shared Ethernet topology that maps Ethernet frames into SONET/TDM payloads. This network interconnects SONET add/drop multiplexers (ADMs) that provide 100BaseT Ethernet interfaces to the customer routers. The service provider provides a managed service with a fixed amount of bandwidth delivered to the customer. The customer is provisioned a physical port interface and sold committed bandwidth. The Ethernet frames are aggregated at the edge, mapped to SONET payloads, and transported across the metro network over a SONET ring to a router that connects to private and public Internet networks. *Figure 5c* shows a dedicated Ethernet service using a meshed network topology. This network interconnects Ethernet Layer-2/3 switches that provide 100BaseT Ethernet interfaces to the customer routers. These switches can do traffic policing, rate limiting, and shaping, allowing the service provider to provide a managed service with varying bandwidth. The Ethernet frames are aggregated at the edge and transported as GbE over dark fiber or optical (e.g., DWDM) connections to routers that connects to private and public Internet networks. This network alternative provides an additional physical path, from the customer site to the carrier network, for redundancy and restoration requirements.

5. *Ethernet Networking Options*

The basic Ethernet networking options presently being explored by carriers include the following:

- Ethernet private lines supporting IP over Ethernet over SONET (refer to *Figure 6*). This network configuration provides dedicated capacity and private line (Ethernet frames mapped to SONET payloads) services.
- Shared Ethernet networking supporting IP over Ethernet over SONET (refer to *Figure 7*). This network configuration provides shared capacity, shared

FIGURE 5



Ethernet over SONET, with full bandwidth available to all customers (i.e., best-effort service).

- Shared Ethernet networking over fiber supporting IP over Ethernet over fiber (refer to *Figure 8*). This network configuration provides shared capacity and full bandwidth available to all customers (i.e., best-effort service). It also introduces potential network operational issues involving the scaling/growing of customers on network and fiber management.

These networks support the following services: high-speed Internet access (IP), shared and dedicated point-to-point services, and shared and dedicated multipoint services. The point-to-point and multipoint services support private corporate/enterprise LANs and metro access networks, with secured interconnections to external and public networks.

Figure 6 shows a network topology supporting dedicated Ethernet services. This network leverages existing access and metro network rings, digital cross-connect (DXC)ing equipment, and metro DWDM transport equipment. A new access platform or native Ethernet interfaces on existing SONET ADM platforms are deployed at the customer location or POP site. These platforms terminate the fiber rings into the POP site, perform SONET payload and Ethernet frame mapping functions, and may perform limited multiplexing functions. In this example, multiple customers are provided 100 Mbps dedicated connections to routers or small Ethernet switches. The customer traffic is mapped to specific TDM time slots and transported across the SONET network—the customer traffic is segregated from other traffic and maintains private-line characteristics. The incentive for this type of deployment is a less-expensive private-line alternative service that is easy to implement and requires minimal operational systems modifications. *Figure 7* shows a network topology supporting shared Ethernet services. This network transports Ethernet transported as point-to-point protocol (PPP) over SONET. This network uses Layer-2/3 Ethernet switches at the POP sites to provide Ethernet traffic policing, rate limiting, and shaping capabilities. The customers are provided 100 Mbps Ethernet interfaces that connect to their routers or smaller Ethernet switches. They may be sold a committed amount of bandwidth with a burstable level—the level of bursting will vary based upon the customer's actual usage, contention with other customers in a given time period, oversubscription factors applied to the noncommitted bandwidth, and provisioned trunked capacity. This network relies on larger Layer-2/3 switches in the carrier network to effectively aggregate, groom, and multiplex traffic for more efficient transport. *Figure 8* also depicts a network topology supporting shared Ethernet services. This network transports Ethernet transported as PPP over dark fiber. This alternative, while potentially cheaper than SONET transport, may yield operational issues regarding scaling (growing/expanding) the network and management of the physical fiber infrastructure.

6. Cost Comparisons of Networking Alternatives

This section and the next section discuss the Ethernet networking costs as compared to traditional data-networking alternatives. A baseline model, IP over TDM over SONET, serves as a comparator to the other network options. The building or POP houses the customers. The access ring, between the building and local terminal, drops an OC–48 of capacity to the building where it is terminated via SONET ADM and associated equipment. The access ring is one fiber pair using 1310 nm wideband optics. The OC–48 ports on the broadband DXC (BBDXC), and SONET ADM are protected. At the building ADM, the OC–48 is converted to electrical signals and demultiplexed to a DS–3 level. Each of the 48 customers in the building receives a DS–3 to his or her customer router equipment. The customer router converts the DS–3 and distributes up to twenty 10BaseT and 100BaseT interfaces to the customer personal computers (PCs) and other Ethernet-based appliances. All OC–48 and DS–3 interfaces are TDM. This baseline model assumes only data services are delivered to the customer. *Figure 9* depicts the baseline network model.

FIGURE 6

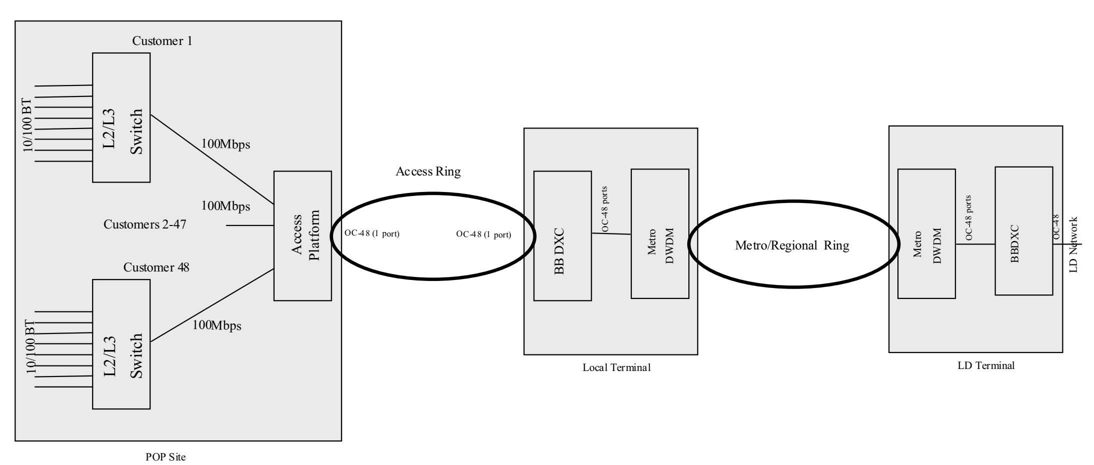


FIGURE 7

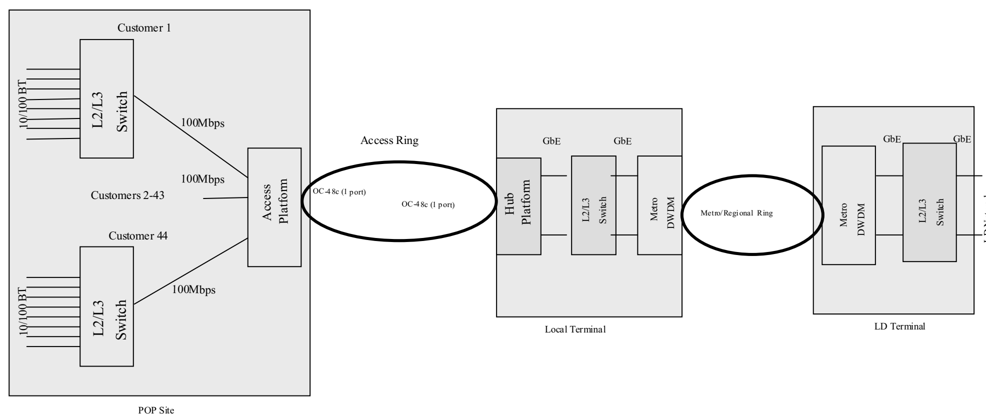

FIGURE 8

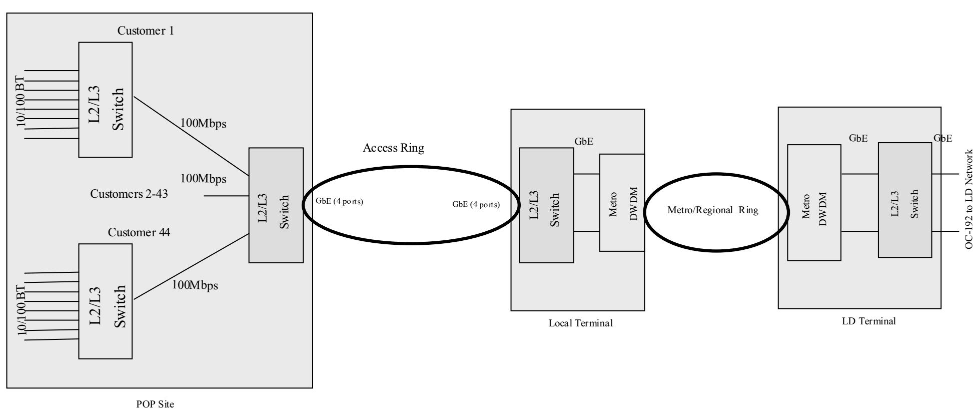
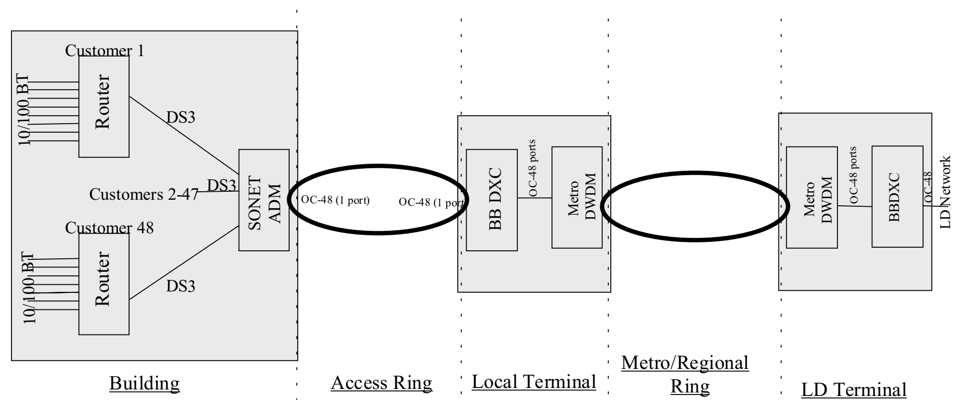


7. *Ethernet/GbE Considerations and Economic Drivers*

A high-level comparison of network capital costs for transporting IP traffic across various networks is included in *Figure 10*. The IP/TDM/SONET model is the baseline model used by many of the legacy carriers today. This model transports IP (layer 3) over PPP (layer 2) over SONET (layer 1) transport—the SONET could be carried over fiber or WDM (layer 0). This model provides TDM or other channelized interfaces to the customer. This model is compared with four other network models. The first model is IP/ATM/SONET, with ATM as the layer-2 technology. ATM is a connect-oriented protocol that provides QoS, flexibility, and supports voice, data, and video services. This model is approximately 46 percent higher in network capital costs than the baseline model (IP/TDM/SONET)—higher costs result from network equipment and interfaces. The second model is Ethernet private line. This model maps Ethernet frames to SONET payloads, with the customer traffic assigned to specific time division slots. The model is similar to the baseline model, except that the customer is provided with a native Ethernet interface (e.g., 10BaseT, 10/100BaseT, GbE). This model is approximately 32 percent less than the baseline model—lower costs result from cheaper customer interfaces. The third model is shared Ethernet over SONET. This model uses Ethernet Layer-2/3 switches to provide switched services. These platforms also provide policing, rate limiting, and shaping of traffic at the POP site. Customers are allowed to burst beyond a committed information rate and share the trunk/network capacity. This model is approximately 41 percent cheaper than the baseline model—lower costs result from lower network and customer equipment costs. The fourth model is shared Ethernet over dark fiber. This model is similar to the third model, except that the Ethernet traffic is transported directly over dark fiber, without Layer-1 SONET. This model is approximately 49 percent cheaper than the baseline model. Some key assumptions of the models include that the carrier builds fiber plant (access and metro/regional rings); no statistical multiplexing gain is applied to cell- and packet-based alternatives; the carrier uses WDM in metro/regional transport rings; and equipment list prices and most recent equipment types are used.

Depending on the volume, nature (voice, data), type of services supported, and customer requirements (e.g., service-level agreements [SLAs]), it is possible to lower the costs in the IP/ATM/SONET and shared Ethernet models. This

FIGURE 9

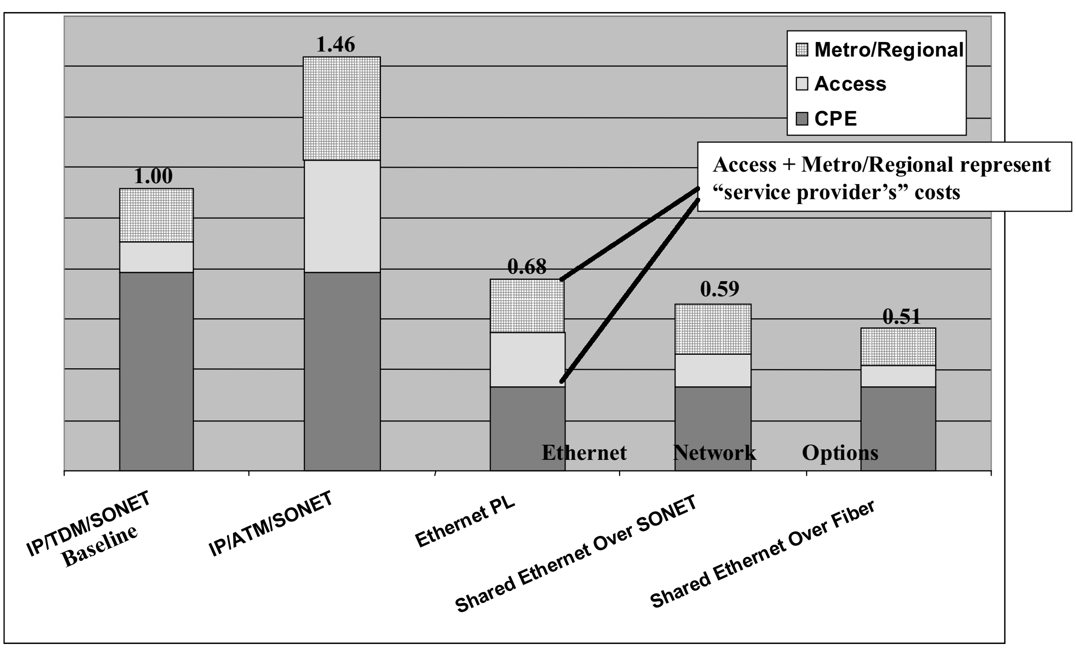


could be realized by applying statistical multiplexing to the shared trunk/network capacity. An over-subscription of 2:1 or 4:1, depending upon the services offered and the customer's requirements, would reduce the network costs. There would be transport savings in addition to DXC and switch port savings.

Some of the reasons for cost differences between the models include the following:

- Shared lines translate to shared costs and less idle bandwidth compared with dedicated transport services.
- TDM private lines
- Ethernet network is seamless and requires no protocol conversion—translating into simpler and less equipment.
- Ethernet equipment is designed for "best-effort" services and is less costly than telco (carrier class) reliable equipment.
- Potentially lower operational costs, dependent upon deployment and legacy infrastructure, may be realized by the carrier—such as the following:
  - WAN verses LAN (cheaper) technical labor and support
  - Faster provisioning of additional bandwidth to existing customers
  - Simpler network monitoring and performance
  - Integrated and simpler back-office systems
- Incremental pricing is possible with Ethernet and Gigabit Ethernet transport services, resulting in finer granularity of bandwidth to be sold to customers by the service provider. Examples include the following:

FIGURE 10



- 10 Mbps Ethernet interface (bandwidth sold in 1 Mbps increments)
- 100 Mbps (fast) Ethernet (bandwidth sold in 5 Mbps increments)

8. Technology Comparisons of Networking Alternatives

In comparing traditional networks, such as TDM and ATM, to Ethernet-based networks, it is important to consider a number of factors. The following outlines some of the basic trade-offs of the different technology choices:

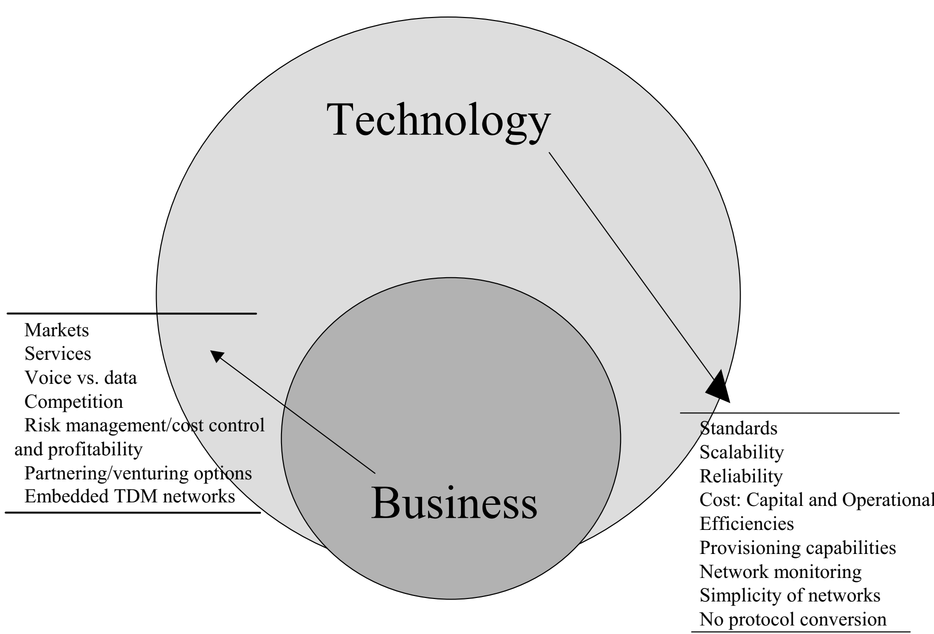
- *Pros of Traditional (TDM, ATM) Networks*:
  - Carrier-level QoS
  - Five-nines reliability
  - Technology platform scales as network (customer base) grows
  - SONET performance, security, and control
  - Supports legacy (high-margin) services
- *Cons of Traditional (TDM, ATM) Networks*:
  - High-cost customer equipment
  - Complex network management
  - Difficult and time-consuming to provision incremental bandwidth and new services
  - Not IP (data) efficient
  - Difficulty in supporting forecasted high growth of IP traffic
- *Pros of Ethernet-Based Networks*:
  - Cheap customer ports/interfaces
  - Reduced customer-premises equipment (CPE)
  - Potentially lower operational costs
  - Increased bandwidth control and efficiencies
  - Supports faster provisioning of new services and bandwidth
- *Cons of Ethernet-Based Networks*:
  - Provides enterprise, not carrier-level, QoS
  - Provides three-nines reliability
  - There are no line-, path-, and section-monitoring capabilities
  - Supports IP only services
  - Requires fiber access
  - Ethernet-based standards are evolving
  - There is an embedded base of legacy/TDM network infrastructure

Some advantages of Ethernet-based networks over SONET and ATM networks include the following:

- *Flexibility:* Ethernet can be purchased in small increments rather than large chunks of bandwidth
- *Provisioning:* Bandwidth provisioning can be done in hours, not days or weeks. Web-enabled capabilities allow the customer to change bandwidth as application needs change
- *Cost:* Less equipment and lower operational costs mean that Ethernet-based networks can be priced at less than SONET and TDM
- *Efficiency for Data:* Ethernet was designed for data transmission, requiring no protocol conversion for traffic that is increasingly data-centric

Figure 11 illustrates the inter-relations between technology and business issues regarding Ethernet-based technologies and networks. There are a number of technology issues, including standards, costs, network simplicity, network efficiencies, scalability, and reliability. There are a number of business issues to be considered. These issues include markets to be served by Ethernet-based technologies, services supported (e.g., voice, data, video), competitive factors relating to newly emerging legacy-free carriers and existing service providers, service-provider partnering and joint-

FIGURE 11



venture opportunities, and the legacy carriers' existing TDM/ATM–based networks—how is Ethernet migrated into the existing network? The carrier must carefully consider and weigh the technology and business issues in making the decision to proceed with Ethernet-based technologies and networks. For the legacy carrier, this decision can be more complex—balancing existing infrastructure investments and customers against new investments, capabilities, and services.

9. Summary and Conclusions

Much of the industry and market hype during the past year or so regarding Ethernet-based network costs is false. Ethernet-based networks are not 1/10 to 1/15 the cost of traditional networks. The capital cost for Ethernet-based networks is approximately 50 to 60 percent less than traditional networks. Other realities of Ethernet-based networks include the following: fiber access makes Ethernet-based network deployments capital intensive; Ethernet is IP–centric and not integrated with legacy services; Ethernet networks don't scale today; and Ethernet QoS levels need improvement to be viable for large national and global carriers. Ethernet-based technologies will grow in number of deployments, breadth of network (moving from the LAN to the MAN to the WAN), and number of customers served. This growth is already happening and will continue to be fueled by the following developments:

- Growth of Ethernet will be proportional to growth of IP traffic and related applications.
- Operations support systems (OSS) and service provisioning/delivery will likely be simpler, yielding lower operating costs.
- Cheaper delivered bandwidth cost (Ethernet is 1/3 to 1/2 the cost of traditional networks) and lower operating costs could make this cost difference/savings even more substantial.
- IEEE standards are evolving that will support large networks and their need to scale:
  - 10 Ggabit Ethernet
  - Resilient packet ring (RPR)
  - Standardized methods to map Ethernet frames to SONET payloads (e.g., X.86, generic-framing protocol)

Ethernet-based technologies are making their debut in the access and metro networks today. As this technology alternative matures and its standards evolve, Ethernet-based technologies should begin to take center stage in the near- to mid-term future.

The MxU Market: Reaching over Current Networks Limitations

Haim Laufer
Vice President, Marketing
Infineon Technologies

Introduction

The demand for added-value broadband services to the home and office is still on the rise despite the recent setback in the telecommunications market and world economy. Increasing Internet penetration into daily activities and the growing need for bandwidth in homes and businesses is prompting service providers to implement broadband access solutions.

Driven by competition for the service and application dollar, incumbent local-exchange carriers (ILECs), competitive local-exchange carriers (CLECs), cable and satellite companies, interexchange carriers (IXCs), and Internet service providers (ISPs) are searching for new technologies that are able to deliver very high bandwidths in a cost-efficient manner. Targeting clustered environments, such as the multitenant/multidwelling unit (MxU) market, and especially those that can be approached as a group (hotels or office buildings), offer attractive business opportunities where the penetration costs required are justified by the potential revenues from services. Broadband access options to the building include fiber optics, broadband wireless (local multipoint distribution system [LMDS]), cable television, or satellite. From this point of building entry, broadband services must be distributed inside the building. Since the basic services to be offered are Ethernet-based, an Ethernet network inside the building becomes the most natural and cost-effective solution.

The MxU Market

A large potential market for MxU installations is in office buildings. Since businesses tend to send as much data as they receive, they need symmetric broadband access for the office local-area network (LAN) environment as well as to connect to the outside world. Residential users, on the other hand, demand entertainment services such as gaming and video. These types of services require very high bandwidths, mostly asymmetric, although services requiring a more symmetric solution—such as music or video-files sharing, photo albums, home networking, etc.—will also make their entry into the residential MxU sector in the future.

Another rewarding MxU segment is the hospitality market. Hotels and lodging facilities have to cost-effectively supply what today's business traveler needs. This goes beyond "bed and breakfast" and extends all the way to the Internet and global communications. Although the wiring infrastructure is already in place, it is not designed to support a LAN to the guest rooms. Therefore, the proprietors must use a solution based on LAN technology with as little trade-off for bandwidth and functionality as possible with the fastest installation, yet avoiding the costly change of their wiring, and with minimum disruption to the normal hotel operation.

Figure 1 shows the anticipated revenues from MxU hardware and services.

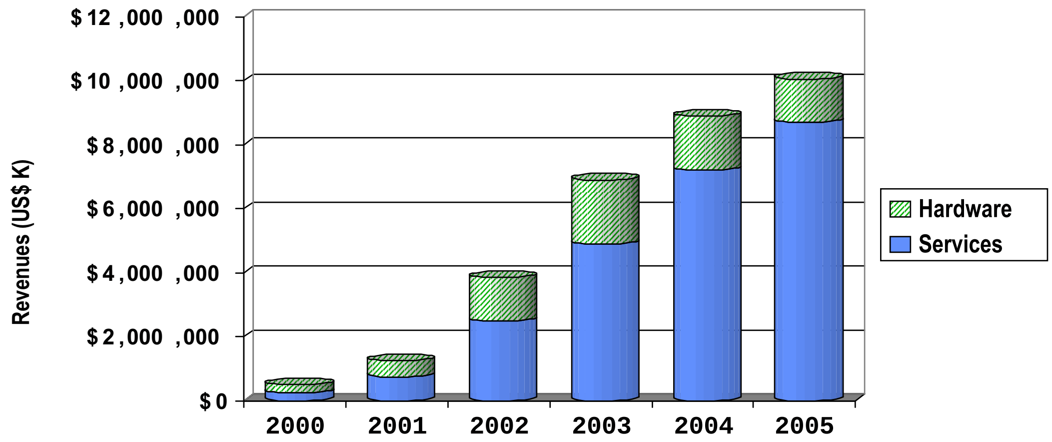
Ethernet In-Building Network Solution

Deploying a standard Ethernet network inside the building seems straightforward. Independently of the transport media used to bring the broadband pipeline to the building—fiber, broadband wireless, or satellite—the inside network will consist of a similar architecture: a 10/100BaseT port provided for each unit, whether a hotel room, apartment, or office. Due to range limitations, a hub must be installed at each floor or every two floors, and all of them should be connected to a switch installed (most probably) at the building basement. The Ethernet switch in the basement serves as an aggregator, connecting the ports to the transport line, at a few 10s of Mbps up to 1 Gbps, depending on the concentration ratio and the media used. When the services/users justify it, an in-building server may be used to reduce traffic and increase the efficiency or to provide local added-value services.

This architecture explained has its well-known advantages: It's simple, easy to install, and uncomplicated to manage. But it also carries some major disadvantages as well. In most of the cases, a Cat 5 cable infrastructure is unavailable and needs to be deployed, especially in hotels and residential buildings. In other cases, it is impossible to install new wiring due to lack of ducts or opposition from the building owners. And in others still, it is very difficult and plain costly. Installing hubs or small switches at each floor may

FIGURE 1

Anticipated Worldwide MxU Hardware and Services Revenues



Source: Cahners In-Stat Group

also be a very difficult and frequently impossible task. A locked room must be prepared for security reasons; a power plug and air conditioning are required—and these are only some the problems encountered in the set-up stage.

A Novel Proposal for MxU Network Applications

There is another possibility to enjoy the advantages of simplicity, manageability, and cost-effectiveness of the Ethernet network solution while avoiding the aforementioned disadvantages. The basic idea is to use a technology that can be implemented over the standard telephony twisted-pair available in all buildings, offering symmetric 10 Mbps over a distance of several hundreds of meters. This technology has a name—it's called 10BaseS™.

Based on very-high–data rate digital subscriber line (VDSL), Infineon Technologies' 10BaseS™ solution merges the Ethernet signal on top of the telephony signal using the latest coding and digital modulation techniques, interfacing smoothly and seamlessly with existing Ethernet solutions. 10BaseS systems take advantage of the unlimited potential of existing telephone wire infrastructure to deliver high-speed video, data, and voice services over greater distances. Combining standard Ethernet technology with the robust VDSL technology, 10BaseS™ presents the ideal solution for in-building data distribution applications.

A 10BaseS network is essentially an Ethernet network with an extended range on each 10BaseS segment. The 10BaseS ports of the 10BaseS switches in the basement of the building are connected through splitters to the telephone infrastructure. Nearly one mile away, at the end of each telephone line, another splitter in the 10BaseS customer-premises equipment (CPE) is installed to separate plain old telephone service (POTS), integrated services digital network (ISDN), or private branch exchange (PBX) digital set signals from 10BaseS signals. A standard RJ-45 jack connects one port of the modem to the user's personal computer (PC) or LAN segment. A standard RJ-11 jack connects another port on the modem to the telephone. Appropriate software on central servers provides operation and management functions that enable Internet access and handles billing. *Figure 2* shows several deployment scenarios utilizing 10BaseS technology.

Cost Effective and Revenue Generating

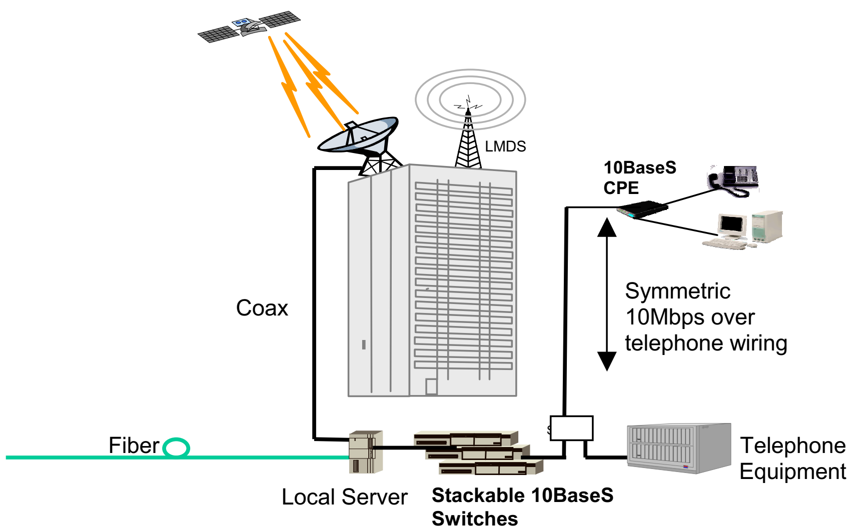
The advantage of 10BaseS is that it uses the existing telephone wire infrastructure. There is no need to rewire the facility with Ethernet grade cables, saving the cost of rewiring and the possible loss of revenue while areas are shut down for laying wires. All the equipment can be installed in the same place, locked, and protected, making the maintenance (including the installation of an uninterruptible power supply (UPS), air conditioning, etc.) easy.

Using existing telephone infrastructures, 10BaseS brings full-speed 10BaseT Ethernet to every telephone extension within a cable mile from the switch, in any facility, without interfering with any existing telephone functionality, based either in regular phone, ISDN, or digital PBX phone. Internet access can even be offered in telephone booths, executive lounges, and cafeterias. Internet access, virtual LAN connectivity with home offices, videoconferencing, locally hosted Web sites, video on demand (VOD), and other data services are all made possible once this Ethernet connectivity is available.

In addition, the residential market offers enormous business opportunities for access service providers, building owners, and ISPs. Today's residential users demand more than just raw Internet and are willing to pay for added-value entertainment services. However entertainment applications—such as interactive games, CD–quality music, and DVD–quality movies on a pay-per-use basis—require bandwidths in the range of 5 to 15 Mbps. Most of today's access systems cannot support this kind of bandwidth or are too expensive to deploy.

FIGURE 2

Broadband Access Applications Utilizing 10BaseS



10BaseS can provide each apartment in a residential building, townhouse, garden-style complex, or dormitory with symmetric 10 Mbps network connectivity. Furthermore, taking advantage of VDSL technology, a 26/3 asymmetric scheme can be achieved—more than enough for five video channels per apartment.

Other 10BaseS applications may include public centers such as airports, convention centers, or shopping malls—all generating a lot of traffic. Public-center proprietors and operators utilizing 10BaseS systems will be able to offer high-speed Internet access at every phone booth on the premises. Information kiosks and travel information can be offered through a locally hosted Web server. Offices located on premises can utilize 10BaseS for LAN applications, and security equipment, including closed-circuit surveillance cameras, can be deployed and controlled through a 10BaseS switch connected to the control station—all of this while maintaining legacy voice services unaffected.

A 10BaseS switch located in the building basement or information technology (IT) room makes every phone jack in the building Ethernet-enabled. Coexisting with telephone communications, 10BaseS offers a true broadband connection to the home enabling simultaneous video, voice, and data services over hundreds of meters of telco-grade copper wires.

Conclusion

The MxU market offers service providers a wide range of new business opportunities for distributing video, data, and voice to a large captured customer base. There are a variety of technologies used in the MxU deployments for the in-building applications—Ethernet, without a doubt, being the most popular and simple of them all. Yet Ethernet requires rewiring entire buildings with Cat 5 cables and has a distance limitation requiring the distribution of hubs throughout the building. The only way to overcome Ethernet's disadvantages and still enjoy its simplicity, cost-effectiveness, and bandwidth capacity is by combining it with a technology capable of carrying very high bit rates over greater distances. The 10BaseS™ solution, an innovative technology that offers the simplicity of Ethernet with the high performance of VDSL, does exactly that. A system built with 10BaseS technology delivers full duplex standard Ethernet and telephony service sharing the existing copper wire infrastructure, across a distance of 4,000ft (1,200m) and more. High-speed, noise-free video and data transmission running simultaneously with POTS, ISDN, or PBX signaling are made available with 10BaseS. Taking advantage of 10BaseS, service providers acquire the right set of tools for upgrading their service offerings, achieving better market penetration, and gaining the competitive edge.

How Universal Plug and Play Speeds DSL Deployment and Lowers Service-Provider Costs

Andrew Liu
Business-Development Manager and Co-Chair, Universal Plug and Play Marketing Committee
Intel Corporation

Marc Abrams
Product Manager, Residential Gateways, Residential Access Division
Intel Corporation

This paper presents recent developments in auto-configuring broadband-connected home networks. It recommends that the customer-premises equipment (CPE) vendor shoulder the responsibility for making the end-user experience invisible and automatic to speed deployment and lower costs.

Customers' Requirements

CPE vendors have two customers: digital subscriber line (DSL) service providers and end users.[1] Although DSL service providers are the center of attention for most CPE vendors, the needs of the end user must also be met for successful digital subscriber line (DSL) deployments. While DSL service providers need compatible, cost-effective CPE, physical compatibility is just the first step. The next is flexible and extensible platforms that can be customized for different usage models and can work with complex back-end infrastructures. Going to this next step can result in lower deployment costs for DSL service providers.

End users need equipment that requires no configuration. Asking them to learn to enter Internet protocol (IP) addresses and the like is not acceptable. The work done in the DSL Forum for CPE auto-configuration, such as technical requirement (TR) 37 interim local management interface (ILMI) along with dynamic host configuration protocol (DHCP) is a good first step, but not the endgame. ILMI and DHCP are only enough to provide basic Internet access, which is becoming a commodity business with low margins and high churn rates.

What's needed is a mechanism that can automatically configure more sophisticated services like virtual private networking (VPN), voice over Internet protocol (VoIP), videoconferencing, video on demand (VoD), and the like.

More importantly, there needs to be a mechanism to automatically configure the home networking adapters and personal computers (PC)—the digital home infrastructure—to support advanced services like VoIP and VPN within the home for end users. This is what universal plug and play (UPnP) can do for service providers.

As the kind and number of home-networked devices is changing and growing very rapidly, moving from just PCs to all kinds of Internet-connected devices such as phones, web tablets, and—yes—even the toaster, refrigerator, and microwave oven, a modular hardware and software architecture is advised for CPE to extend the duty cycle and reduce equipment and support costs for the service provider.

Modular Platforms

What does it mean to have such a flexible, extensible, and customizable platform? Offering a low-cost, fixed-function product can be deceptively expensive. Consider the never-ending requests for quotations (RFQ), the CPE qualification process, and even just offering a single CPE to your customers. They all tie up resources and limit the ability to differentiate services and generate new revenue opportunities. Offering multiple CPE drives vendor costs higher and increases training expenses because everyone needs to learn about more equipment. Multiple CPE also challenges the sales and logistics personnel and increases inventory liability for equipment that may not be used.

A modular platform consisting of both software and hardware can solve these problems. When adding a new feature to CPE, such as 802.11b wireless networking, one does not need to requalify the whole platform. The new feature is an add-on. And adding new software features—for example, VoIP functionality—does not require that the modem be requalified.

Having a modular platform can greatly minimize the costs of sales and support training. Service-provider personnel need only learn about the new feature, not a whole new product. And the logistics of inventory becomes less complicated because the modular platform can be used for any kind of installation that requires networking and related services.

DSL Auto-Configuration Is Not Enough
There is a very active special interest group within the DSL Forum working on CPE auto-configuration. Building on the work of TR37 (ILMI) are several new proposals for configuring more and more complex services. These include WT59, WT60, WT65, and WT77. Each builds on the next to help service providers auto-configure even the most complicated types of services and lower operations and support costs.

However valid, the DSL Forum efforts focus on service-provider issues with services configuration. According to Parks Associates Research, an end user is nine times as likely to have a home network as a non-broadband customer. What that means is that once end users get broadband, they want home networking. So how can a CPE vendor meet the no-configuration requirement for these customers if they aren't paying attention? Are vendors addressing the need at all?

CPE Pre-Configuration Is Not Enough
Currently, CPE vendors pre-configure CPE per service-provider requirements. In the cases where an end user needs to provide information to get connected to the network, CPE vendors provide wizard-driven graphical user interfaces (GUI) that direct end users to enter their IP addresses, then enter this, and then enter that.

How does a wizard-driven setup work for a PC? The modem ships with an installation CD for an end user's PC. The installation screen asks if the end user has automatic addressing (DHCP) or is an advanced user who needs some special IP addressing. By answering the questions on a single screen and pressing a few keys, the end user can complete the installation.

Many providers offer a simple setup procedure for DSL modems in which the end user goes to a Web page that the modem hosts. From there, end users take only a few steps and provide a few pieces of information. The steps and questions vary from product to product, but generally at the Start page end users click Begin and answer questions about the type of connection they have. Depending on their service providers, they may have point-to-point protocol over asynchronous transfer mode (PPPoA) or point-to-point protocol over Ethernet (PPPoE) and can have others for more complex services. Also, depending on their service they may or may not have point-to-point protocol (PPP) authentication.

The next screen, which concerns IP, may already be completed if the vendor knows the user and has preconfigured the firmware on the modem. Users who later need to change this information can do so on this screen. The final screen summarizes the modem setup—the results of completing the preceding screens. That is all end users need to do to setup their modems.

Built-in diagnostics let the end user test the modem, the DSL connection back to the digital subscriber line access multiplexer (DSLAM), and the connection to the Internet service provider (ISP). Suppose the ISP fails its test? What the end user wants to know is: "what's broken?" It is not the modem; it is not the DSLAM; it is the connection to the ISP. Debugging is the hardest and most time-consuming part of installation; this approach helps the end user quickly discover what went wrong.

Universal Plug and Play

The previous section discusses what is available to end users today. What is coming next is universal plug and play (UpnP), which should be a requirement for all future CPE from vendors because it can solve many support issues that service providers face today.

Network Address Translation
Network address translation (NAT) allows several PCs on a network to share one IP address to simplify the provisioning of services and to provide some rudimentary security services. However, NAT breaks the very applications that attract people to broadband, such as video conferencing, VoIP, multiplayer gaming, and other interactive or streaming applications. The first call that end users usually make after their broadband connection goes up is to their service providers complaining that their applications aren't working anymore.

A UPnP–enabled CPE can fix these problems. For example, with UPnP enabled on the Internet gateway, Microsoft Messenger can now configure the CPE NAT so that it listens for its calls and makes sure they are sent. An incoming call automatically gets routed to the Messenger PC. This activity is transparent to users, meaning that they do not need to configure their firewalls, open their ports, or perform other similar tasks. Also, when the application finishes, the open port automatically closes, thus reducing security risks.

Service Providers and Customer Support

UPnP will also help service providers when they want to provide new services. Customers can access, or *self-provision,* these services automatically, and they will work. Customers do not need to do anything to their PCs or networking devices to make them work with your new service. Deploying VoD or VoIP or multiplayer gaming will be much less challenging and more profitable.

UPnP also helps local-area network (LAN)–side installation by eliminating the need for software setup for applications. UPnP–enabled PCs can automatically discover and configure services deployed to the CPE without having to install software from CDs that cost money to inventory and ship and will be lost immediately by end user.

A simple example is that if the service provider changes the end user's email server address, a UPnP–enabled PC will automatically reconfigure the email application without user intervention, thus eliminating the support call that will undoubtedly follow.

Event Notification
UPnP provides event notification so that when things happen, good or bad, users can be informed. For example, suppose a wide-area network (WAN) connection goes down. Users usually call tech support and say, "I cannot connect."

Now this information can be sent to client PCs that have a CPE status display. Users will know that a WAN connection is down and being taken care of; they can also be informed of new services and asked to please call to learn more.

Service providers must imagine and plan how to implement event notification in a way that assures users that they are getting better service and have more control. Customers see service providers that notify them of problems or new services as more proactive and are less prone to switch to another carrier. When the link does go down, end users can quickly determine what the problem is. When a WAN is down, users often work through a 10-step process. They spend time and effort checking their power supplies, their cable connections, and so on. Now a user can look at the status screen. If it says the WAN connection is down, the user knows exactly where the problem is.

Event notification also makes other services in the home network easier to manage. Imagine that someone wants to disconnect their Internet connection between midnight and 7:00 am to prevent children from using it. What if another adult wanted to use the Internet during those hours? Knowing that Dad disconnected it and the LAN is not down would help that person. Notifying all PCs in the house of this event is easy, and it cures many of the headaches of managing a network.

Summary

CPE vendors can and must help ramp DSL deployment. The CPE auto-configuration efforts of the DSL Forum are a good start for WAN setup, but LAN and PC setup solutions also merit considerable attention. LAN and PC auto configuration is possible, and a standards-based solution such as UPnP does exist.

Notes

1. VPN clients are also potential customers who can benefit from UPnP, depending on their VPN software. Some VPN software that works through NAT today would not change for a UPnP Internet gateway.

Overlay Networks versus Converged Technology Platforms

Ron Longo
Vice President, Sales and Marketing
Mahi Networks, Inc.

This paper offers an in-depth comparison of overlay networks and integrated technologies, or converged technology platforms. It will draw from a number of business case studies undertaken by major carriers on the benefits of deploying converged platforms. In addition to the numerous competitive advantages that converged platforms provide, the studies demonstrate the profound capital expenditure (CAPEX) and operational expenditure (OPEX) savings that result when converged platforms are deployed in carrier networks.

Today's carriers are faced with intense scrutiny from Wall Street, along with ever-shrinking profit margins. More than ever they need technologies and business strategies that will save them dollars, bring in more income, and enhance profitability. Converged networking platforms that collapse data-communications capabilities with transport functionality meet these needs by reducing CAPEX and OPEX by orders of magnitude, supporting value-added service offerings, and enabling new, Internet protocol (IP)–based revenue models. Furthermore, converged platforms provide the added benefit of a smooth, self-paced migration path to true next-generation networking.

Historically, transport has been associated with capacity and reliability, rather than speedy provisioning. It has meant big, fat pipes, long distances, and dependable service, but certainly not dynamic switching. In fact, in the transport world, provisioning an optical carrier (OC)–3 between San Francisco and New York City can take months to complete. In contrast, data networking is all about rapid, intelligent, dynamic switching, rather than reliability. In the data world, there is not a 100 percent guarantee that a signal will get through to its destination correctly the first time. However, a person can log onto the Internet and send a packet of data from San Francisco to Budapest in a matter of seconds.

Wanting the best of the transport world and the data world, today's largest carriers are demanding converged technology. According to J.P. Morgan's Backbone! Report, the next-generation network will be a mixture of traditional transport, emerging data networks, and converged platforms—a mixture keenly designed to enable next-generation service delivery and new revenue models. The report takes care to note that during their migration to next-generation networking, carriers must not lose sight of what is "keeping the lights on"—the leased line and public switched telephone network (PSTN)–based services. Because they comprise as much as 70% of a carrier's revenue stream, these legacy services must be protected and optimized.

Securing Revenues, Growing Profits

A big challenge facing today's carriers is securing revenue while growing profits. To accomplish this, carriers must first flatten their networks. The last five years saw a huge build-out of discrete element, overlay networks. In a mad rush to win and secure customers from the growing competition that was made possible by deregulation and easily available capital, carriers of all types rapidly and perhaps unwisely "threw" equipment at their networks, building up inefficient and costly overlay structures. With the current economic downturn, these overlay networks are proving to be a dangerous drain on resources and dollars, as well as a hindrance to rapid service delivery and the deployment of new revenue-generating services. Carriers are taking a fresh look at their network architectures and are asking, "How can I optimize my existing network?" and "How can I extend its useful life while preparing my network for the coming migration to converged next-generation equipment?"

The second requirement for securing revenue and growing profits is the facilitating of new revenue models. In February 2000, carriers could charge $33,000 a month for a digital signal (DS)–3 circuit from New York to London. Twelve months later, in February 2001, the going rate was down to $12,000 a month, according to RateXchange Corporation. From a revenue-per-bit perspective, this represents a quick, tremendous decline. Clearly, carriers need a way to change this unhealthy revenue plan.

Converged technology meets carriers' needs in each of these areas. It flattens their networks while allowing them to fully leverage their installed infrastructure and extend its lifecycle. It also enables carriers to deliver advanced multimedia services and enact "revenue-per-service" or "revenue-per-value" business models.

Converged platforms also give carriers a smooth, self-paced migration path from their current infrastructures to the fully converged network architecture of tomorrow.

The Carriers' Checklist for the Next-Generation Platform

A number of common themes can be found when we analyze the requests for information (RFI) and requests for proposals (RFP) that carriers have been issuing during the past 18 months. Each of these themes point to carriers' need to drive discrete elements out of their network architectures (see *Figure 1*).

FIGURE 1

The Carriers' Checklist

RFI / RFP Requirements	Reason
Multi-Function	Flatten the network, remove elements
Multi-Protocol	Internetwork between today's and tomorrow's protocols
Terabit Scalability	Meet rising demands in the metro core
Rapid Service Activation	Faster service deployment, lower ops cost, less revenue lag
Global Platform	Meet ANSI and ETSI specs for global internetworking
Legacy Support	Full support of legacy, representing revenue majority
Non-disruptive Migration	Bridge legacy networks & Next-Gen networks, no disruption
Carrier-Class Data	Deployed in carrier networks, requires 99.999% resiliency

An examination of the RFIs and RFPs shows that carriers want multiprotocol systems capable of bringing their networks from the time division multiplexing (TDM)–based infrastructure that proliferated during the last 100 years to the IP–centric infrastructure that will be vital in the future. They want multi-terabit scalability to handle ever-increasing traffic. They want rapid service activation to secure and retain their customer base and bring revenue in-house as quickly as possible. Gone are the days when carriers can leave revenue on the table for six months or more while an OC–3 is provisioned from San Francisco to New York City. Because many of today's carriers are global by nature, they want their equipment to meet both American National Standards Institute (ANSI) and European Telecommunications Standards Institute (ETSI) specs. They need equipment that supports their current, revenue-generating legacy services. They want to provide carrier-class data services. And, they want equipment that allows them to smoothly and non-disruptively migrate from their existing infrastructure to a fully converged, next-generation architecture.

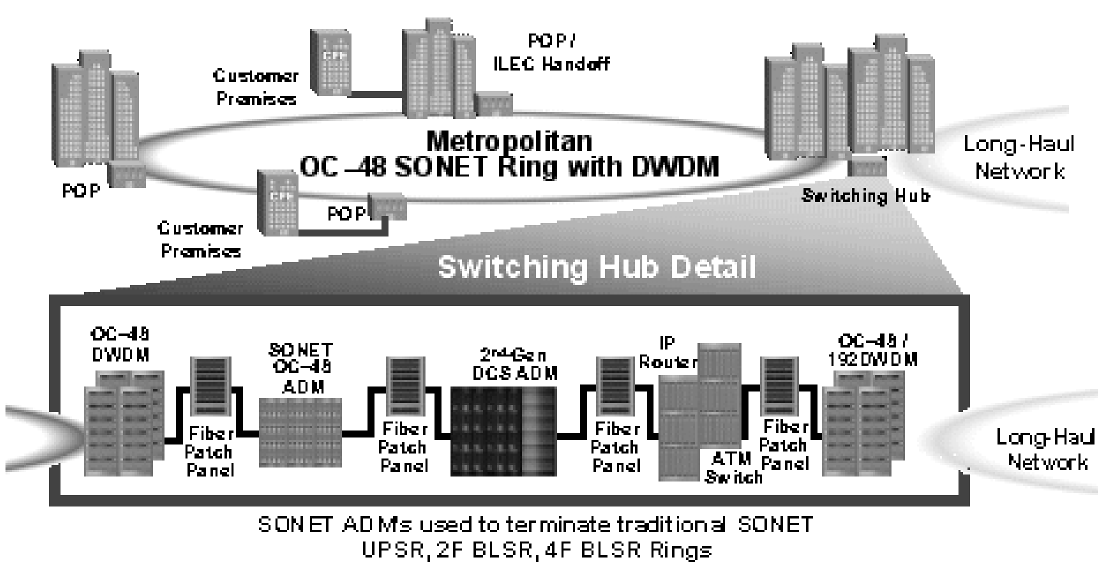
Current Architecture

Why do carriers need converged platforms? A look at the current architecture of a carrier's network provides numerous insights. Let's look at "a day in the life of an OC–48" as it travels from San Francisco to New York City (see *Figure 2*).

In a single central office (CO), the OC–48 will touch five distinct network elements (NEs), including synchronous optical network (SONET) add/drop multiplexers (ADMs), broadband digital cross-connect systems (DCSs), IP routers, asynchronous transfer mode (ATM) switches, and dense wavelength division multiplexing (DWDM) equipment. In between, the OC–48 will go through fiber-optic patch panels that are not manageable remotely. In this CO example, there are also 10 expensive, non-revenue-generating optical line interface units.

FIGURE 2

The Current Architecture



To add insult to injury, there are discreet management centers for each of these separate NEs, resulting in an incredibly complex and inherently inefficient network-management architecture to control the OC–48.

Converged Technology

With converged technology, the discreet NEs are reduced into a single platform, all managed from a unified management system. To be truly effective, converged platforms must enable "virtual separation with physical integration," which means that network operators can easily control their portion of the multiservice system via familiar interfaces. The IP manager interacts with the converged platform in the same way he or she interacts with an IP router. The broadband DCS manager interacts with the converged platform in the same way he or she has been interacting with his legacy DCS equipment. This eases the transition and lessens retraining impacts. Then, when the carrier is ready and when its business plan allows, it can smoothly migrate to a unified network operations center (NOC) for additional savings and efficiencies.

Economic Benefits

Of course, the key driver for moving to a converged platform is cost reduction—in terms of both capital and operational savings. On the far left of *Figure 5* is a depiction of a legacy network comprised of four discreet, first-generation components: a wavelength division multiplexer (WDM), an

FIGURE 3

The Current NOC Architecture

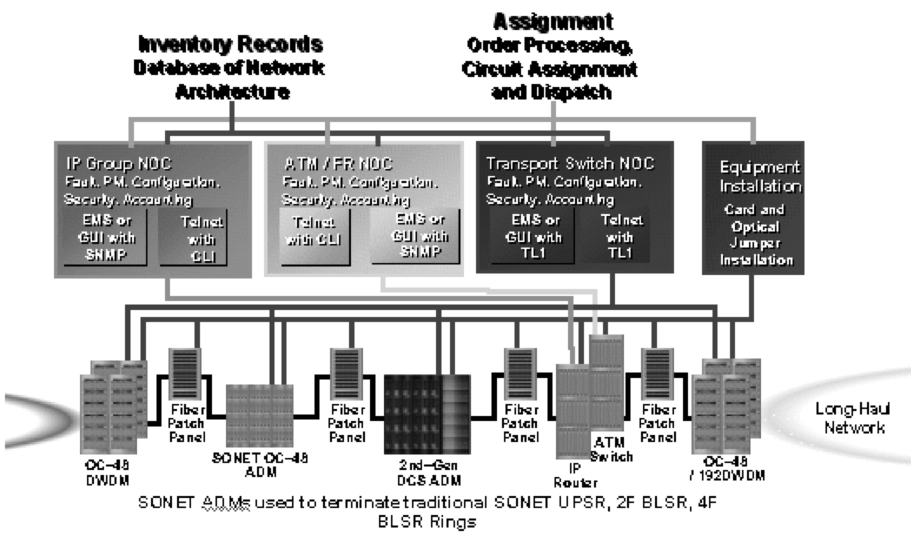


FIGURE 4

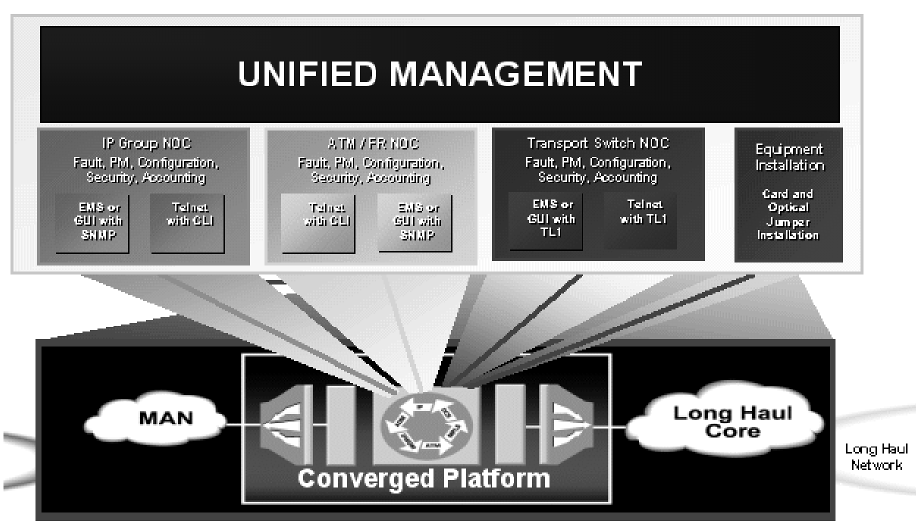
Converged Technology Platforms



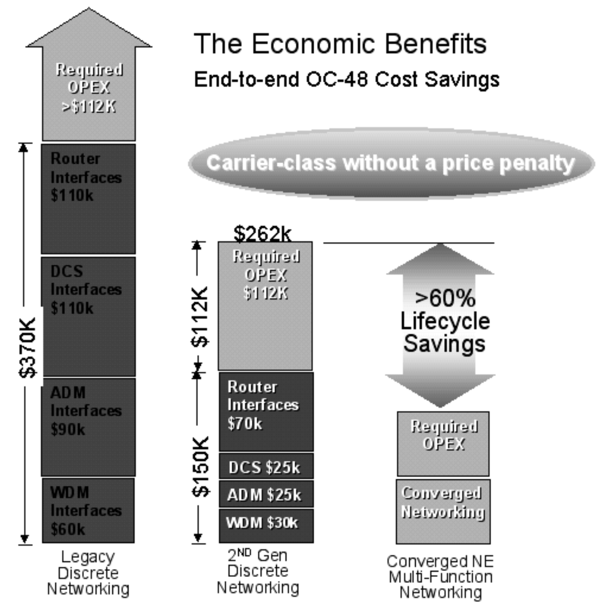
ADM, a DCS, and a router. An OC–48 going through a CO structured in this manner costs about $370,000 in CAPEX, with an additional $112,000 in OPEX.

The next column in *Figure 5* depicts the cost of the same OC–48 going through a network comprised of second-generation (2G), discrete NEs. These products take advantage of advances in application-specific integrated circuit (ASIC) technology to deliver incremental cost savings to carriers from a CAPEX perspective. However, the 2G DCS, for example, still looks like a DCS, behaves like a DCS, and is managed like a DCS. So, the network's operating expenses are not reduced, and the improvement in network functionality that they provide is only incremental.

As *Figure 5* shows, converged platforms are the breakthrough technology that deliver true, dramatic CAPEX and OPEX savings. When the network is configured through a multifunction, multiprotocol device, CAPEX savings are realized from the simple reduction in the number of elements, the reduction of physical ports from 10 to two or four, and the reduction in the number of non-revenue generating optical line interface units. OPEX savings are realized as space and power requirements are reduced, and as truck rolls are cut back. In all, numerous case studies conducted by some of the world's largest carriers have shown an average savings of more than 60% in CAPEX and OPEX through converged technology platforms.

FIGURE 5

The Economic Benefits



Conclusion

In summary, market conditions are forcing today's carriers to focus on their bottom lines and to implement more intelligent business strategies. Quite simply, today's discrete element, overlay networks are incapable of meeting the growing demands for bandwidth and next-generation services, as well as the scrutiny of today's financial markets. Converged technology platforms give carriers a "smarter" network—one that supports and maximizes existing revenue streams with zero disruption to current operations, reduces capital and operational expenditures by orders of magnitude, and provides an easy, "at-their-own-pace" migration path to a next-generation network topology capable of rapidly delivering higher margin value-added multiprotocol services.

Next-Generation Optical Metro Networks and the Global Lambda Grid

Joel Mambretti
Director, International Center for Advanced Internet Research
Northwestern University
Director
Metropolitan Research and Education Network

Introduction

Even as the digital communications industry develops new economic models in response to a more dynamic market, new opportunities are being generated by next-generation networking technology innovation, which continues to advance at an ever-faster pace. Not only are multiple next-generation Internet research and development (R&D) projects and implementations progressing quickly (MAM99), but leading-edge infrastructure architectures, technologies, and methods are also enabling powerful new applications and services, particularly those based on optical networking (STE99, RAM99). These developments are particularly observable in metro areas, as optical networking technologies traditionally used in long-haul networks migrate to regions, cities, and enterprises. Optical networks are becoming a foundation for digital communications services not possible previously, such as those based on dynamically provisioned wavelengths. This technology transition is giving rise to a more flexible transport model for networks, providing for services based on extremely high performance routers interlinked with intelligent core optical networks. This approach can support multiple new services with digital transparency. Some of these new designs are now beginning to be realized in prototype infrastructure and services, including Internet protocol (IP)–over-lightwave networks, controlled by IP signaling. Such signaling can be used not only for the dynamic provisioning of lambdas "on demand," but also for other types of rapid resource allocations. Within metro areas deploying technologies based on lambda switching, it will soon be possible to create OCX facilities as exchange points for "global lambda Grids," utilizing optical VPNs. These global Grids will become a powerful platform for multiple, innovative distributed worldwide applications.

Architectural Design

Emerging digital services and high-performance applications require significantly enhanced network architecture. Infrastructure designed to support optimally traditional services, such as circuit-switched voice communications, is being replaced by infrastructure that is optimized to support connectionless data communications—digital flows that are less predictable, characterized by bursty traffic, asymmetric streams, and multiple temporal and local variations. For example, increasing high volumes of self-similar Internet traffic, as well as a wide range of bandwidth-aggressive next-generation applications (some individually requiring 10 gigabits per second [Gbps] point-to-point bidirectionally), cannot be supported appropriately by current architectural implementations. Consequently, standards bodies are developing architecture for new, flexible, scalable, and high-performance digital communications, and these designs are beginning to be realized in prototype infrastructure and services. For example, the Internet Engineering Task Force (IETF), the Internet architecture standards organization, has a concept of a powerful, "smart" network core, while placing at the edge of the network as much complexity and intelligence as possible. In contrast, the classic telecommunication model was oriented to provisioning complexity at the core, e.g., within central offices (COs) and simple devices at the network edge.

Many current architectural initiatives are directed at removing hierarchical layers to eliminate cost and complexity and to advance the goal of providing digital services with transparency. Although today some data services are still supported by an infrastructure consisting of asynchronous transfer mode (ATM) over synchronous optical network (SONET)/synchronous digital hierarchy (SDH) over fiber, other providers have eliminated the ATM layer and in favor of packet over SONET (POS). The next step is to remove the SONET layer. Although SONET is highly reliable and provides for efficient, well-known management and traffic-engineering techniques, it is neither optimal nor cost-effective as a support foundation for digital services. Its equipment and management costs remain high and its typical deployment in two parallel bidirectional rings—one for production, the other for protection—requires 50 percent of deployed capacity to be idle. Also, it does not allow for fast deployment of new and enhanced services and capacity. To replace the reliability and restoration capabilities of SONET, a range of techniques can be used in conjunction, including implementing multiple potential paths via mesh topology and using standard and extended L3 IP techniques. Some form of framing is still required, and several potential options have been suggested for this function, such as lightweight SONET, Ethernet, and new types of protocols. At this time, Gigabit Ethernet (GbE) is a particularly popular framing techniques, driven in part by the growing demand for metro GbE services as enterprises extend local-area networks (LANs) across cities.

To a significant degree, this architecture takes advantage of the capabilities of the same dense wavelength division multiplexing (DWDM) and related technologies that have been used in long-haul networks for since the late 1980s and that have begun to be deployed in regions and metro areas. DWDM divides a beam of light into multiple "colors," lightwaves, or "lambdas," so that multiple optical signals can be transmitted through fiber in parallel—extremely high volumes of data can be communicated through each strand of optical fiber. Newer technology provides capabilities for dividing the light into many dozens of channels on each fiber length and for sending tens of gigabits or more through each channel. Single fibers are capable of transmitting extremely high volumes of data, which will lead to ubiquitous broadband and significantly lower cost for digital services. The many lightwave channels within DWDM–based networks not only provide increased capacity for high volumes of data traffic within a common physical infrastructure, but they also allow different wavelengths to be dedicated to a separate services and classes of service. Multiple types of digital communications services based on different classes can be provisioned. Designing and redesigning networks by manipulating lightpaths instead of creating and dismantling physical infrastructure allows for flexibility when creating digital communications systems. Optical networks also have a significant potential for rapid direct provisioning and redeployment of individual wavelengths and services on those wavelengths, a feature sometimes called "point-and-click provisioning."

Because these techniques can be implemented more easily in metro areas, some of the earliest deployments may be within cities, supported by a new generation of optical metro devices. Many first-generation optical metro devices were merely long-haul systems that were redeployed within cities, for example, to support transit. Newer devices are being designed specifically to meet the requirements of metro-area digital communications services. In addition, innovative tunable filters and tunable lasers are being incorporated to allow enhanced flexibility and customization. Other efforts are being directed at creating complementary metal oxide semiconductor (CMOS)–based OCXs as edge and enterprise devices. Consequently, in a number of metro areas, consideration is being given to transitioning from SONET over time and to provisioning digital services directly over fiber, creating a new type of optical network—one that is less oriented to point-to-point implementations and more to the dynamic provisioning of digital services based on lightwaves ("lambdas on demand").

Signaling Architecture

There are various approaches to implementing signaling architectures related to provisioning digital services over optical networks. Some current efforts are directed at defining an IP control plane that would interface with optical control and traffic planes. There are four general models, with multiple hybrids. One is an overlay model, which defines separate domains. Another is IP–centric, and yet another is optical-centric. In this model, IP transit is supported by optical networks, much as it was supported by ATM. In this model, lightpaths are much like permanent virtual circuits (PVCs), and fairly static provisioning is presumed.

Another is a signaled overlay model, which provides for separate domains, but also for a wide range of interactions between the IP layer and the optical layer, allowing for resources on demand, end-to-end lightpaths between any two edge points, via out-of-band signaling. This architecture, which is the focus of significant development, provides for signaling for various levels and types of services and related requirements (e.g., priority, protection class, etc.), resource discovery and availability mechanisms, lightpath management (create, delete, change, swap, reserve), optimization and other performance processes, survival/protection and restoration processes, etc. Another architectural model is the peer model, which envisions IP devices (e.g., routers) and optical devices (optical switches) as cooperative components, each with IP identifiers and within a shared infrastructure fabric and using a common routing protocol and state data. A fourth major model is an integrated model, which envisions a single network fabric with a high degree of integration of IP and optical components.

Architecture Standards Activities

The International Telecommunication Union–Telecommunication Standardization Sector (ITU–T) is defining architectures for an optical transport network and automatic switched optical networks, including provisions for network-to-network interface (NNI), user network interface (UNI), control signaling, etc. The Optical Internetworking Forum (OIF) is also developing architectures for UNI and NNI. The Optical Domain Service Interconnect (ODSI) forum is developing architectures defining UNI specs for routers as clients to optical systems, and OXCs (all optical as well as electric core OCXs). They are also beginning to address avelength division multiplexing (WDM) line terminals and optical add/drop multiplexers (OADMs). The IETF has undertaken a variety of efforts within multiple working groups. Key efforts are those that relate to the link management protocol and the control plane efforts related to GMPLS.

IP–Centric Control Plane Architecture for Optical Networks

As the progress toward IP over optical networks continues, the importance of control-plane architecture has been increasingly recognized. The IETF has undertaken a number of efforts related to designing a common IP–centric control plane that would provide for precise out-of-band management of lightpaths within and across domains. The development of these management capabilities will allow for greater network flexibility, for example, replacing static point-to-point WDM implementations with methods for dynamic provisioning of not only lightpaths, but also a wide range of other network resources. Consequently, investigating optimal architectures for such a control plane is an important issue—especially those providing extensions related to new technologies, such as enhanced photonic components, all-optical cross-connects, channel distance attributes, and large numbers of high-performance channels. An IP control plane must provide for extremely high performance capabilities for a variety of functions, such as optical node identification; service-level descriptions (e.g., request characterizations); managing link-state data, especially for rapid revisions; allocating and re-allocating resources; establishing and revising optimal lightpath routes; determining responses to fault conditions; etc. General functions include the following:

- Specifying and updating lightpath addressing, employing unique identification of path end points
- Determining lightpath availability and reachability
- Dynamically provisioning lightpaths through lambda processing (discovery, add, delete, switch, change, restore, etc.)
- Multiservice and multiprotocol supports, including IP, GbE, 10 GbE, etc.
- Traffic engineering
- Performance monitoring and analysis
- Survival and protection

GMPLS

Currently, the generalized multiprotocol label switching (GMPLS) architecture (MAN01, BEL01, ABO01, ASH01a), being developed by the IETF, has gained significant momentum. The primary IP–over-wavelength optical architectural models previously described and can utilize GMPLS. GMPLS is the generalized extension of multiprotocol label switching (MPLS) (CAL99, ROS99), a signaling protocol with a flexible framework which specifies separating forwarding information from IP header information, allowing for forwarding through label swapping and various routing options. The MPLS architecture assumed a forwarded plane that recognized packet or cell boundaries and provided processes based on packet or cell headers. GMPLS provides for extensions that include forwarding planes that are not capable of recognizing such boundaries, such as traditional devices based on time division multiplexing (TDM) (e.g., SONET add/drop multiplexers [ADMs]) and newer devices, based on wavelengths (optical lambdas) and spatial switches (e.g., in flow port or fiber to out flow port or fiber). Consequently, GMPLS allows for forwarding decisions to be based on time slots, wavelengths, or ports. Path determination and optimization is based on labeled-switched path (LSP) creation and implementation. This process gathers the information required to establish a lightpath and determines characteristics, including descriptive information (address identifiers, reachability, etc.)

Extensions to GMPLS provide for a range of extensions for routing, open shortest path first (OSPF), and general traffic-engineering functions. GMPLS–TE extensions include those that allow for constraint-base routing–label distribution protocol (CR–LDP) specific formats and mechanisms and for resource reservation protocol–traffic engineering (RSVP–TE) signaling (ASH01b). Path protection ensuring the protection of existing paths is a key requirement, and requires continual high-performance monitoring of state information. Detecting and locating faults at both the IP and optical layers and rapid responses are also high-priority functions. Currently, GMPLS development is focused on intra-domain networks. Other efforts with the IETF are attempting to develop techniques that address interdomain networking while avoiding link-state protocols and their related complexity (STA00, XUY01).

Given the importance of the IP control plane, the high level of activity, the multiple emerging standards, the amount of current architectural tasks, and the controversies, the IETF has formed a specific effort, the Common Control and Measurement Plane (CCAMP) working group, which is coordinating various efforts defining a common control plane and a separate common measurement plane.

Physical-Layer Considerations

An important consideration related to advanced optical networks based on lambda switching is that lower-level functions require ongoing monitoring of various physical processes to protect multiple potential impairments, including conditions resulting from impairment accumulation. Physical performance monitoring, verification, adjustment, and restoration are required for such functions as output leveling across wavelengths, excessive decibel (dB) loss, maintenance of wavelength precision, chromatic dispersion effects, etc.

Advanced Research Projects

Networks based on wavelength provisioning are rapidly migrating from long-haul service domains to regional areas, metro areas, and the enterprise. To take advantage of this trend, the International Center for Advanced Internet Research (iCAIR), with partners worldwide, has established a number of major R&D projects that are developing new capabilities based on wavelength switching. These projects include those that are creating high-performance applications for network-linked computer clusters (using optical links as computer backplanes), new types of network middleware (IETF RFC 2768, AIK99), and next-generation optical network infrastructure. With the Electronic Visualization Lab of the University of Illinois, iCAIR is designing a global optical exchange point (StarLight). iCAIR is also participating in the architectural design and development of international, national, regional, statewide, and metro-area optical networks, including one that will connect as many as 2,000 sites in Chicago. Recently, iCAIR established its Optical Metro Network Initiative (OMNI), which is creating a reference model for next-generation metro networking infrastructure.

Enabling In-Service Migration from Ring to Mesh Architectures in Metro Networks

Emanuel Nachum
Vice President, Marketing
Lightscape Networks

Introduction

The demand for bandwidth for multiple services has been increasing at lightening pace. As new network applications such as e-commerce, network storage, and corporate data and video continue to grow, service providers are struggling to grow the bandwidth in step with the traffic. While optical technologies can provide the bandwidth for these high-traffic applications, one of the biggest challenges facing the industry today is building a network that meets today's needs but scales in-service to meet those of future years.

To accomplish this, network flexibility in terms of supporting multiple network topologies, such as ring and mesh, is a critical factor. Choosing multi-topology, multilayer integrated platforms, which can migrate easily from ring to mesh architecture in-service, will assure the flexibility and scalability needed to allow carriers to scale networks cost-effectively on a "when and where" basis.

Until now, metro optical transport networks, built during the last 10 years, were based primarily on synchronous optical network (SONET)/synchronous digital hierarchy (SDH) equipment deployed in a hierarchy of ring topologies as access rings, collector rings, and metro core rings. Such metro networks were appropriate for the voice era, when carrier traffic was highly predictable and slow to change.

Most analysts agree that data traffic will dominate over voice in our networks from now on. With the rapid growth in data traffic, these metro SONET/SDH ring hierarchies have become a scalability and provisioning bottleneck in connecting users and businesses with core, national, and regional backbones. Additionally, the ring hierarchy-based networks are rigid time division multiplexing (TDM) pipes and require up to 50 percent capacity for protection. These networks waste the majority of bandwidth for traffic engineering, upgrades, and protection mechanisms, especially for the dynamic nature of data traffic. For example, an optical carrier (OC)–12 metro ring can be upgraded to no less than an OC–48 ring, which implies significant waste if the user needed only marginal increase over the OC–12 bandwidth. An entire ring has to be upgraded to increase bandwidth even in a section. Additionally, any geographic extension of the network to include extra nodes requires an additional ring (or rings) to be built. Gradual extensions, which include one node at a time with point-to-point links, are impossible.

To alleviate these issues, many service providers are looking to transition from ring- to mesh-based metro network architectures. Mesh architectures are flexible, bandwidth-efficient, and cost-effective, and offer on-demand scalability and tiered-protection services. Additional bandwidth can be turned up on demand even on a link-by-link basis. Adding new sites requires mere point-to-point fiber extensions. Depending on the application, a choice among multiple protection services can be offered to customers. For example, customers can choose to leave their traffic unprotected or choose to protect with various levels of SLAs, including guaranteed protection switching in the sub 50 ms range for mission-critical applications. Such differentiated services are likely to be critical factors needed to maintain a competitive advantage and develop new revenue streams.

Most national carriers have been building their dense wavelength division multiplexing (DWDM)–based core backbone networks in mesh topology. The next step in this evolution is going to happen in the metro networks. In the metro networks, carriers need network solutions that support today's ring topology while providing migration to mesh—building it section-by-section if customer traffic demands warrants. To meet these needs, carriers should be able to configure (or reconfigure) in-service to multiple topologies in the network, including ring, star, linear, and mesh or virtual mesh-in-ring.

Carriers can build their networks today with next-generation hybrid optical platforms that support both multi-ring SONET/SDH architecture as well as DWDM–based optical mesh architecture. Carriers can initially run these metro networks as SONET/SDH rings and later migrate in-service to optical mesh, allowing them to scale their networks and/or add differentiated services.

This paper covers the following:

- The benefits and challenges of running current metro networks with SONET/SDH ring architectures
- Suggestions on how next-generation platforms can support migration from today's SONET/SDH ring architecture to DWDM–based optical mesh architecture
- Descriptions of the advantages of running mesh-based metro networks

Challenges with Rings Architectures

Current metro optical transport networks are based primarily on SONET/SDH equipment, deployed in a hierarchy of OC–3/OC–12/OC–48 ring topologies. Among the key benefits of SONET/SDH hierarchy are self-healing and survivability, features that have served the carriers well for voice traffic and cannot be compromised in other applications. SONET/SDH ring networks are relatively immune to traffic interruption because of the dedicated multiple protection paths provided in the ring itself. SONET/SDH rings can recognize a fiber cut and reroute traffic along the alternative pre-allotted protection path, before any significant degradation in performance can occur.

There are two types of SONET/SDH rings: a unidirectional path-switched ring (UPSR) and a bidirectional line-switched ring (BLSR). The former (Bellcore spec TR-496, path switched) switches individual paths and the latter (Bellcore spec GR-1230, line switched) switches the entire optical line capacity. There are differences in their architectures that significantly affect the bandwidth utilization of the network.

Major carriers in the United States have typically built their metro networks as SONET/SDH rings. UPSR rings are commonly found in the metro access and aggregation rings, while BLSR rings are more often deployed in the metro regional core network and sometimes even the national core network. Additionally, most carriers have typically used linear or mesh connectivity for their long-haul inter-city DWDM networks. Even the SONET/SDH traffic on these long-haul networks may be in point-to-point configuration, which is unable to capitalize on the survivability features of the SONET/SDH rings. As a result, cable cuts in these sections could result in an outage for voice traffic, unless protected by an alternative protection mechanism in the optical layer. However, data-networking devices, such as Internet protocol (IP) routers, do not necessarily need SONET/SDH or optical protection, as they can usually identify the broken link and reroute the traffic around the fiber cut sections.

UPSR sends traffic both ways around the two-fiber ring for redundancy, thereby reserving 50 percent bandwidth for protection. The receiving end monitors both signals and selects the better one. Because of this dedicated use of protection capacity, UPSR systems have less fundamental capacity for paying traffic than BLSR rings. A four-fiber BLSR ring sends traffic only in the required direction during normal operation. Each direction has a working fiber and a protected fiber. During a fiber interruption, the traffic is routed around the break in the opposite direction. This method allows the ring to share the protection capacity, which increases the overall traffic carrying capacity of the system.

Ring architecture has proven very reliable for sub 50 ms protection guarantees that were important for the networks carrying predominantly voice traffic. BLSRs are very effective when the metro core is a single SONET/SDH ring, interconnecting multiple central offices (COs) or points of presence (POPs). Indeed, BLSR performs three functions very well. First, it allows the network to recover from failures very quickly, normally in less than 50 ms. Second, it provides a shared pool of protection bandwidth within a given ring so that carriers do not need to pre-allocate protection bandwidth on a one-for-one basis. Third, it allows pre-emptable traffic to traverse the protection channels when they are not carrying protection traffic.

However, the BLSR begins to show limitations as traffic growth forces service providers to install multiple parallel BLSRs. Because a BLSR only provides the ability to share protection traffic within a given BLSR, multiple parallel BLSRs cannot have a shared pool of protection bandwidth amongst themselves. Also, a BLSR is required to be symmetric, with the same amount of working and protection bandwidth all the way around the ring. These limitations result in the addition of "extra" or "wasted" bandwidth whenever the demand on the various segments of the SONET/SDH rings is unequal. With the BLSR, each ring must be sized to accommodate the busiest segment of that ring. The inefficiency of this solution is apparent by looking at the amount of working bandwidth on each segment of a ring in comparison to the traffic on other segments. Furthermore, the inability to share protection between adjacent rings adds unnecessary segments. Clearly, the efficient restoration technique of the BLSR ceases to be bandwidth efficient while scaling the metro core network to a multi-ring environment.

To scale the bandwidth of any section in a ring, the entire ring has to be matched up with that capacity. This leads to significant waste of network capacity. The problem with UPSR/BLSR architecture goes beyond the wasted protection bandwidth. Carriers lose competitive advantage when they are not able to carry out on-demand network scaling cost-effectively. Moreover, the BLSR does not enable service providers to define differentiated protection services.

In summary, the BLSR, when used for multi-ring metro core or regional/national backbone network restoration, is not the most efficient way of using the network bandwidth. Additionally, it limits the carriers' ability to offer differentiated services and cost-effectively scale their network in-service. In contrast, an optical meshed architecture eliminates these deficiencies and makes network provisioning, operation, and scaling highly cost-effective, providing next-generation carriers with a significant competitive edge. In the absence of support for mesh architecture in their backbone network, carriers sometimes create a set of interconnected rings (logical rings over physical mesh) to cover regions and even an entire country. This helps carriers provide at least for the survivability of the network without adding any of the advantages of the mesh network previously outlined.

Carriers should begin building networks that support SONET/SDH rings *and* allow them to migrate cost-effectively to optical mesh architecture in-service at a later date.

Migration to Mesh Architecture

Mesh optical networks are the future model for all networks, both metro and national backbone. Carriers need to build ring-based networks today, especially in metro areas, and need to be able to migrate in-service to mesh in the near future. Carrier's next-generation networks can support both ring and mesh topology at every node today. Topology definitions of their network are embedded in the element-management system (EMS) and network-management system (NMS) and do not require replacement of any hardware at the time of migration from ring to mesh architecture. In this process, if the traffic routes are to be modified and higher traffic to be accommodated in certain links, the required hardware changes also can be undertaken in-service. Such an upgrade is carried out in three easy steps: (1) route the live traffic over its protected path momentarily, (2) replace the card, and (3) route the live traffic back on to the upgraded card.

Metro mesh networks support not only the survivability attribute of the ring architecture in the optical layer, but also offer multiple levels of survivability options based on dedicated or shared protection bandwidth or dynamic search for protection routes (e.g., Gold, Silver, and Bronze classes). Additionally, it adds another distinct value to a metro optical network: instant and cost-effective scalability of the network.

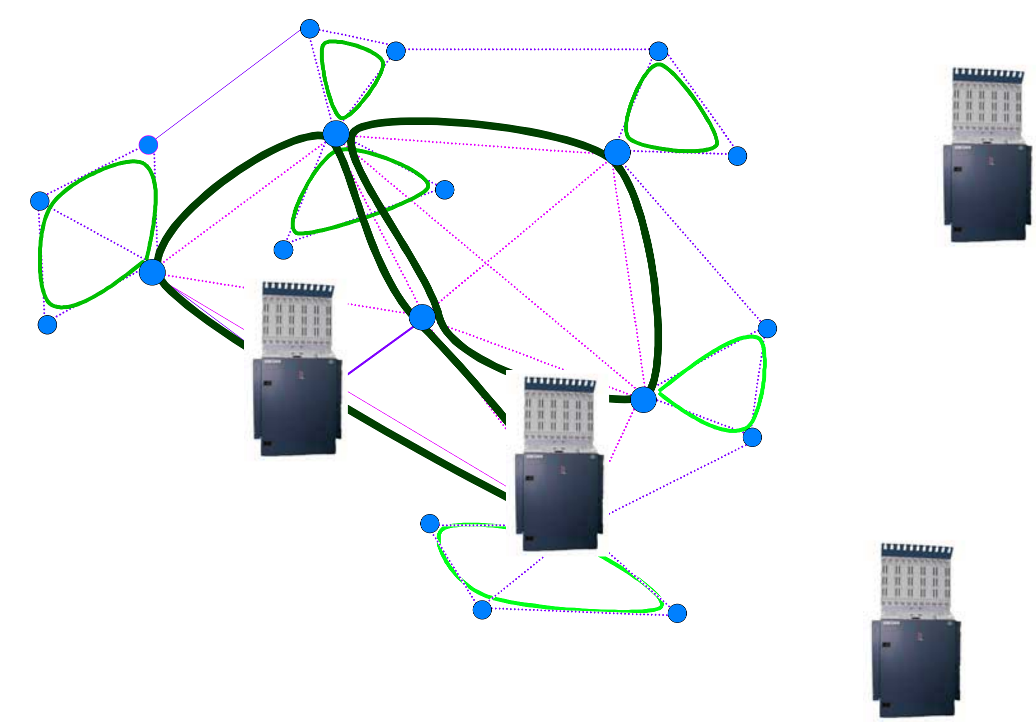
The network shown in *Figure 1* is a representation of how next-generation multi-topology platforms can recognize both SONET/SDH rings and optical mesh architectures in a network. This allows seamless migration from ring-based networks to mesh. As a mesh, this network can grow not only the bandwidth of any of its existing links in-service, but also allows for physical extensions of the network by building a new point-to-point link (or links).

Advantages of Mesh Networks

Survivability with Bandwidth Efficiency

In mesh networks, service provisioning between two points takes the traffic along the most cost-effective path available with tiered protection, as desired and paid for by the customer. Depending on the type of service, it could mean allocating a predefined reserved 1:1 protection path (Gold service), 1:N shared protection path (Silver service), or a dynamic routing algorithm to search for a new restoration path (Bronze service). Mesh networks can provide transport service without compromising the guaranteed protection of sub 50 ms for mission-critical applications required by banks, financial institutions, and real-time e-commerce traffic. However, for many corporate data services, this architecture can allow carriers to offer no pre-allocated (and wasted) protection bandwidth. In such cases, the network recovers from a breakage by using the intelligent automatic fault sensing and rerouting feature of its optical switches. Assuming many of the carriers' services are likely unprotected or shared protection data services, the potential saving of network bandwidth is dramatic. This adds significant cost advantage to the carriers and helps them to beat the competition.

FIGURE 1



Based either on dynamic routing algorithms or pre-allocated protection bandwidth, an optical switching-enabled mesh architecture can also provide self-healing capabilities without the complexity associated with ring software. Some intelligent optical switches are designed with software intelligent enough to retain the advantages of the BLSR while at the same time eliminating the inefficiency of multiple parallel rings. Introduction of optical switching transforms the network topology from a ring or linear architecture to a mesh architecture, providing for optimum routing of lightpaths from source to destination and fast rerouting around network failures without the need to reserve protection bandwidth for all types of applications.

As an example of bandwidth savings under predefined shared protection scheme (see *Figure 2*), consider 1:4 shared paths as follows:

- Three different optical trails are routed between sites A and D (full lines).
- One reserved shared path (dotted line) offers protection bandwidth for the four working paths, allowing for a significant bandwidth savings over a 1+1 protection that wastes 50 percent of the network.
- Upon sensing a failure in one of the working paths, traffic switches to the shared path automatically by the optical layer.

Revenues from Tiered Protection Services

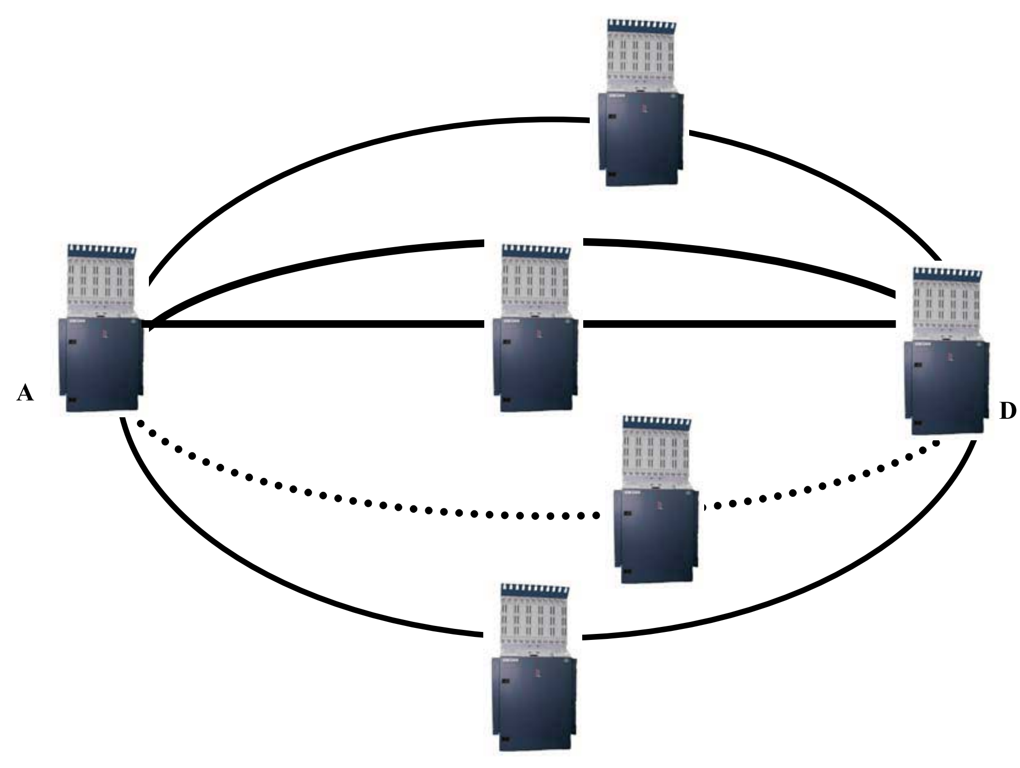
One of the challenges in today's climate is to help carriers maximize their revenues by evolving from just selling bandwidth as a commodity to providing more enhanced services. To face this challenge successfully, carriers need to offer both differentiated premium services as well as basic services. Mesh architectures enable a carrier to sell tiered services, such as Gold (guaranteed), Silver (guaranteed with delays), and Bronze (best effort). This strategy can help a carrier to generate new revenue streams by differentiating from others that may be unable to sell any premium services.

Data-Optimized Network

It is known that overlaying data services networks, such as IP and asynchronous transfer mode (ATM) backbones, are mesh networks, made up from complex interconnections of IP/ATM routers and switches. These devices choose the most efficient of the multiple options over the mesh to ship traffic from origin to destination. Naturally, traffic engineering of IP and ATM traffic is more aligned with metro optical mesh networks. This facilitates better connectivity and bandwidth utilization throughout the network. Being bitrate and format independent, the optical mesh can carry both data and voice traffic efficiently.

The emergence of optical cross-connects (OXCs) represents a landmark in evolution of mesh networking, as it enables current networks built up with point-to-point DWDM links and SONET/SDH rings to evolve into a unified next-generation intelligent mesh network. The DWDM/optical layer not only provides hundreds of channels of capacity for the explosive growth of data traffic, but also becomes a means to integrate multiple data services on to an intelligent mesh network. Alternate routing through the mesh either by the

FIGURE 2



IP/ATM router/switch or OXC becomes a highly optimized solution that can match tired protection needs of multiple applications. Additionally, metro mesh networks also enable carriers to offer auto-provisioned lambda and data services efficiently.

Network Scaling

As the number of lightpaths or channels traversing the network increases, optical switching in a mesh environment is required to continue to efficiently scale the core of the metro network. Mesh networks can truly scale on a "when and where" basis: carriers can add capacity to existing networks on a link-by-link basis—*on demand*—without having to upgrade an entire ring or network. They can also extend the geography of the network to new nodes by merely adding point-to-point links that become part of the single unified mesh network, instantly and effortlessly.

Conclusion

Ring topology-based metro networks served the carriers well in the voice era, when a network-wide self-healing in the sub 50 ms range was the key issue. Limitations of rings toward bandwidth efficiencies and on-demand scaling were not critical. Now, carriers need to build metro networks that support both ring and mesh architectures and can migrate from ring to mesh cost-effectively and in-service.

Mesh-based metro networks are more bandwidth efficient, as there is not always a need to reserve additional spare capacity for protection purposes. The tremendous cost advantage of mesh networks is the ability to free up to 50 percent of bandwidth for revenue-generating traffic, providing carriers with a significant competitive edge.

Mesh-based networks enable service providers to configure tiered services. That means providing only as much working and protection bandwidth as is actually being paid for and needed to support the contracted service-level agreement (SLA). For example, mission-critical services can receive 100 percent guaranteed sub 50 ms protection, while non-critical services can receive shared, delayed, or even no protection at all. Only selected (paying) services need to be provided with additional spared protection bandwidth, not the entire network.

Mesh networking provides carriers with on-demand and in-service scaling capabilities. Carriers can add bandwidth only in the sections or links where additional traffic demands.

HomeRF: Optimized for the Broadband Internet Home

Kevin J. Negus
Chief Technical Officer
Proxim

This paper will discuss technology from the Home Radio Frequency Working Group (HomeRF). HomeRF leverages what digital subscriber line (DSL) brings to the household. This paper will introduce the broadband Internet home, discuss some of the candidate wireless technologies for networking that home, and then go into detail on how HomeRF works. It will end with a comparison of candidate technologies.

Broadband Internet Households

A lot of homes in America are going to have broadband services in the near future. *Figure 1* shows the projected numbers of households that will have broadband services such as cable, DSL, and wireless by 2004.

Services Consumers Want from a "Telecom Bundle"

What all U.S. consumers expect from a bundled set of services coming into the broadband Internet home—the one feature that stands out—is voice (see *Figure 2*). But most people at networking or data conferences do not believe it—they believe high-speed Internet is the driver of everything. And while it certainly is a big factor, voice, streaming media, audio, and video are all equally or more important in terms of bringing revenue into the service provider.

Candidate Wireless Home-Networking Technologies

The large number of wireless networking technologies can be very frustrating. There are definitely many more than the three discussed here. The bad news, depending on one's perspective, is that there are many more to come. The nature of wireless is that it is an unbounded medium. It is not a physical wire. The physics of wireless enable more consumer choice, so consumers demand and get an optimum solution for whatever application they have.

Consequently, wireless equipment providers cannot have one wireless standard that does everything. It would end up being substandard in performance for any given application and probably would not sell. Thus the industry ends up with a lot of different standards, and there is no easy alternative.

What makes wireless particularly difficult is not only that there are a lot of different standards, but that they interfere with each other. They go beyond not working together and actually hurt each other. That is definitely true of the three discussed here, which all operate in the 2.4 gigahertz (GHz) band.

IEEE 802.11b (or "WiFi")

The Institute of Electrical and Electronics Engineers (IEEE) 802.11b technology is one of the latest in a long line of wireless technologies going back to OpenAir, WaveLAN, and the original 802.11DS and 802.11FH. All of these, in different ways, are trying to be the wireless equivalent of Ethernet.

HomeRF

In terms of data, HomeRF is in many respects no different from 802.11b. It is wireless Ethernet as well. But it adds the toll-quality cordless voice capability that Digital European Cordless Telecommunication (DECT) has, which has been the most successful digital multiuser cordless standard in the world to date. HomeRF also adds the ability to do multiple prioritized streaming-media sessions, which currently are typically audio or low-rate video sessions. Its other advantage compared with 802.11b is that it addresses the major interference and security problems inherent in that technology.

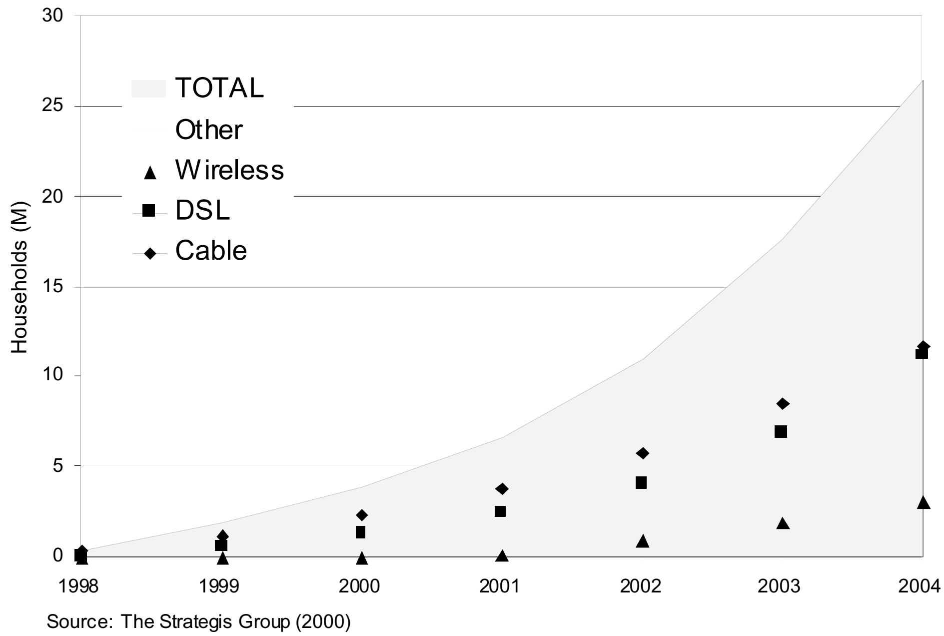
Bluetooth

The third technology, Bluetooth, has had a lot of fanfare and actually has some tremendous potential. Bluetooth is also a 2.4 GHz wireless communications technology, but it provides a unique wireless connection that is literally always on and always able to make an ad hoc connection, yet draws very little power. Of course, solving that problem does not necessarily make Bluetooth a backbone home network, a wireless version of Ethernet to the home, or a cordless telephone. It was really not designed for networking, but rather as an extremely low-cost and low-power cable replacement.

Nevertheless, there are tremendous predictions for Bluetooth penetration, including it being in every cell phone

FIGURE 1

Broadband Internet Households



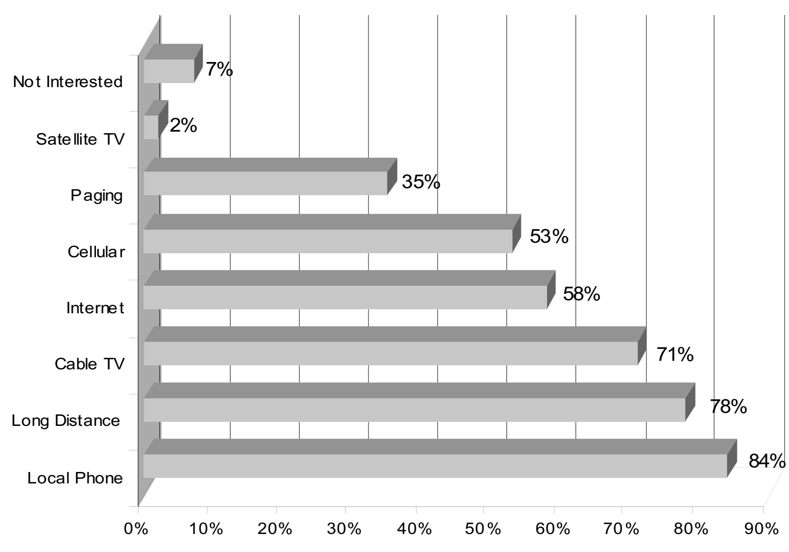
and personal digital assistant. And if Bluetooth is going to be in these devices, it will be in the home. Bluetooth is therefore a major factor for home wireless networking, even if just as an interference source. Being able to operate in the presence of multiple Bluetooth devices is important for any successful home wireless-networking technology.

HomeRF 2.0 Capabilities Summary

Version 2.0 of HomeRF, which is shipping today, has a 10 megabit-per-second (Mbps) peak data rate with fallback modes of 5 Mbps, 1.6 Mbps, and 0.8 Mbps that are used to extend the range or to improve performance in high-inter-

FIGURE 2

Services Consumers Want from a "Telecom Bundle"



ference environments. It has powerful and effective security measures against eavesdropping, service denial, and unauthorized access, as well as active interference avoidance and mitigation techniques.

A key feature is its ability to prioritize up to eight simultaneous streaming-media sessions for audio and video. And it is unique in its ability to mix in four simultaneous toll-quality two-way cordless voice connections based on DECT.

HomeRF Capabilities Roadmap

HomeRF started in 2000 with shipments of 1.6 Mbps, data-only devices, and it was quite successful. Products from a variety of vendors were very easy to install and in fact were the first products used in the universal serial bus (USB), a tremendous advance.

This year the real focus has been bringing out 10 Mbps devices that handle voice, audio, and basic video, including cordless phones and simple streaming devices such as gateways, music devices, and Web tablets.

For the future, the Federal Communications Commission (FCC) is presently changing the rules in the United States to make it much more similar to the rest of the world in the 2.4 GHz band, and it is actually possible in the long run to scale this technology up to even 100 Mbps. But HomeRF has always been application driven, so as it moves forward it will look at additional video-streaming applications such as video tablets and set-top boxes and at data rates that will support them appropriately.

HomeRF Network Topology

HomeRF has a flexible network topology (see *Figure 3*). It is based on an integrated access device (IAD) at the core of the home network, providing a control point or referee functionality. The client devices can be quite varied, from traditional personal computer (PC) devices called asynchronous nodes (A–nodes) to appliances such as a Web pad that might do Web browsing to streaming applications such as games or videos. There could also be a very simple light client such as a portable Moving Pictures Expert Group (MP)3 player that plays directly off a DSL broadband connection or a traditional cordless-phone handset. In addition, while information flows predominantly from the IAD or central controller, all of these devices can communicate directly with each other. They do not need to loop back through the host.

Network-Layer View of HomeRF

An abbreviated version of the open systems interconnection (OSI) seven-layer network stack is shown in *Figure 4*. HomeRF, like most of these wireless networking technologies, tends to focus on the two lowest layers, the data link control and the physical layer (PHY) of the stack.

Most of the 802.11 systems were essentially wireless Ethernet, as were all of the legacy proprietary wireless data systems such as OpenAir and WaveLAN. They went up through the Internet protocol (IP) stack using carrier sense multiple access with collision avoidance (CSMA/CA). Similar to Ethernet, CSMA/CA is a random-access system in which nodes that want to access the network will randomly jump on the media after counting "empty" time slots since last known network activity. If by unfortunate circumstances two get on at the same time, they collide, back off, and try again later. The PHY is of course related to the 2.4 GHz band access and the appropriate modulations that are used.

HomeRF is a little different from other wireless networking technologies in the way that it works in this stack. The

FIGURE 3

HomeRF Network Topology

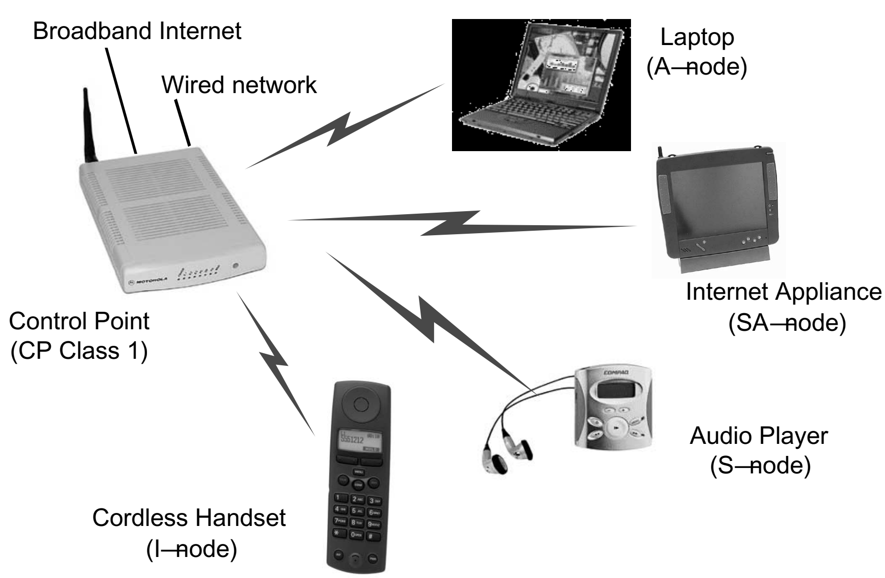


FIGURE 4

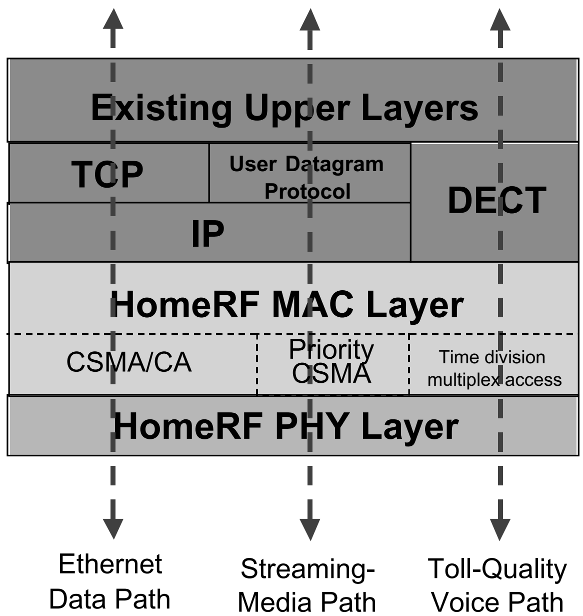
Network-Layer View of HomeRF



unique ability that HomeRF adds to the CSMA portion is the ability to grant some nodes higher-priority access to the media than others. Rules and regulations are present to prevent every node from being a high priority node and thus consuming all the bandwidth.

Another feature that distinguishes HomeRF is the ability to use time division multiple access (TDMA) as well as CSMA in the same frame. TDMA makes it possible to exactly, although dynamically, allocate slots for voice conversation to an individual handset. The handset is not precluded from going to voice over Internet protocol (VoIP) up an IP stack.

HomeRF: Media Access Control Layer Basics

Figure 5 shows the events that happen in HomeRF at the media access control (MAC) layer. The bulk of the time in a given frame, which is typically 10 or 20 milliseconds (ms) long, is dedicated to data networking, as long as there are no voice calls or priority streams. Within the data-networking time, streaming-media sessions get priority access. The time periods reserved for voice calls are based on the number of active voice calls. Voice calls will be divided up into multiple smaller slots depending on the number of calls. By reserving that time hard, there is no chance that data networking, printing a file, or Web browsing will interfere with the voice calls. That is a key attribute of HomeRF.

Dynamic Bandwidth Allocation

Another interesting and unique feature of HomeRF is that the proportion of voice calls to data networking will change depending on the number of calls. If there is only one call, only a very small amount of the available time will be used for voice calls. But four calls would actually require about half of all the available time in a given frame, so half the time would be dedicated to voice. It is all adjusted dynamically. So, for example, if a user has three handsets in his house and VoDSL service with three unique lines, it is not necessary to reserve three-eighths of his or her available bandwidth at all times just in case those lines ring. The system will simply use the bandwidth dynamically when it needs it.

Immediately Retransmits Voice Packets

Another unique feature of HomeRF is used if there is an interference problem, for example from a microwave oven. Less than 1 percent of homes in America have wireless networks, but 98 percent have microwave ovens. And wireless networks have to share the bandwidth with microwave ovens; thus the ovens cause interference. When that occurs, as soon as HomeRF hops to the next frequency, it will reserve time and immediately retransmit those voice packets ahead of any of the data networking events and prioritized streams.

Because the length of the frame is 10 ms, it can do all of that in a bounded time period. Thus it guarantees that in a given 10 ms period, there will be at least two chances to get data through. And hopping to a different frequency at a different spot in the band unrelated to the last is a very powerful way to avoid interference with voice packets.

The data does this as well, but on a much longer time period. The voice traffic has a pre-emptive prioritized capability to do it. This effectively squares the data rate. Since the two frequencies are independent, a raw packet-failure rate of a few percent (typical around microwave ovens) gets squared to much less than 1 percent—this means excellent voice quality with the chosen coder/decoder (CODEC).

HomeRF/Bluetooth PHY Layer Basics and Commonality

Band and Channel Access

The key thing to emphasize about the PHY is how it drives cost. It is a 2.4 GHz frequency-hopping system that is basically identical to DECT. In fact, both HomeRF and Bluetooth are basically identical to DECT. There is really no difference among HomeRF, Bluetooth, and DECT that has any substantial impact for the RF engineer. 802.11b is a different animal, however.

Modulation and Transmitter

HomeRF and Bluetooth use a very simple modulation, frequency-shift keying (FSK), and they use direct conversion and constant envelope modulation, which remove the need for linear power amplifiers and save a lot of complexity. Nominally they achieve 100 milliwatts (MW) saturated output power.

Transceiver Architecture

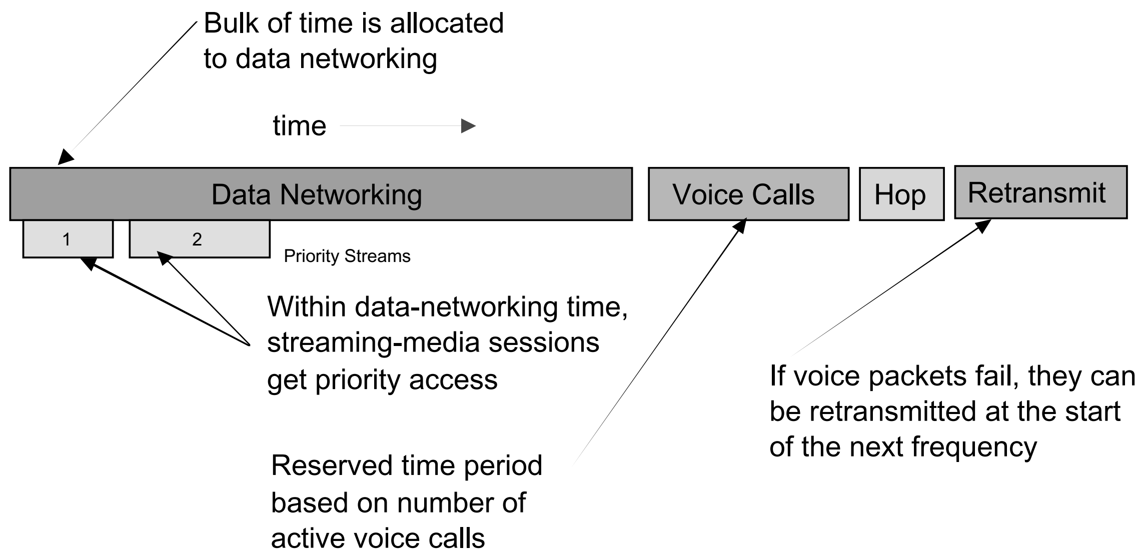
All of these wireless systems are half duplex. If they must be turned around very quickly, that adds cost. In the case of HomeRF and Bluetooth, there are 200 microseconds—an eternity—to turn around these transceivers using standard synthesizers on a single voltage-controlled oscillator (VCO).

Single-Chip PHY Complementary Metal Oxide Semiconductor Radio Frequency Integrated Circuit

Single-chip PHY complementary metal oxide semiconductor (CMOS) radio frequency integrated circuit (RFIC) is

FIGURE 5

HomeRF—MAC Layer Basics



practical today for either HomeRF or Bluetooth, or dual mode for both. When people talk about the $5 radio, they are really talking about doing the entire radio on a single CMOS chip. This is already available for DECT and will soon be available for Bluetooth. The same technology is equally applicable to HomeRF.

Key Comparison Attributes between HomeRF and IEEE802.11b

The following sections will compare HomeRF with 802.11b, which is probably the most talked-about candidate right now outside of HomeRF or wireless home networking. The two are differentiated by their voice support, streaming media support, interference immunity, scalability, and security.

Voice Support

Voice support is an important feature. Consumer voice revenues in America are more than 10 times greater than the cumulative consumer/residential data revenues. And although the wireless local-area network (LAN) industry is very proud of having passed its first million-unit year, there are 50 million cordless phones sold every year in America. The cordless phone is a device that consumers are more familiar with, and it outsells wireless data devices by more than 50 times. The level of voice support is a major difference between HomeRF and 802.11b.

802.11b Has No Explicit Voice Support

Voice support is probably the single biggest hole for 802.11b—it has no prioritization for voice, no bounded-latency mechanism for voice, and no standard software stacks for voice features. And it cannot be Band-Aided to get voice support. The basic frame structure of 802.11b does not lend itself to any of the conventional voice-networking stacks.

HomeRF Was Designed to Support High-Quality, Multiline Cordless Telephony

HomeRF is the exact opposite. It was designed to support high-quality, multiline cordless telephony. The fact that it can map directly into DECT and use all of the service-provider CLASS features means that any cordless-telephone solution out there today can use all those standard networking features as it adapts to HomeRF. HomeRF handles up to eight simultaneous voice connections and has a 10 ms bounded latency. Frequency diversity and hopset adaptation provide high quality even with severe interference. And it is the only ratified global standard for multiline cordless telephony.

Streaming Media Support

Streaming-media support is another point of differentiation between 802.11b and HomeRF. Internet audio and video are key applications for broadband, making streaming media support important.

802.11b Has No Explicit Streaming Media Support

802.11b does not currently support streaming media overtly. Demos work fine, but network loading can wreak havoc on VoIP phones or streaming videos. 802.11b can handle a little low-rate MP4 video, but there are big problems with printing a file, placing a lot of networks in an apartment building, or bringing an interfering device nearby. Some of the worst problems are with cordless phones. But interference and scalability issues notwithstanding, 802.11e should eventually address much of this issue.

HomeRF Was Designed to Support Multiple Prioritized Streaming-Media Sessions

With HomeRF, self-interference is not an issue because it can prioritize. HomeRF can handle up to eight consecutively prioritized levels and either one-way (audio/video) or two-way (VoIP/videophone) traffic. Frequency diversity and flexible retry buffer lengths provide high quality even with severe interference.

Interference Immunity and Scalability

Sources of interference include Bluetooth, cordless phones, microwave ovens, and high-density housing with many adjacent networks. Interference immunity is very important, because when people pay for a service, whether they pay $5 or $30 a month, they expect the service to work. Consumers will not understand that because their Bluetooth device came home or their neighbor turned on a microwave oven, they cannot dial their sister or access their voice mail. That will be unacceptable.

802.11b Has Only Three Wide, Static Channels

802.11b divides the 2.4–GHz band into three wide, static channels. 802.11b always shares bandwidth with foreign networks. The channel bandwidth has a fixed location and is about 17 MHz. The whole network sits there without any mechanism for moving around. The only interference-avoidance mechanism is time diversity. If there is an interferer, such as a microwave oven or a cordless phone coming on, the network must wait for the interferer to leave—that is, for the microwave oven or cordless phone to turn off.

The problem is not so acute for data. Microwave ovens tend to be on only half the time on a 60-cycle repeat, so data can usually get through, although with sharply reduced throughput. If consumers are simply accessing the Internet, they are used to the Internet being flaky and slow anyway, and they blame any delays on the Internet rather than on the microwave oven or wireless products.

But the inability to avoid interference is obviously unacceptable when it comes to voice. The microwave oven shutting down the VoIP connection will be very unpopular. And a devastating problem can be caused by a fast hopper such as Bluetooth. In some respects it is worse than the microwave oven because it hops so fast. At 1,600 hops per second, there will be a Bluetooth transmission sitting in that one-third of the band once every 2 ms. That does not provide much opportunity to get the packets through, especially when it is only randomly accessing the media to begin with. Bluetooth is a very hard device on 802.11b.

Another problem is hit or miss, but when it hits, it can be much worse—namely, a variety of proprietary direct sequence spread spectrum (DSSS) cordless phones. Most of them are six channel, meaning they divide the band into sixths. And within the one-sixth that they randomly pick, once they close their link, they have their call. As long as they have an acceptable packet-error rate, they remain static and will just sit there. For example, if one of these cordless phones closes a link and happens to be on the same channel as an 802.11b, the phone actually has something like a pilot carrier and it also operates full duplex. And it will just sit there continuously and shut the entire 802.11b network down—not to low throughput but to no throughput. The network is dead once that happens.

HomeRF Has Narrower, Dynamic Channels

HomeRF, of course, is very different for two reasons. First, the channel bandwidth is much lower, at 1 or 3.5 MHz. Thus rather than using up 1/3 of the band at a time, HomeRF uses in the voice mode only 1/75 of the band at a given time. On top of that, when interference does occur, HomeRF is always in motion, moving around to different parts of the band. That allows it to use both frequency diversity and time diversity to get around interference.

And HomeRF has the ability to adapt its frequency hopping on the fly. So if it encounters interference in a certain portion of the band, it can try to adapt around it so that it spends less time in that band, or at least never spends time in that band two times in a row, making the retry mechanism is most effective.

HomeRF also ignores foreign networks for graceful degradation in high-network-density environments.

Security

Regarding security, PHY/MAC attributes are critical because end-to-end solutions are generally not available in the home. Security is an important issue, although it can also be greatly overblown. Still, the issues that consumers care about are important ones for the industry, even if they are not always rational.

802.11b Has Three Well-Publicized Security Flaws

802.11b has three security flaws that have been highlighted both by the popular press and by industry experts. The first flaw, weak encryption with only a poorly defined, 24-bit initialization vector (IV) management, is completely overblown. It is unfair to 802.11b because even if MAC layer data was decrypted, it is usually useless without full access to the applications associated with the data.

The second flaw, however, is real. Open network access says that with an 802.11b device, a user can troll around the homes in his neighborhood looking for an 802.11b gateway. It is pretty trivial for the uninvited user to get on. Once on, the user could get a neighbor's DSL service that he or she was not paying for, or even get onto a neighbor's network, check out his or her hard drive, and look at his or her phone logs.

A third problem that has not been publicized as well is mass denial-of-service susceptibility—basically, a protocol attack. A good example of this is when people shut down the CIA Web site or MSN or Yahoo. This is vandalism. It is the electronic equivalent of painting on subway cars and in 802.11b, unfortunately, the protocol works such that the control signals are in the clear and are not network–ID dependent. It is very simple to build a device that goes into a neighborhood and broadcasts instructions to shut down all the 802.11b networks.

HomeRF Addresses All Three Concerns

HomeRF thought about these issues and addressed them. The solution for the first concern was to add 128-bit encryption and develop a tamper-resistant 32-bit initialization vector.

But the big difference, and this one is much harder for 802.11b to deal with, is that in HomeRF there really is no equivalent of the 802.11b open-access mode. Furthermore, a spec-compliant device has no way to pass what are called "promiscuous packets" up above the MAC. "Promiscuous packets" means listening for any packets that are valid HomeRF packets but are not on the listener's network ID. In

HomeRF, a spec-compliant device can not pass those up. In 802.11b, because it uses upper-layer techniques for authentication and access, it basically is required to pass them up. And that makes drive-by hacking very easy to do. With HomeRF there simply is no equivalent to this.

With HomeRF, mass denial of service is virtually impossible because of its frequency-hopping PHY and ignoring of foreign network IDs. If there are three static channels and a low-level protocol command to shut them down as in 802.11b, then it is fairly easy to jump across three channels that are fixed in time and shut them all down. With HomeRF however, multiple networks in a neighborhood or apartment building are all on random hopping sequences that are not known in advance. They are on different phases and time bases. They also ignore anything that does not come from their own network ID. And they have a unique 24-bit network ID that is not known in advance. A device that can figure out these network IDs, time bases, and phases and send low-level protocol commands could be built by the CIA, but not by drive-by hackers.

Other Comparison Attributes

Cost

In the end, cost will be the most important issue. HomeRF starts from a cordless-telephone cost basis, but the market sets the price. HomeRF is basically the same as DECT from a cost point of view. Thus it is cheaper than 802.11b.

But cost is one thing; price is another. Some very aggressive pricing among the 802.11b services has obscured HomeRF's cost advantage, and thus cost has not yet been as big a differentiating factor for HomeRF as it will be in the long run.

Range

HomeRF2.0 and 802.11b have roughly similar ranges.

Peak Throughput

HomeRF 2.0 and 802.11b have roughly similar peak data-only throughput. HomeRF actually has much more significant throughput if there is a lot of interference present, but outside of that case they are similar.

Power Consumption

Power consumption is a big differentiator for HomeRF, just as it is for Bluetooth. And HomeRF can be done with much, much less power than 802.11b. HomeRF power-saving devices consume less than 10 milliwatts standby with full transmission control protocol/Internet protocol (TCP/IP) connectivity.

Network Topology

HomeRF uniquely supports host-client and peer-to-peer simultaneously.

What about IEEE802.11a?

More and Cleaner Bandwidth

802.11a products operate in the 5 GHz band, where there is more and cleaner bandwidth. There is far less interference because that band has 300 megahertz (MHz) total in the United States today, and probably closer to 470 MHz total in Europe, although only 100 MHz so far in Japan. Unfortunately, it is different in all those countries. By contrast, a beautiful thing about the 2.4 GHz band is that it truly is global. The rules are close to identical globally, and the band allocation is virtually identical globally. That remains a big advantage for the 2.4 GHz band over the 5 GHz band.

Same Ethernet-Oriented MAC Layer as 802.11b

802.11a is basically the same as 802.11b in the sense that it is wireless Ethernet. It still lacks explicit voice and streaming-media support, relies on upper layers for security, and has the same security issues as 802.11b. But 802.11a can put 54 Mbps in 12 channels at 5 GHz, while 802.11b puts 11 Mbps in three channels. That is a 10-fold increase in system capacity.

Conclusion: Ideal Solution for the Enterprise

Overall, the far greater system capacity of 802.11a makes it an ideal solution for very dense enterprise deployment. For offices of the future, or even offices of today where they do not put in wire, the system capacity that 802.11a represents is tremendous.

Market Positioning

Will this technology come home? Some of the core technologies used in 802.11a will be very applicable to the HomeRF roadmap, and 802.11a will likely come home just as 802.11b has. There is no question that these will show up in people's homes. But the center of the home market is really HomeRF because of its cost, security, toll-quality voice, and streaming media.

Nothing can provide ad hoc connectivity and low power like Bluetooth, and future mobile markets will be Bluetooth-centric. It is a tremendous technology that also is low cost.

In the business market, 802.11a is where the future is going to be, because it offers wireless Ethernet, performance, and roaming.

Summary

HomeRF combines 10 Mbps data, toll-quality voice, and streaming media for the broadband Internet home. It is uniquely optimized for the broadband Internet home, and it can be scaled to more than 50 Mbps data rates under new FCC rules.

Addressing the Deployment Dilemma

How to Select the Right Remote Terminal Enclosure for Sophisticated Broadband Equipment and Enhance its Revenue-Generating Capability

Minesh Patel
Formerly Director, Product Management
Marconi Communications

Deploying outside the plant to bring high-revenue–generating broadband services to residential subscribers finds service providers trapped between two fundamental issues: technical requirements of the sophisticated broadband equipment and right-of-way restrictions imposed by local governments.

On the one hand, broadband equipment consumes more power, requires more battery backup, generates more heat and, in some cases, is more complicated to connect than conventional telephone equipment. This suggests larger, more robust enclosures and the potential for greater acoustical noise from fans and air conditioners.

On the other hand, municipalities and other local governing bodies, responding to complaints of property owners, are increasingly reluctant to allow deployment of additional, larger, noisier enclosures in residential neighborhoods.

This is a challenge to service providers and enclosure manufacturers alike. The provider must understand the physical requirements and limitations of broadband equipment. And the manufacturer must be able to develop an "enclosure system" to contain the equipment, maintain the right thermal environment, allow room for ample battery backup, provide physical access for service, and maintain form factors and footprints compatible with local restrictions at a reasonable cost.

Service Providers' Responsibilities

Enclosure manufacturers are already addressing "broadband readiness" issues so suppliers can obtain new enclosures to accommodate the new services. However, providers need to know what to ask and what to tell the manufacturer to get the proper solution. And they need to understand what manufacturers claims and specifications actually mean—particularly new competitive local-exchange carriers (CLECs) that may have limited understanding of the technical issues and choose to rely totally on the enclosure manufacturer's expertise.

A manufacturer might say, "This cabinet cools 5,000 watts." While it may cool 5,000 watts when the cabinet is empty, the ventilating system may not be able to cool anywhere near 5,000 watts when equipment is installed. The reason is "system impedance." Equipment inside the cabinet will restrict airflow and cause a pressure drop that reduces the amount of air moving through the electronics and heat exchangers—thus reducing the amount of heat that gets removed.

Or the manufacturer may recommend the addition of a fan shelf to increase cooling. Depending on where it is placed and how it is operated, the shelf can, in fact, *reduce* the cooling. The fan shelf may only be operating at 200 cfm, while the cabinet thermal system may be operating at 600 cfm. In this case, the slower moving fans in the fan shelf, instead of helping, have further impeded the airflow and therefore diminished the cooling effect.

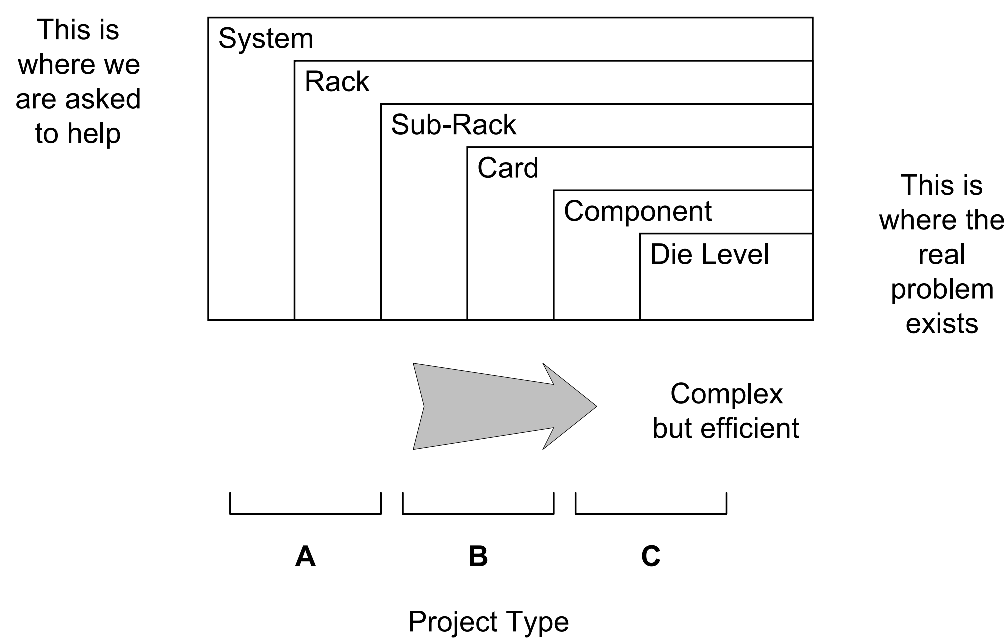
The service provider must tell the cabinet manufacturer what specific equipment the cabinet will contain, and the manufacturer must have the skill sets to know that equipment and how it will affect the thermal system within their cabinet. The equipment layout and relative positioning can also be a key to successful "packaging." Service providers must be flexible to allow the configuration to fit the enclosure as much as the enclosure fits the configuration.

Thermal Management

Proper thermal management is necessary to ensure the dependable operation of sophisticated heat-generating equipment that requires the protection of a sealed enclosure. The heat must be transferred from the points at which it is created to the outside air. In a broadband-ready enclosure, this becomes a complex problem, as illustrated in *Figure 1*.

Heat is generated at the silicon die level and transfers through the chip to the component, the card, the sub-rack, the rack, the air circulating inside the enclosure, and finally to the heat exchanger. Since the broadband enclosure may contain hundreds of these heat sources, with many components, cards, racks, and other obstructions (system impedance) to air flow, it becomes a very complex problem for the enclosure manufacturer to remove all of this heat in a cost-effective manner.

FIGURE 1



The Telecordia GR-487 (General Requirement) provides specifications for a sealed heat exchanger system that the telecommunications enclosure industry follows. While most incumbent local-exchange carriers (ILECs) are familiar with Telecordia specifications, newer providers may not be, or may overlook the fact that the specification may not have been followed. Some may be unwilling to pay for the cost of a properly engineered sealed system, since low initial cost is important to their business plan.

However, when equipment fails or need for expansion occurs, the cost to upgrade is considerably greater than installing properly designed equipment with room for expansion in the first place.

Thermal "redundancy" of the enclosure thermal management system—its capacity to handle "unforeseen" thermal events—is a critical concern when selecting an enclosure. With all of the heat generated by broadband equipment, a catastrophic failure can leave very little time before temperatures exceed 85°C, the upper limit for most electronic circuitry.

Air-quality requirements within a broadband-ready enclosure are the same as those for previous generations of cabinets containing sensitive equipment. The objective is to keep humidity and contaminants out as much as possible with a sealed enclosure design that employs a heat exchanger system.

Thermal Control and Acoustical Noise

Acoustical noise is an important concern when using high-speed fans and motors. Many remote enclosures are going to be placed in residential neighborhoods (sometimes close to bedroom windows!). To move the amount of air necessary to cool broadband equipment, fans are going to be pretty noisy. How do you minimize that noise and still maintain the desired thermal environment? With a thermostat controlling the whole system, everything turns on whenever the contacts close. However, with a more sophisticated controller that monitors or "polls" the environment, you may determine that only the fan shelves need to be on at a given moment, but not the heat exchanger fans—thus reducing the amount of noise.

Thermal monitoring is also required to assure that, if the cabinet temperature exceeds 65°C, appropriate alarms (including fan failure alarms) are sent to the network alarm center. Usually, there are separate alarms for environment and power distribution (failure) conditions; but from a "system" perspective, it is generally more economical to combine all alarms in a single package that communicates with the network alarm center.

"Scalable" Cooling

In some deployments, you may not need a full broadband cooling package and everything that goes with it. Providers should realize that cooling can be scaled down and cost taken out of the enclosure. If you give your enclosure manufacturer a complete description of the type and amount of equipment to be housed, the manufacturer can size the fans or heat exchangers appropriately. However, this must be done in the factory. If you find you need greater thermal capacity later, it will be difficult to "scale up" without interrupting service to your customers. In any case, the field is not the place to tamper with the capacity of critical cooling systems.

Battery Backup and Cabinet Space

With broadband, the equipment consumes more power and, to get the customary eight hours of battery backup, you need more battery space. In many older cabinets, slide-out battery drawers held top-post batteries. The drawers and support brackets consumed a lot of volume, making battery compartment utilization poor at best.

Today, new front-access batteries with a different form factor are available and drawers are being eliminated. If the provider has standardized on a particular battery, the form factor of the battery compartment in the cabinet they choose must be compatible with their battery and allow the most efficient utilization of that space inside that cabinet. If the utilization is low, backup capacity will be reduced. The choice becomes "choose another battery" or "choose another cabinet," depending where the provider is in the enclosure selection process.

As with thermal systems, the provider can save money on battery backup by knowing what type of equipment a particular enclosure will house. If it is high-speed data equipment and not lifeline telephone service, the provider should decide if a less-than-eight-hour battery backup system is adequate. The cabinet manufacturer can then configure and equip the cabinet accordingly.

A Cabinet As a System

Often, the enclosure is viewed simply as a protective "wrapper" around the revenue-generating equipment. But today, you can't always get approval to increase the size of the "wrapper" to hold the additional equipment required by a broadband terminal. So you need a broadband enclosure with the flexibility to integrate as many of the components as possible within the enclosure—in other words, a "system."

Enclosure "system" components include the power-conversion equipment, power distribution, environmental monitoring and control, battery management, and cable management. All of these components take up space. And with broadband deployments, you need "more" of each component. But "more" of these components limits the space for the revenue-generating electronics.

The system concept can lead you out of this dilemma. By requiring manufacturers to design broadband enclosures from a system perspective, network providers can stimulate manufacturers to be more creative and find ways to pack more into that wrapper—but still give you the "craft friendliness" that you want.

For example, with the increased cooling requirements, larger fans will be needed to drive air through denser heat exchangers. Unfortunately, the power curve for these fans is exponential—doubling the speed of the fan may only increases the airflow by 25 percent. Rather than fuse these larger fans with a separate distribution panel, the power distribution can be integrated within the same device that provides the environmental monitoring and control.

As another example, when you deploy a remote terminal, you normally deploy a separate standalone transfer switch and a cross-connect at that same location. Integrating a power transfer switch as part of the cabinet system is another way to cope with the right of way issue—and eliminate another headache for the provider.

The more thought you and the manufacturer put into your cabinet before it leaves the factory, the more suitable it becomes—as a system—for your broadband application.

Fiber and Hybrid Management

With fiber, copper, and coax entering and leaving the remote broadband enclosure, media management and protection become critical issues in enclosure design. There must be enough room to attach the fiber troughing that maintains minimum bend radii and appropriate spacing—and enough room for the equipment. There must also be enough space between, above, and below the equipment for fiber management.

If an enclosure is poorly designed, it may have enough room to hold the equipment at initial deployment; but when maintenance or troubleshooting are required, there's no room to get your hands in to handle the cables to do connectorization, routing, lacing, etc. There are many systems for fiber splicing and patch panels, and providers have their own preferences. It is the cabinet manufacturer's job to provide adequate room for the components the provider selects.

The service provider must know where the access ports are on the chosen equipment when talking to the cabinet manufacturer. Location of the ports varies greatly. It may be front access or rear access. If it's rear access, do you need a swing frame? Or can you get to it some other way? Swing frames are costly, heavy, and take up cabinet space. Before settling on swing frames, see if there is a way—via configuration—that your enclosure supplier can save you from the additional expense of swing racks.

Ease of Deployment and Maintenance

Now that you have much more revenue being generated out of your cabinets, you can't afford excessive downtime. Nor can you afford to disappoint the many customers who may be served by a single cabinet. How easily can you install your enclosure? After you've installed the cabinet, how easy is it to get the cables in and out of the cabinet in a safe manner? With higher-heat equipment, if something does go wrong, you have to get to the site quickly, and equipment must be quickly serviceable when you get there.

The provider should ask, "How much maintenance am I going to have to do? Am I going to have to go out often to clean filters, replace fans, and replace heat exchanges, etc.? Or do I just deploy the enclosure, let it go, and only service it every four or five years when the fan burns out? And when something does need replacement, how easy is it for me to replace? Will it take eight hours to replace a fan? Will I have to tear equipment out of the cabinet?" All these questions should be asked before you choose an enclosure—not after it's deployed in the field.

Compartmentalization

Compartmentalization is an extremely important issue because different craft grades will be accessing the cabinet. With sensitive electronics, providers often want to restrict access to different parts of the cabinet, and enclosure manufacturers have stratified the crafts by compartmentalizing the enclosures and installing different padlocks on each compartment.

Not only does this restrict crafts to the appropriate compartments, but when a technician is working in one compartment, only that compartment is exposed to the elements. Splicing could be going on eight hours a day, for a couple of days, with the doors wide open. Without compartmentalization, the equipment would be exposed to heat, dirt, moisture, etc. With it, equipment in other compartments remains undisturbed in separate controlled environments.

Absorbing the Cost of Broadband Readiness

While new broadband enclosures may be restricted to present form factors and footprints by municipal mandates—and may look much the same outside—do not be confused by the similarities and do not confuse the costs. There is an added cost for cooling, for battery backup, and for media management. But when you and your enclosure manufacturer work together, you will find creative ways to absorb the added costs and enjoy the increased stream of revenue that your broadband-ready cabinets will help you generate.

Scaling to Handle DSL Demand

Mark Peden

Vice President, Technology Marketing

Simpler Networks

This paper discusses scalability, the number-one issue network service providers (NSP) face today as they deploy digital subscriber lines (DSL). It presents the issues that prevent the industry from achieving scale. The paper begins with a brief introduction to loop management and then discusses recent advancement in loop qualification, provisioning, testing, line maintenance, and, finally, service assurance.

Yesterday's Provisioning Process

Figure 1 shows yesterday's provisioning, an expensive and time-consuming process. It was very manual, laborious, and error prone. The end user placed the order either over the Web or with a phone call. It involved some order loop prequalification that, in the case of a competitive local-exchange carrier (CLEC) or data local-exchange carrier (DLEC), could take from a week to 10 days.

The second step was to get a local service request (LSR). Again, the CLEC or DLEC itself actually ordered the service or the pair, depending on the type of service, from the incumbent local-exchange carrier (ILEC). The next step, scheduling the workforce, took anywhere from a month to a month and a half. Designing and assigning the digital subscriber line access multiplexer connection point (DSLAM CP), which included setting up the virtual path identifier/virtual circuit ID (VPI/VCI) modeling, took about another week. Manually provisioning DSLAM took another one to three days. Rolling a truck took perhaps two or three days. Then the bills started to come.

In the early days, even the well connected needed to beg and plead with the local telephone company to get DSL.[1] The reason? The digital loop carrier (DLC) was between the requestor and the central office (CO). After finally agreeing to supply DSL, the telephone company said, "Look, we are going to get it for you, but you cannot tell anyone." That is because the telephone company had to re-engineer the loop plant to deliver DSL service. But others could not get this exciting, wonderful service for another two to three years.

The telephone company hangs notices on doorknobs and slips ads in every bill to promote cable service. "Call us today—no contract necessary, only $19.95 a month. Within one week, we will install it and guarantee that it works." These marketing efforts reflect how far cable service has come; real progress has been made. No service provider anywhere is promoting DSL like that, so DSL has not reached the mass market.

Reaching Mass Market

What does it mean to reach mass market? Mass market is not 1,000 lines a day; it is not 5,000 lines a day. It begins to happen when a single service provider can actually deploy 10,000 lines a day. No service provider in the industry today can actually do that.

How can the industry position itself to reach mass market? By meeting these important requirements:

- General product availability
- Standardized products
- Product interoperability
- Consumer awareness
- Product and service alternatives

Product Availability

DSL products must be generally available. The physical DSLAMs must be installed, or, better yet, the next generation of digital carriers deployed in COs or remote terminals.

Standardization and Interoperability

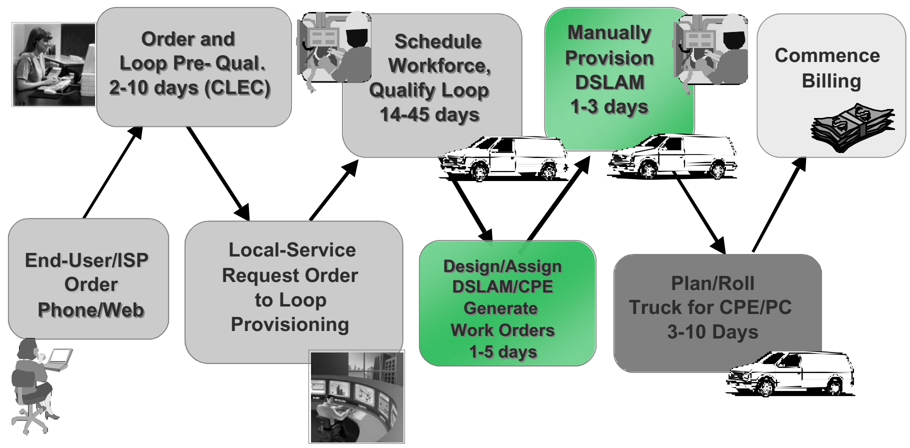
Products need to be standardized to allow standards-based interoperability. The DSL Forum has made significant progress toward facilitating standardization. At the last SUPERCOMM, more than 30 vendors demonstrated standards-based interoperability. It was exciting to see the whole industry come together and demonstrate standards-based products and how they could all work. Those efforts and work within the DSL Forum will bring the industry to the point where it can offer a retail model. Then anyone can go to a retail store, buy a product off the shelf, go home, plug it in, and be up and running fairly quickly. The industry is progressing toward that goal, but it is not there yet.

Consumer Awareness

Consumer awareness has increased. Everyone is talking about DSL now. People know what it is; they actually understand what it means and the value that it can provide. That is rewarding for the people who have worked on this technology for so long.

FIGURE 1

Yesterday's Provisioning Process



Product and Service Alternatives

Both ISPs and competitive access providers (CAP) have begun to offer some product and service alternatives that add value by rolling out services, addressing security, voice over, video on demand (VOD), voice over digital subscriber line (VoDSL), and virtual private networks (VPN). Koreans use the term KOD–karaoke on demand. Karaoke is very popular is Asia; it is part of the social scene. Now it is actually being delivered over DSL. Servers provide localized content caching and deliver karaoke directly to the end user. That is just one example of how creatively people are using and applying DSL.

Today's Provisioning

Provisioning still presents some challenges, such as

- Accurate loop provisioning
- Support for electronic bonding
- Establishment of physical connections
- Errors resulting from manual processes
- Correction of impairments

Accurate Loop Provisioning

The two key barriers to accurate loop qualification in the provisioning space are false positives and false negatives. A false positive occurs when a customer learns DSL is available and calls or goes on-line to order it. The service provider makes a quick assessment, perhaps some book qualification, and worse yet, some narrowband qualification. Believing it can deliver DSL, the service provider spends some money, tries to get a line to the customer, and perhaps delivers a new line. After spending time, money, energy, and personnel resources, the service provider discovers it cannot provide DSL to the customer. That very costly and very real issue affects about 20 to 25 percent of today's orders.

A false negative occurs when the service provider says a customer cannot get DSL. This customer operates over the border in a gray area. The service provider feels strongly confident of where it can and cannot deliver DSL. So it tells a customer that is just outside of its area, "No, we cannot get it to you." However, by spending a little money, the service provider could provide DSL to the customer.

In California, when Pac Bell first rolled out stored program control (SPC), it limited loop reach to 12,000 feet. Why? Because it knew that 99.99 percent of the time it could deliver services to customers within that range. Trials and tests of the technology concluded that it could deliver with a loop reach of 23,000 feet. And yet Pac Bell decided to limit it arbitrarily to 12,000 feet. Doing so made Pac Bell highly confident that it could have DSL up and running and deliver the service consistently.

Generally, some carriers initially limited the service and then expanded it over time. They placed some restrictions on loop reach because, with a shorter loop, they could be more confident about the delivery of service. Over time, some service providers extended the loop reach to service a wider customer base.

Electronic Bonding and Physical Connection

Electronic bonding is enabling true flow-through provisioning. Once the loop has been qualified, it occurs between Internet service providers (ISP), potentially between DLECs or CLECs, and then between ILECs. Another key issue is establishing the physical connections, especially in a competitive environment where providers might use a line-shared loop. The industry is still working through yet another key challenge that concerns splitter usage and positioning. Different models currently have industry support. But there is no one simple answer, because competitive carriers and their unique challenges make the issue more complex.

Errors and Impairments

Manual processes frequently result in errors, and impairments in the loop may need addressing by the provider once the loop is qualified to address data-rate options through testing. Many service providers automate their testing using the Class-5 switch. They connect the test head and qualify through the Class-5 switch. However, that is a form of a narrowband testing used for *broadband* qualification.

Using a narrowband test does give throughput options. It does no spectral testing per se, and spectral issues might potentially exist within the binder. A narrowband test does tell with some level of accuracy whether a customer can actually get service. Service providers consistently report that 75 or 80 percent of the time, a narrowband test accurately predicts whether they can actually deliver services.

A number of service providers are working aggressively to reach the mass market. As they approach the goal of 10,000 lines per day, their narrowband tests may result in as many as 2,000 false positives or false negatives. That means they cannot provide a service-level agreement (SLA) if they use a narrowband test, and they cannot guarantee data rate throughput.

Post-Qualification Concerns

Many concerns must be addressed after loop qualification. Interconnection issues between the ISP, CLEC, and ILEC become critical with throughput. So do issues related to the CPE–to–DSLAM auto configuration. The industry is working to develop a common model. Many service providers now support Tech 59, an approach being developed within the DSL Forum. Simplified installation with plug and play (PnP) is also widely supported. Both improve consumers' experiences with DSL. They can buy the product, take it home, plug it in, and use it fairly quickly. The news is good—many service providers are succeeding in providing a PnP model that consumers can install.

External Factors

Carriers are committed to and focused on providing long-distance services. They consider competitive access key to facilitating their entry into that market. To accomplish that, a number of external factors must be considered:

- Regulatory issues
- Emerging technologies
- IP and ATM issues
- New network and content methods
- Usage drivers

Regulatory Issues

Public utility commission (PUC) issues vary from state to state. In Illinois, for example, the state's PUC and the local carrier were in conflict about the former's ability to deploy in a DLC environment. The carrier decided to hold or suspend some deployment until hearings were held and the issue was resolved. State issues affect deployment, as do federal issues.

The Network Reliability Interoperability Council (NRIC) is an organization endorsed by the Federal Communications Commission (FCC). Its mission is to develop policy recommendations for the FCC. To some extent, the NRIC is a subset of Committee T1/E1.4. Many who have been involved in standards work within committee T1 are also involved in the NRIC. The council has posted some of its policy recommendations on the Web at www.nric.org.

Emerging Technologies

New technologies are constantly being developed and deployed. Some new technologies, like repeaters, are known disturbers of DSL deployment, but others are actually more spectrally friendly to different DSLs. For example, G.shdsl is more spectrally friendly to asymmetric digital subscriber lines (ADSL). Still other new technologies being deployed provide some interesting challenges in the loop.

IP, ATM, and New Technology Issues

Internet protocol (IP) over asynchronous transfer mode (ATM), or IpoA, is a different issue. New network content models are being developed for voice over digital subscriber line (VoDSL). Quality of service (QoS) is coming. So are usage drivers, new content, and applications for home networking drivers.

Ongoing Challenges

The industry must tackle availability constraints immediately by helping providers to complete CO rollouts and helping the next-generation digital loop carriers (NGDLC) provide ubiquitous service. SBC has earmarked $6 billion for buildout, much of which will go to NGDLC. SBC has taken the leadership and made a commitment to addressing the residential market.

Accurately qualifying and automating what remains of the manual provisioning process continue to be goals. The industry must provide support for QoS, service-level agreements (SLA), VoDSL, and some value-added services. As new technologies are introduced, they will encourage DSL deployment, increase the number of customers served, and enable new content, home networking, and other access devices.

Loop Management

The DSL Forum undertook a project on loop management systems (LMS). A white paper describing the LMS project, "DSL Form 2001.067," is now available at the DSL Forum Web site (www.dsl.forum.org). A white paper is also available on LMS.

The project summarized some problems described in this paper: increased operating complexity, slow response to customers, poor QoS assurance, managing the line-sharing environment, high customer-service churn, and poor loop record. Then it attempted to identify some solutions, including loop testing and qualification, better test-access functionality, service migration and provisioning, line sharing, and automating sub-loop unbundling.

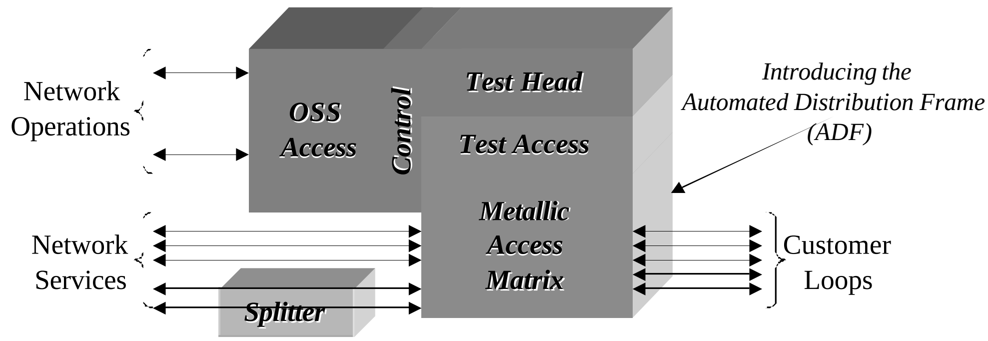
Figure 2 is a diagram of the LMS architecture. The system contains multiple elements to automate testing, provisioning, and maintenance functions, and it enables service providers to install, troubleshoot, manage, and maintain existing and emerging services on the local loop more efficiently.

The LMS architecture includes network operations, operations support system (OSS) access, a control interface, a test head, test access, a metallic access matrix, and a splitter. The four basic items in the functionality are provisioning (physical switching), test access, optional test-head or devices, and remote management.

An LMS system could exist in a co-location cage where a competitive carrier may use it. *Figure 3* shows how it could exist within the CO just off the frame or at an intermediate distribution frame; some carriers might potentially use automated or remote switching within a DLC. Some

FIGURE 2

LMS Architecture



providers are looking at introducing DSL into commercial buildings—for example, in hotels or motels—where they can automate switching or introduce high-speed services at the remote terminal.

Current Needs

To develop an automated system, a relay is necessary. A relay makes a physical connection that enables any type of cross-connection. Typically a relay is on a relay board, and it is big. A few companies have been working on micro relays similar to the one illustrated in *Figure 4*. The micro relay is a solution to the space limitations of loop management.

The development of the micro relay is also an effort to address some of the industry's "future" needs; in particular, to provide real-time testing and qualification of access to copper lines and to make full integration possible. Testing can no longer be limited to narrowband, which, as mentioned earlier, is the most common method of broadband qualification because it can be automated through the classified switch. Efficiencies of space and power; optimal use of DSLAM or DSL ports; easy, cost-effective ways to upgrade customers; and the ability to address both protection switching and reconfiguration—all of these are important factors in providing technical solutions. In addition, some regulatory issues must be addressed through technical solutions.

Broadband Distribution Frame

Based at the CO, yesterday's deployment included provisioning at the frame, where someone physically connected pairs (see *Figure 5*). A new concept, the broadband distribution frame (BDF), helps to provide any-to-any, non-blocking, protocol- and vendor-independent distribution. *Figure 6* illustrates its support of flow-through provisioning.

By coupling inputs and outputs remotely, BDF automates many functions that required site visits. It automates testing, provisioning, and maintenance functions in supplying DSL services, activities that become even more complex in a remote terminal or a DLC environment. BDF can provide test access to any loop, and testing is no longer limited to narrowband testing. The tests can be full broadband or full spectrum. BDF also allows independent management of DSL and plain old telephone service (POTS) on the shared loop. It keeps configuration records and provides easy

FIGURE 3

LMS Applications

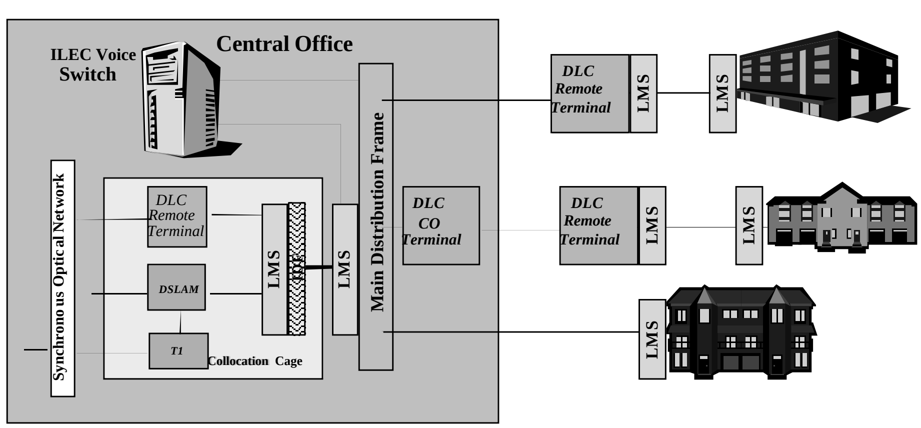


FIGURE 4

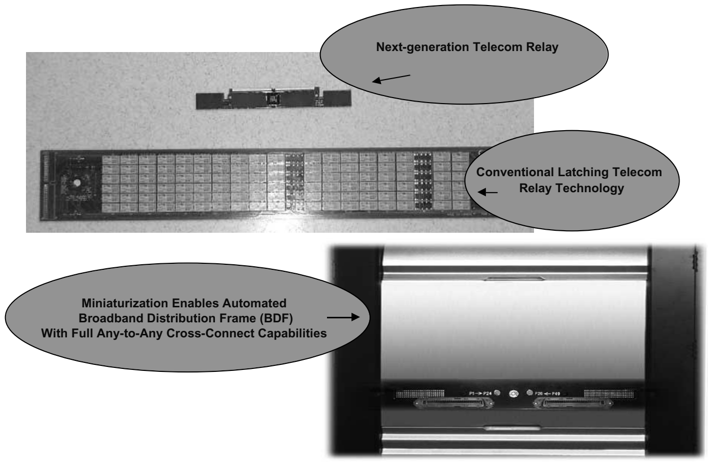
A Micro Relay



implementation of service changes and integrated protection switching.

A BDF or an LMS with automation can actually address and potentially eliminate the workforce qualification, which could take up to 10 days in the manual provisioning process. Finally, auto-configuration techniques now actually address the designing or assigning of the DSLAM customer-premises equipment (CPE) via auto configuration techniques. Automating the loop-management element can potentially reduce the waiting period from weeks to only a few days.

How BDF Works

Figure 7 is a graphical representation of how BDF works. Many companies offer fairly similar products in which all pairs basically come through a frame, perhaps in a remote environment. The CO in the corner could also be a remote terminal where the pairs simply pass through an additional box.

FIGURE 5

Yesterday's CO–Based DSL Deployment

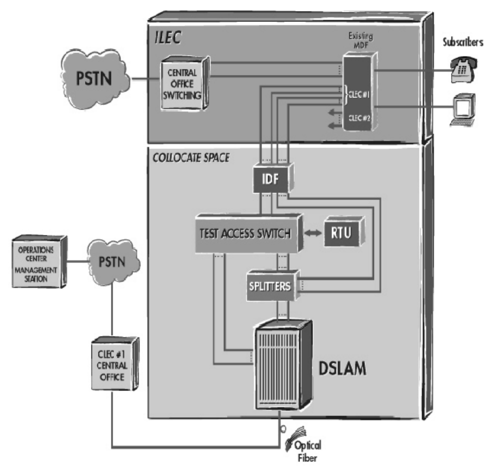


FIGURE 6

Flow-Through Provisioning with a BDF

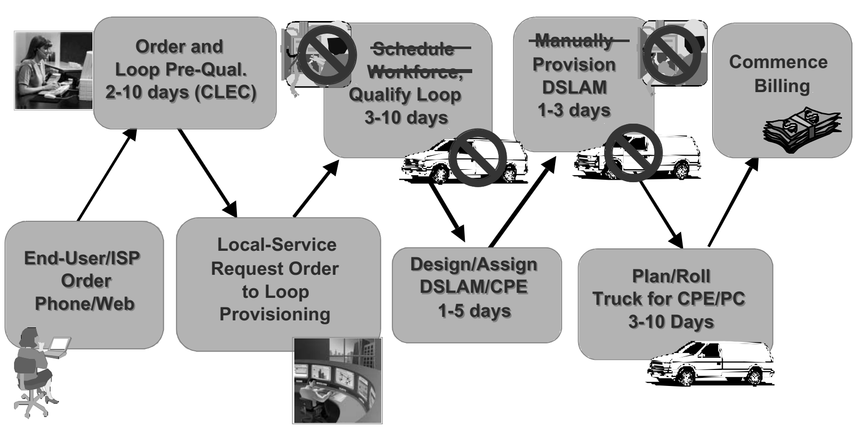

FIGURE 7

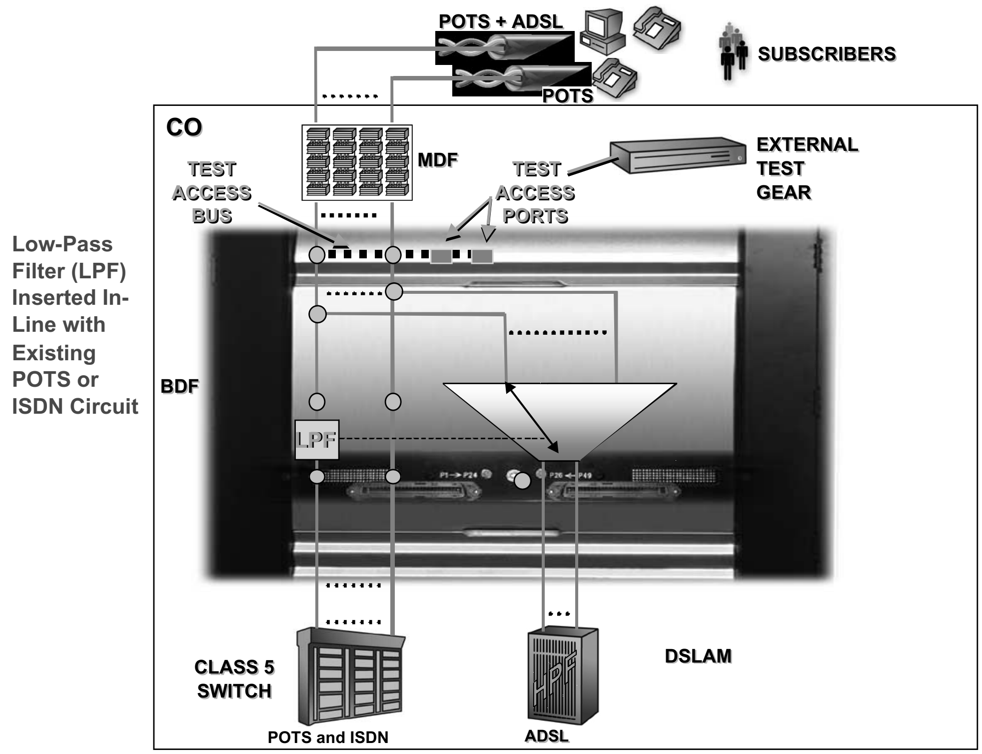
Pre-Wired BDF and DSLAM



Some lines coming into this product perform what is considered a half tap and actively terminate a DSLAM. The low-pass filter (LPF) shown in *Figure 7* can be remotely inserted in-line with an existing POTS or integrated signal digital network (ISDN) circuit. It can also help facilitate the deployment of a line-shared loop. With respect to test access, lines can now be tested directly off the frame, fully automated or remotely. Unlike the narrowband test previously done through the classified switch, these tests can be performed on any pairs and are no longer restricted. Again, the testing can be full scale or full spectrum.

A new concept introduced to the industry is the switchable splitter illustrated in *Figures 8* and *9*. If a pair comes out to the customer premises, the voice would typically terminate in a classified switch and the DSLAM. Now those pairs can pass through a switchable splitter. The voice line goes to the loop just as it always has, but the splitter dynamically closes the loop and introduces an LPF. It also taps in to provide test access. All these activities take place remotely and can be potentially fully automated. The switchable splitter is important because it enables independent management of both POTS and ADSL services.

Figure 10 shows how the switchable splitter can potentially provide cross-connections if the DSLAM port fails. So rather than sending someone out to reconnect a pair to another DSLAM port, that pair can be dynamically switched to another active port on the DSLAM.

Providing port redundancy and also addressing service assurance are keys to reducing downtime. When providing an SLA and QoS to a customer, downtime becomes critical, particularly when a remote terminal or digital carrier is involved. An automated system like the one illustrated in *Figure 11* virtually eliminates downtime because switching occurs in less than a second.

FIGURE 8

Switchable Splitter

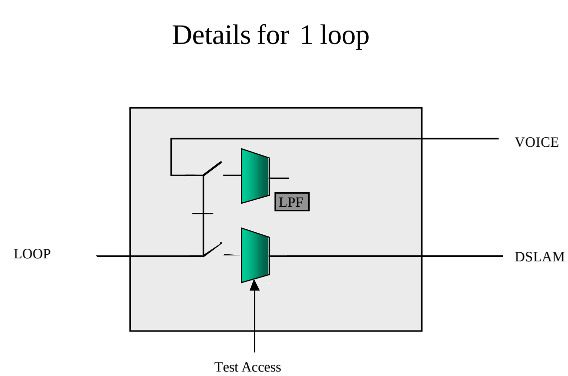


FIGURE 9

ADSL Service Activation

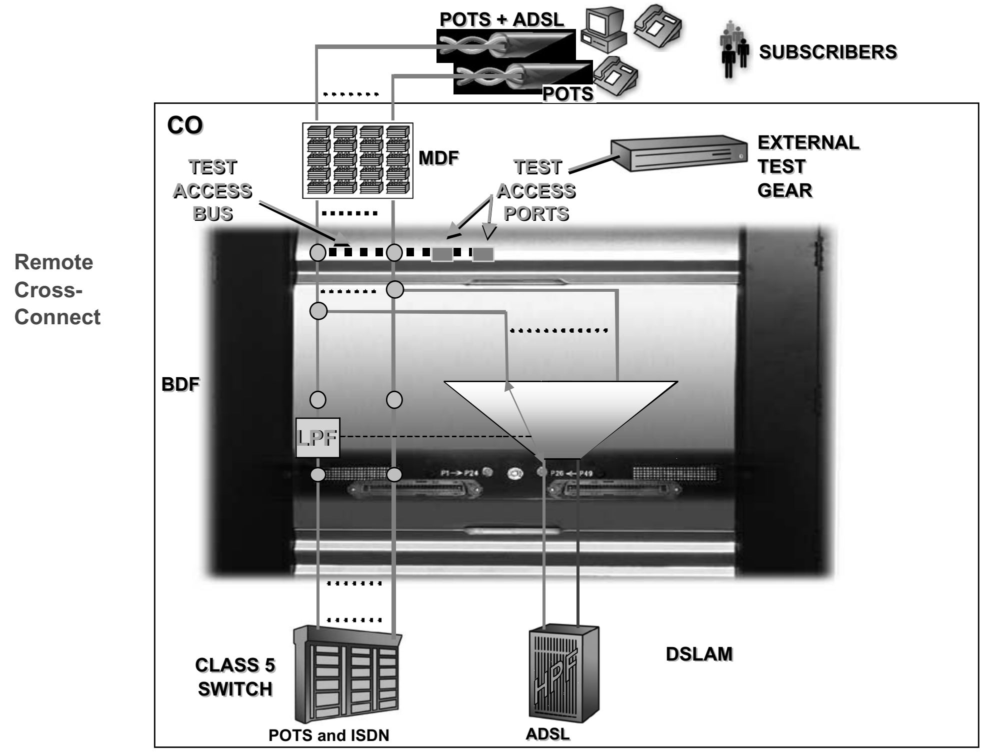

FIGURE 10

Protection/Fail-Safe Switching

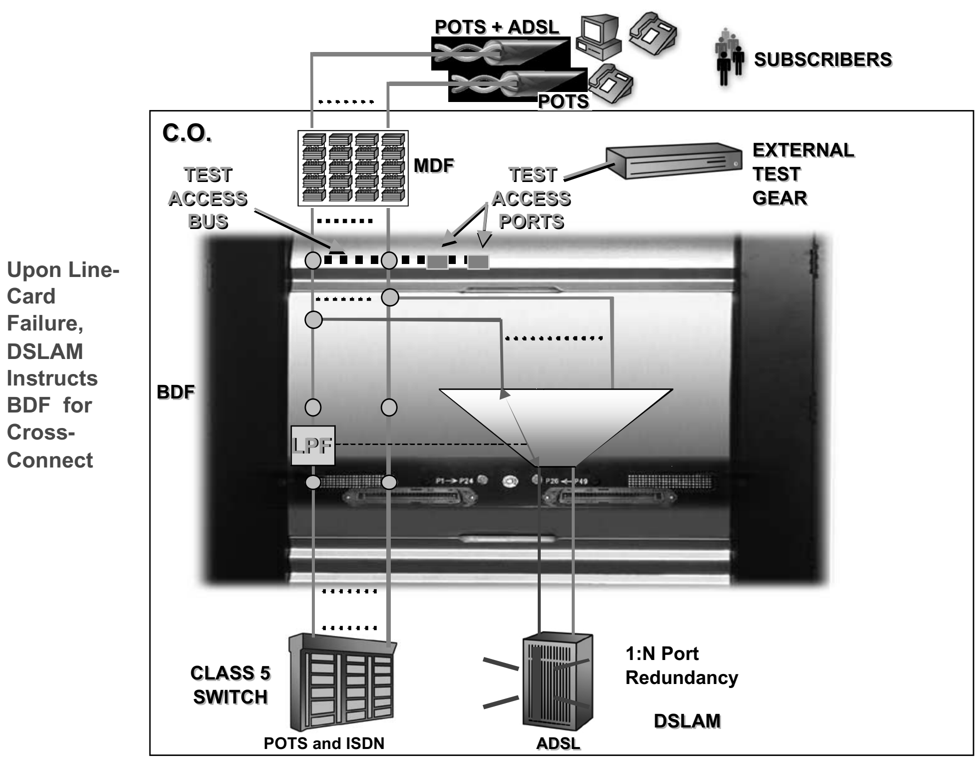

FIGURE 11

Protection/Fail-Safe Switching

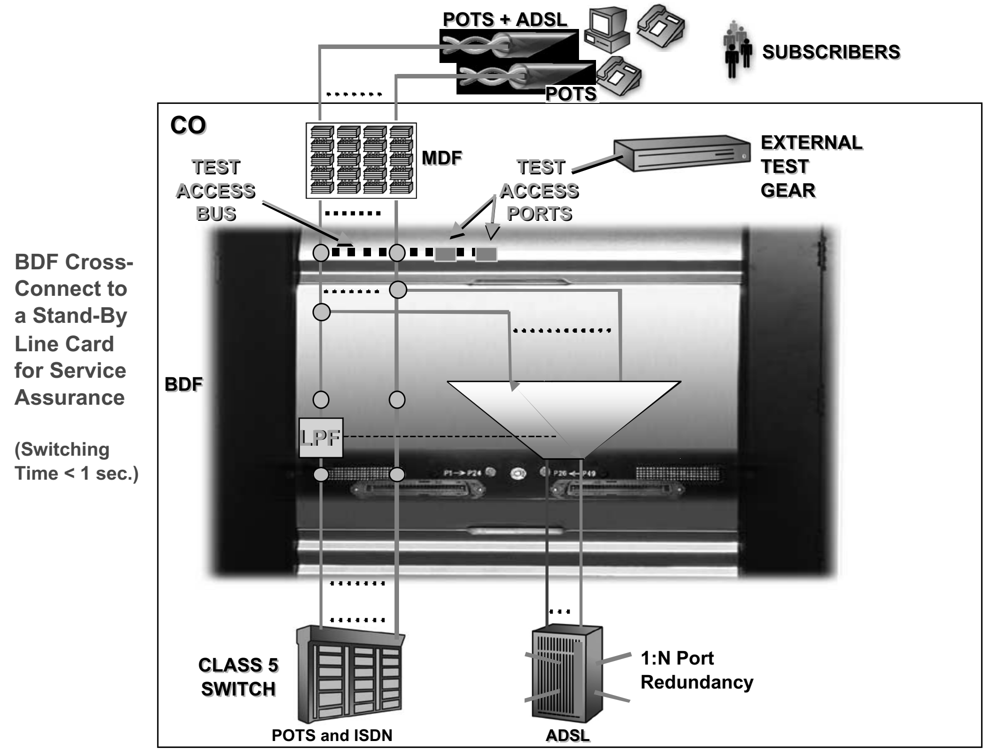

Figure 12 shows how some regulatory issues regarding delivering wholesale or other services can be addressed.

A carrier that introduces an LMS into its network can now facilitate and potentially automate the delivery of services to other carriers as well. With pre-wiring, it can now dynamically switch any pair to any potential customer. The carrier could be a CLEC or DLEC that is interested in deployment of services.

The NRIC unanimously recommended that all the carriers—CLEC or DLEC—no longer have to invest in their own test access infrastructures. The incumbent carriers would provide fair and reasonable test access for a fee. This is not policy yet; it is what the NRIC recommended to the FCC. However, It is the first time the carrier community has made a unanimous recommendation to the FCC. Pricing has not been determined and will perhaps be addressed at the state level.

The LMS discussed here can provide full broadband test qualification and limited or restricted access. When a customer orders a pair, a carrier can give the customer test access to those pairs through an LMS that has management or restricted test access.

Software and Remote Integration

Some software integration and some remote automation are needed to tackle some issues relating to good database records and the ability to clean up the database. *Figure 13* shows how integrated software and LMSs play a key role in doing just that.

Remote loop qualification reduces the time and cost necessary to build and maintain a qualified loop database that changes with the introduction of new services. Remote provisioning and test access facilitates faster service to new customers, thereby improving cash flow. It virtually eliminates the cost of manual intervention for service upgrades and churns, and reduces the trouble calls associated with initial provisioning. Traditionally, 15 to 35 percent of customers have made such calls—10 to 20 percent because of misconnections or no connections to the access network; 5 to 10 percent because of incorrect circuit length; and 0 to 5 percent because of undetected load coils.

Ongoing loop management reduces the cost of accuracy. Many carriers assume the costs of 5 to 10 percent of errors. With 10,000 lines per week, an error rate of 10 percent means 1,000 receive bad service or perhaps no service at all. Those are the types of issues that loop management can tackle.

BDF Benefits Summary

Some BDF benefits include the ability to do the following:

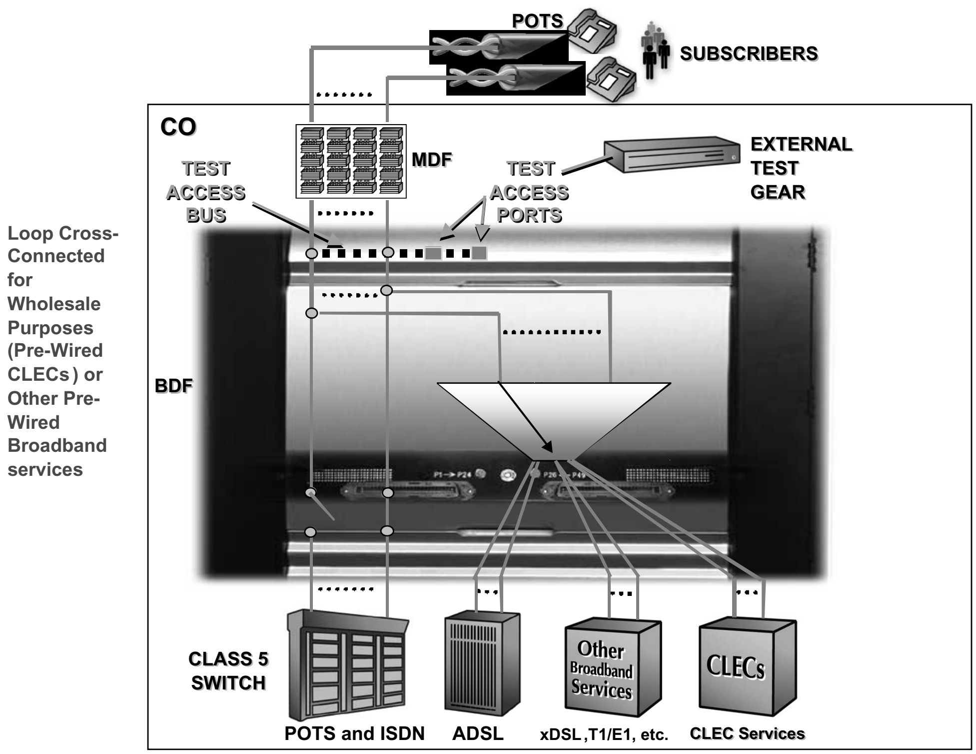
- Scale DSL deployment, connecting customers rapidly and remotely
- Meet specific requirements of a remote environment

Other benefits include the ability to do the following:

- Restore service rapidly during outages. Fast switching time allows on-the-fly maintenance and protection

FIGURE 12

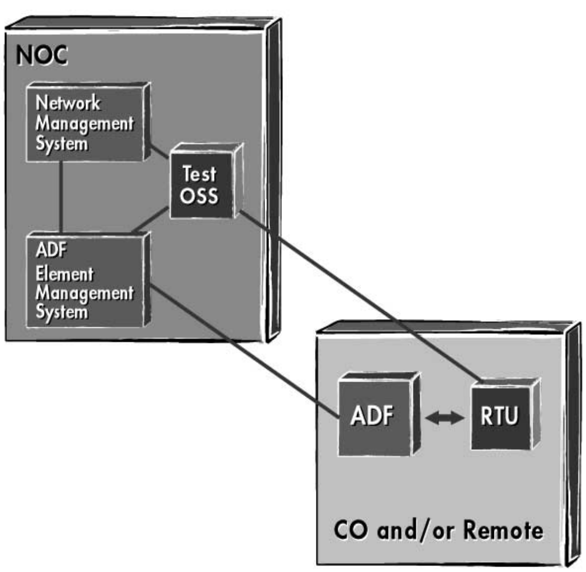
Wholesale or Other Services



switching. During power loss, BDF maintains the circuit connections.
- Support multiple and redundant key components. BDF has no single point of failure.

FIGURE 13

Software Integration



- Provide for service churn and upgrades through passive electromechanical processes transparent to protocols.
- Perform loop qualification through testing, monitoring, loop-back features, and integration to existing operations support systems (OSS).
- Simplify access management by keeping configuration records and easing the implementation of service changes. BDF's modular architecture lets service providers and customers both grow as they go.
- Provide a high-density solution that addresses cable management. The frame's compact switching gear is integrated within the connector block system and requires 50 percent fewer cables.
- Simplify local-network infrastructure deployment further with the remote version.

To these many benefits, add better, faster, and cheaper service with automated flow-through; lower operating and transportation costs; and higher density that enables integration of remote services. BDFs enable line sharing and VoSDL applications. They also reduce ILEC/DLEC dependence by resolving splitter-positioning issues and setting the demarcation point. By placing an adaptability feature in LMS, they reduce capital costs, and with protection switching embedded in LMS they enhance reliability and enable self-healing networks. By offering service on demand, they generate revenues.

Market Potential

The DSL industry is expanding rapidly, and the introduction of such capabilities as LMS contributes to that expansion. The expansion must continue in order to serve the millions of customers eager to use it.

TeleChoice estimates that 9.6 million U.S. businesses and residences will have DSL by 2003. Pioneer Consulting estimates 12.46 million. Revenues from residential markets will increase. Multiple additional applications will share the high-speed loop, providing integrated voice and data (VoDSL) at lower cost and, in many instances, replacing ISDN lines. Faster and better DSL deployment will increase revenue and address the cable threat. Some improvements described in this paper will help resolve problems related to class of service (CoS), QoS, and SLAs, and will increase revenues by as much as 60 to 80 percent per year. Compelling services are becoming available and will continue to roll out.

Learning More and Keeping Up

Many Web sites offer information on DSL

DSL Life (www.dsllife.com) is the DSL Forum's Web site for consumer education. It is a great resource that answers customers' questions about DSL.

TeleChoice publishes the latest announcements in the industry on its Web site, www.xdsl.com. On any given day, visitors might find 10 or 15 new DSL–related announcements.

The DSL Forum (www.dslforum.org) is the heartbeat of activity in the DSL industry. Most major service providers involved in DSL deployment today rely on and participate in it.

Notes

1. The author had this experience, even after working with the local telephone carrier for years to develop the technology and rollout some of the first DSL field trials.

"Battleground for the Consumer" or "Cable versus Telco"

Karl Rookstool
Vice President, Business Development
ADC Telecommunications

Introduction

The "war" for the residential customer is heating up again. The residential customer represents a very substantial bundle of telecommunications services ($150–$250) that both cable companies and incumbent local-exchange carriers (ILECs) are aggressively pursuing. This bundle of services is depicted in *Figure 1*.

Presently, the cable companies own the video market (90+%) while the ILECs own the voice market (90+%). The current battle is being fought over Internet access and the cable companies are winning. The next front will be cable's attack on voice. If Paul Revere were alive today and worked for an ILEC, he would be shouting: "The cable companies are coming! The cable companies are coming!" The big question is: What will be the telco's response?

Cable Threat

Revolution Round 1: Lasers and Digital Subscriber Lines
It was only 10 years ago that the first laser went into service in a cable network and initiated the hybrid fiber/coaxial revolution. The cable companies (and ILECs) immediately realized that new service opportunities were possible on this robust and scalable architecture. Beyond expanding channel choice, the first service on the cable companies' minds was voice. Around the same time, digital subscriber line (DSL) technology was emerging with the promise to dramatically increase capacity of twisted-pair copper wires. In these pre-Web years, the ILECs had video on their minds. With sabers rattling, many expected a war to break out between the multiple-system operators (MSOs) and the ILECs with video and telephony as the turf. But the first cable company thrust into voice and the initial trials of ILEC video were both essentially false starts and the expected battle never happened. The cable companies slow rolled telephony and the ILECs largely abandoned video. These early efforts were already on the wane when the next revolution round began.

Revolution Round 2: The World Wide Web and Satellites
The 1990s were only half over when two new revolutions showed up more or less at the same time: the Web and direct broadcast satellite (DBS) video. The Web opened a whole new application for DSL technology as well as an additional motivation for an upgraded hybrid fiber/coax (HFC) network. The cable companies began a five-year plant upgrade process that would expand channel capacity to compete with DBS and simultaneously enable two-way cable data. Meanwhile, the ILECs embarked on their own deployment plans for asymmetric DSL (ADSL) data service after abandoning video.

Current Competitive Status: Cable Ahead 2 to 1
Today, the cable companies and ILECs have delivered broadband data to more than 10 million North American subscribers. *Figure 2* shows some fairly recent quarterly subscriber additions for cable versus DSL. At least two cable-modem subscribers are turned up for every DSL subscriber. Why? There is no single explanation for this lead, but it is important is to understand the architecture and status of the cable-company HFC network in comparison to the ILEC twisted-pair network. A quick summary follows.

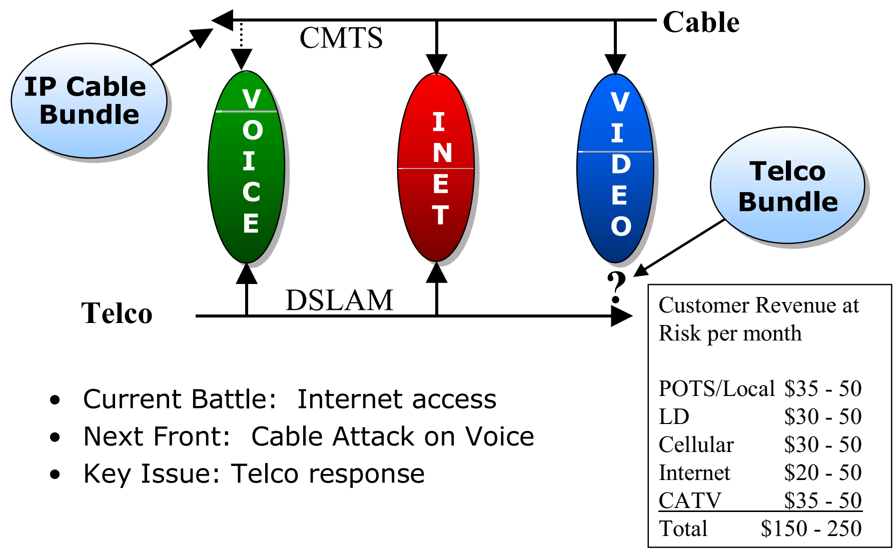
Superior Network: Capital Spent and Fiber Deep
The major cable companies are 80 percent to 90 percent complete with their upgrade effort. They have spent approximately $50 billion over five years to position lit fiber to within 3,000 to 6,000 feet of their residential subscribers. The HFC outside plant in place is highly scaleable going forward, and it is unlikely that large-scale upgrades will be necessary again anytime soon. As such, capital will increasingly shift to incremental, success-driven expenditures.

A common complaint about the HFC architecture is that upstream bandwidth is small relative to downstream. This is indeed true in a relative sense, but an operator has a number of relatively low-cost options to increase effective upstream bandwidth. Generally, they all follow a theme of reusing the available bandwidth through node decombining, radio frequency (RF) block conversion, etc. Importantly, these upgrade options can be carried out as needed and with *no additional fiber penetration.* Truck rolls, yes; trenching/boring crews, no.

Unified Standards and More Favorable Regulation
CableLabs drives cable-company technology consensus, writes end-to-end specifications, and certifies equipment.

FIGURE 1

War for Residential Customer

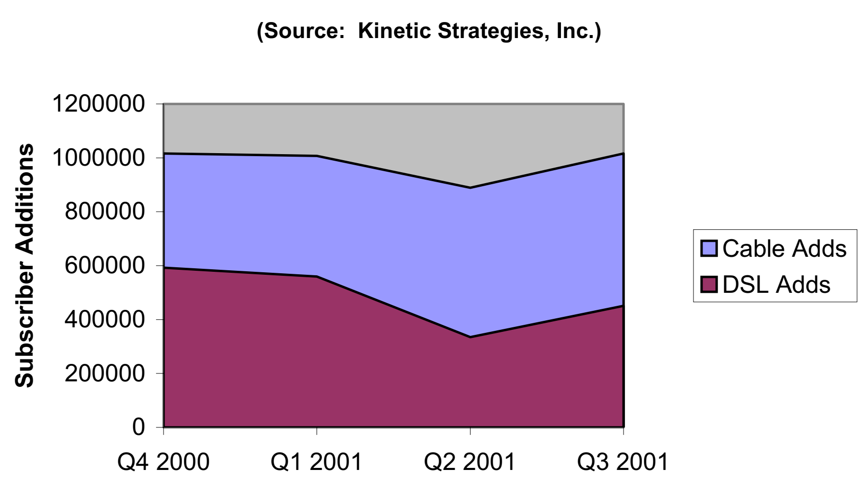


This unified front creates scale on many levels and drives down equipment and operating costs. It is an efficient and technically competent organization that has brought a great deal of order to the cable environment. After successfully launching best-effort data over cable service interface specifications (DOCSIS) 1.0, CableLabs is now certifying equipment for DOCSIS 1.1. DOCSIS 1.1 is the cornerstone around which the cable companies will introduce voice over Internet protocol (VoIP) and quality of service (QoS) into their shared access network. There is no counterpart to CableLabs for telcos. Telcordia Technologies, since its privatization, no longer provides this end-to-end interoperability industry function for the ILECs, although it may be contracted to assist on an individual company basis.

Cable companies are classified as Title VI service providers by the FCC, which affords them an advantage over ILECs that are classified as Title II incumbents. The Title VI designation does not require unbundling in the way that ILECs are forced to provide co-location facilities and physical access to loops. (AOL Time Warner is required to offer open access unbundling as a part of its merger terms and conditions. However, this is so-called packet unbundling as opposed to the more onerous co-location cages and physical unbundling.)

FIGURE 2

North America Subscriber Additions



Telephony for Cable Companies Is Incremental and on Its Way
